CONDITIONS FOR STOP-START TO OCCUR Before the PCM engages the stop-start function, the following parameters must be achieved:

- Engine speed is within idling range.
- Accelerator pedal is not depressed.
- Vehicle speed is low or zero, depending on the type of starter used.
- Battery state-of-charge (SOC) is above threshold.
- Hood is closed.

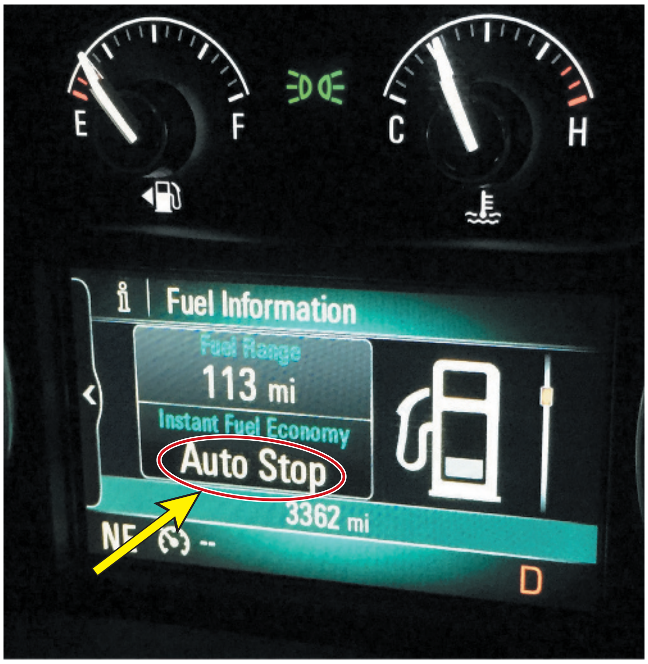

FIGURE 49–26 A Buick Auto Stop system lets the driver know when the engine is stopped.

STOP-START SYSTEM COMPONENTS It is estimated that a stop-start system starts the engine about 500,000 times in the life of the vehicle compared to about 5,000 times for a conventional starting system. A typical stop-start system includes the following components:

1. An absorbed glass-mat (AGM) or enhanced lead–acid (ELA) battery.
2. Battery sensor—Used by the PCM to determine the current entering and leaving the battery in order to estimate the battery SOC.
3. Hood switch—Used by the PCM to disengage stop-start if the hood is open.
4. HVAC control unit—Used to start the engine if cooling or heat is required in the passenger compartment.

STARTER MOTOR DESIGNS Because the engine needs to be restarted many times a day, if driving in heavy congested traffic, the starter used must be robust and capable of starting the engine over 500,000 times during the life of the system. There are three designs of starters used in stop-start system including

1. **Advanced Engagement (AE) Starter.** An advanced engagement starter works like a typical starter. When energized, the pinion shifts forward by the starter solenoid and engages with the engine's ring gear/flywheel, and immediately spins. This starter design requires that the engine speed is zero before re-engagement and engine restart can occur. To survive, the increased usage requires long-life electrical brushes, plus an enhanced pinion spring mechanism that reduces ring gear/flywheel wear.
2. **Tandem Solenoid (TS) Starter.** Using a starter that has two solenoids allows the starter to engage the flywheel of the engine when it is still moving, such as when the vehicle is coasting to a stop. A tandem solenoid starter design is also able to start the engine within 0.5 and 1.5 seconds, compared to about 3 seconds for a conventional starter. A conventional

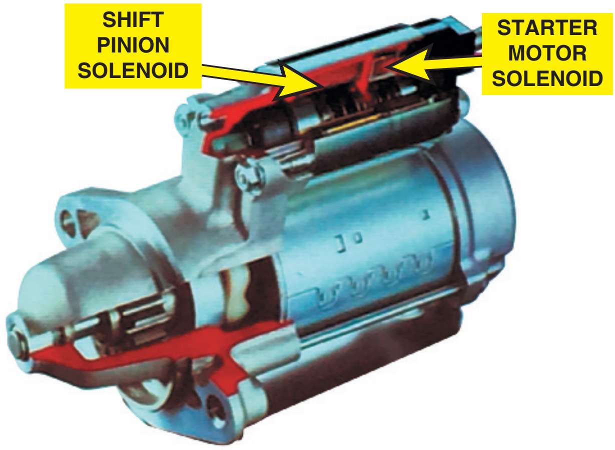

FIGURE 49–27 Using two solenoids allows independent control of the pinion gear and motor energization.

starter uses the solenoid to engage the starter pinion, then, when it is being held by the hold-in winding, the solenoid energizes the starter motor cranking the engine. The use of a dual solenoid allows the two functions of the starter solenoid to work independently: One solenoid is used to engage the starter drive into the engine ring gear. The other solenoid is used to engage the operation of the starter motor. ● **SEE FIGURE 49–27**. This allows the engine to be re-engaged (and restarted) by the starter motor when the engine RPM is falling from idle (about 600 RPM) to zero RPM. A tandem solenoid starter is almost identical in size and shape, so it can be used on almost any engine.

3. **Permanently Engaged (PE) Starter.** A permanently engaged starter delivers the quickest and quietest restart times of all starter motor-based systems. In this system, the starter and flywheel gears are permanently connected, so there are no concerns with gear engagement and disengagement. The PE starter eliminates the starter pinion gear shifting mechanism with its slight delay in activating by mounting the starter to the engine permanently engaged with the flywheel. When a restart is needed, the motor is simply energized, which immediately re-cranks the engine. There is no waiting or delay since the starter gear is already mated to the flywheel. The flywheel does require a special clutching mechanism to disconnect it from engine RPM after engine start.

FREQUENTLY ASKED QUESTION

Can a Stop-Start System Be Turned Off?

Sometimes. Some vehicles equipped with a stop-start system can be turned off using a button on the dash or center stack. ● **SEE FIGURE 49–28**.

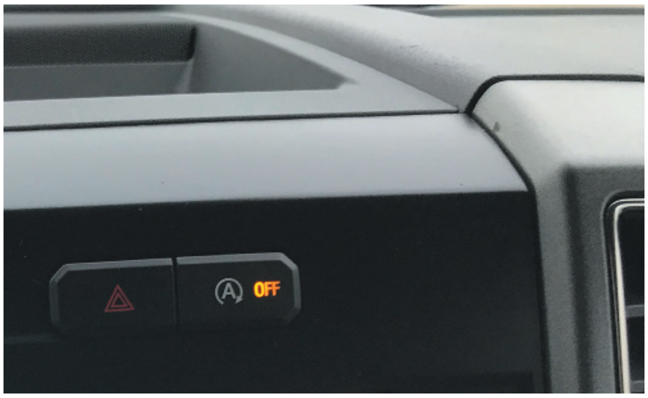

FIGURE 49–28 The stop-start system on this Ford F-150 pickup truck can be turned off using a switch on the dash.

REVIEW QUESTIONS

1. What is the difference between the control circuit and the power (motor) circuit sections of a typical cranking circuit?
2. What are the parts of a typical starter?
3. Why does a gear-reduction unit reduce the amount of current required by the starter motor?
4. What are the symptoms of a defective starter drive?
5. Why are there two windings in the starter solenoid?

CHAPTER QUIZ

1. Starter motors operate on the principle that __________.
   a. the field coils rotate in the opposite direction from the armature
   b. opposite magnetic poles repel
   c. like magnetic poles repel
   d. the armature rotates from a strong magnetic field toward a weaker magnetic field
2. Series-wound electric motors __________.
   a. produce electrical power
   b. produce maximum power at 0 RPM
   c. produce maximum power at high RPM
   d. use a shunt coil
3. Technician A says that a defective solenoid can cause a starter whine. Technician B says that a defective starter drive can cause a starter whining noise. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. The neutral safety switch is located __________.
   a. between the starter solenoid and the starter motor
   b. inside the ignition switch itself
   c. between the ignition switch and the starter solenoid
   d. in the battery cable between the battery and the starter solenoid

5. The brushes are used to transfer electrical power between __________.
- **a.** field coils and the armature
- **b.** the commutator segments
- **c.** the solenoid and the field coils
- **d.** the armature and the solenoid

6. The faster a starter motor rotates, __________.
- **a.** the more current it draws from the battery
- **b.** the less CEMF is generated
- **c.** the less current it draws from the battery
- **d.** the greater the amount of torque produced

7. Normal cranking speed of the engine is about __________.
- **a.** 2,000 RPM
- **b.** 1,500 RPM
- **c.** 1,000 RPM
- **d.** 200 RPM

8. The push button used on a push button starting system is used to signal the__________
- **a.** PCM
- **b.** starter solenoid
- **c.** field coils
- **d.** armature

9. Permanent magnets are commonly used for what part of the starter?
- **a.** Armature
- **b.** Solenoid
- **c.** Field coils
- **d.** Commutator

10. A stop-start system includes what components?
- **a.** A special starter
- **b.** An AGM or ELA battery
- **c.** A switch to turn the system off in some vehicles
- **d.** All of the above

Chapter 50

STARTING SYSTEM DIAGNOSIS AND SERVICE

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain the procedure to troubleshoot a starting system problem.
- Discuss how to perform a voltage drop test on the cranking circuit.
- Perform control circuit testing.
- Perform a starter amperage test and determine necessary action.
- Describe the procedure to remove a starter motor.
- Explain starter motor bench testing.
- Describe the procedure to install a starter motor.
- Describe how to troubleshoot starting systems based on their symptoms.

KEY TERMS:

Bench testing 575 • Voltage drop 572

STARTING SYSTEM TROUBLESHOOTING PROCEDURE

OVERVIEW The proper operation of the starting system depends on a good battery, good cables and connections, and a good starter motor. Because a starting problem can be caused by a defective component anywhere in the starting circuit, it is important to check for the proper operation of each part of the circuit to diagnose and repair the problem quickly.

STEPS INVOLVED The following are the steps involved in the diagnosis of a fault in the cranking circuit:

STEP 1 **Verify the customer concern.** Sometimes the customer is not aware of how the cranking system is supposed to work, especially if it is computer controlled.

STEP 2 **Visually inspect the battery and battery connections.** The starter is the highest amperage draw device used in a vehicle and any faults, such as corrosion on battery terminals, can cause cranking system problems.

STEP 3 **Test battery condition.** Perform a battery load or conductance test on the battery to be sure that the battery is capable of supplying the necessary current for the starter.

STEP 4 **Check the control circuit.** An open or high resistance anywhere in the control circuit can cause the starter motor to not engage. Items to check include

- "S" terminal of the starter solenoid
- Neutral safety or clutch switch
- Starter enable relay (if equipped)
- Antitheft system fault (If the engine does not crank or start and the theft indicator light is on or flashing, there is likely a fault in the theft deterrent system. Check service information for the exact procedures to follow before attempting to service the cranking circuit. ● **SEE FIGURE 50–1**.)

STEP 5 **Check voltage drop of the starter circuit.** Any high resistance in either the power side or ground side of the starter circuit causes the starter to rotate slowly or not at all.

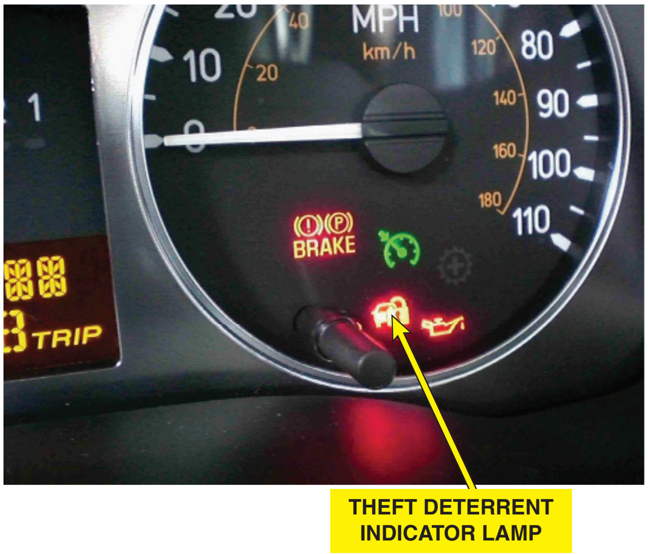

FIGURE 50–1 A theft deterrent indicator lamp of the dash. A flashing lamp usually indicates a fault in the system, and the engine may not start.

TECH TIP

Voltage Drop Is Resistance

Many technicians have asked, "Why measure voltage drop when the resistance can be easily measured using an ohmmeter?" Think of a battery cable with all the strands of the cable broken, except for one strand. If an ohmmeter were used to measure the resistance of the cable, the reading would be very low, probably less than 1 ohm. However, the cable is not capable of conducting the amount of current necessary to crank the engine. In less severe cases, several strands can be broken, thereby affecting the operation of the starter motor. Although the resistance of the battery cable does not indicate an increase, the restriction to current flow causes heat and a drop of voltage available at the starter. Because resistance is not effective until current flows, measuring the voltage drop (differences in voltage between two points) is the most accurate method of determining the true resistance in a circuit.

How much is too much? According to Bosch Corporation, all electrical circuits should have a maximum of 3% loss of the circuit voltage to resistance. Therefore, in a 12 volt circuit, the maximum loss of voltage in cables and connections should be 0.36 volt ($12 \times 0.03 = 0.36$ volt). The remaining 97% of the circuit voltage (11.64 volts) is available to operate the electrical device (load). Just remember:

- Low-voltage drop = Low resistance
- High-voltage drop = High resistance

VOLTAGE DROP TESTING

PURPOSE **Voltage drop** is the drop in voltage that occurs when current is flowing through a resistance. That is, a voltage drop is the difference between voltage at the source and voltage at the electrical device to which it is flowing. The higher the voltage drop is, the greater is the resistance in the circuit. Even though voltage drop testing can be performed on any electrical circuit, the most common areas of testing include the cranking circuit and the charging circuit wiring and connections. Voltage drop testing should be performed on both the power side and ground side of the circuit.

A high-voltage drop (high resistance) in the cranking circuit wiring can cause slow engine cranking with less than normal starter amperage drain as a result of the excessive circuit resistance. If the voltage drop is high enough, such as that caused by dirty battery terminals, the starter may not operate. A typical symptom of high resistance in the cranking circuit is a "clicking" of the starter solenoid.

TEST PROCEDURE Voltage drop testing of the wire involves connecting a voltmeter set to read DC volts to the suspected high-resistance cable ends and cranking the engine. ● **SEE FIGURES 50–2 THROUGH 50–4**.

NOTE: Before a difference in voltage (voltage drop) can be measured between the ends of a battery cable, current must be flowing through the cable. Resistance is not effective unless current is flowing. If the engine is not being cranked, current is not flowing through the battery cables and the voltage drop cannot be measured.

STEP 1 Disable the ignition or fuel injection as follows:

- Disconnect the primary (low-voltage) electrical connection(s) from the ignition module or ignition coils.
- Remove the fuel-injection fuse or relay, or the electrical connection leading to all of the fuel injectors.

CAUTION: Never disconnect the high-voltage ignition wires unless they are connected to ground. The high voltage that could occur when cranking can cause the ignition coil to fail (arc internally).

STEP 2 Connect one lead of the voltmeter to the starter motor battery terminal and the other end to the positive battery terminal.

STEP 3 Crank the engine and observe the reading while cranking. (Disregard the first higher reading.) The reading should be less than 0.20 volt (200 millivolts).

STEP 4 If accessible, test the voltage drop across the "B" and "M" terminals of the starter solenoid with the engine cranking. The voltage drop should be less than 0.20 volt (200 millivolts).

STEP 5 Repeat the voltage drop on the ground side of the cranking circuit by connecting one voltmeter lead to the negative battery terminal and the other at the starter housing. Crank the engine and observe the voltmeter display. The voltage drop should be less than 0.2 volt (200 millivolts).

−
STARTER

FIGURE 50–3 Voltmeter hookups for voltage drop testing of a Ford cranking circuit.

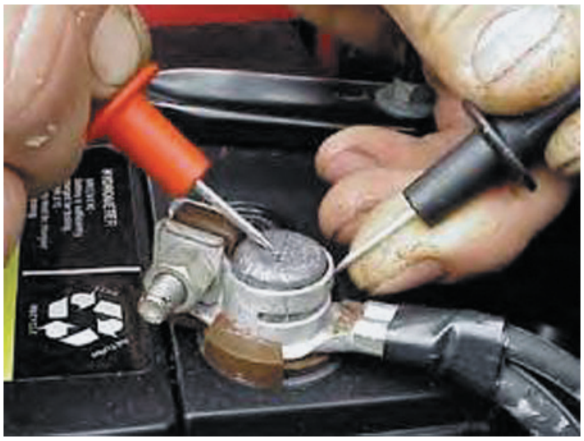

FIGURE 50–4 To test the voltage drop of the battery cable connection, place one voltmeter lead on the battery terminal and the other voltmeter lead on the cable end and crank the engine. The voltmeter reads the difference in voltage between the two leads, which should not exceed 0.20 volt (200 millivolts).

TECH TIP

A Warm Cable Equals High Resistance

If a cable or connection is warm to the touch, there is electrical resistance in the cable or connection. The resistance changes electrical energy into heat energy. Therefore, if a voltmeter is not available, touch the battery cables and connections while cranking the engine. If any cable or connection is hot to the touch, it should be cleaned or replaced.

CONTROL CIRCUIT TESTING

PARTS INVOLVED The control circuit for the starting circuit includes the battery, ignition switch, neutral or clutch safety switch, theft deterrent system, and starter solenoid. When the ignition switch is rotated to the start position, current flows through the ignition switch and neutral safety switch to activate the solenoid. High current then flows directly from the battery through the solenoid and to the starter motor. Therefore, an open or break anywhere in the control circuit prevents the operation of the starter motor.

If a starter is inoperative, first check for voltage at the "S" (start) terminal of the starter solenoid. Check for faults with the following:

- Neutral safety or clutch switch
- Blown crank fuse
- Open at the ignition switch in the crank position
- Starter relay or module, if equipped

Some models with antitheft controls use a relay to open this control circuit to prevent starter operation.

STARTER AMPERAGE TEST

REASON FOR A STARTER AMPERAGE TEST A starter should be tested to see if the reason for slow or no cranking is due to a fault with the starter motor or another problem. A voltage drop test is used to find out if the battery cables and connections are okay. A starter amperage draw test determines if the starter motor is the cause of a no or slow cranking concern.

TEST PREPARATION Before performing a starter amperage test, be certain that the battery is sufficiently charged (75% or more) and capable of supplying adequate starting current. Connect a starter amperage tester following the tester's instructions. ● **SEE FIGURE 50–5**.

A starter amperage test should be performed when the starter fails to operate normally (is slow in cranking) or as part of a routine electrical system inspection.

SPECIFICATIONS Some service manuals specify normal starter amperage for starter motors being tested on the vehicle; however, most service manuals only give the specifications for bench testing a starter without a load applied. These specifications are helpful in making certain that a repaired starter meets exact specifications, but they do not apply to starter testing on the vehicle. If exact specifications are not available, the following can be used as general *maximum* amperage draw specifications for testing a starter on the vehicle. (Ignore the initial current surge when the starter is first engaged and just record the cranking amperage.)

- **4-cylinder engines** = 150 to 185 amperes (normally less than 100 amperes) at room temperature
- **6-cylinder engines** = 160 to 200 amperes (normally less than 125 amperes) at room temperature
- **8-cylinder engines** = 185 to 250 amperes (normally less than 150 amperes) at room temperature
- High *mechanical* resistance = High starter amperage draw
- High *electrical* resistance = Low starter amperage draw

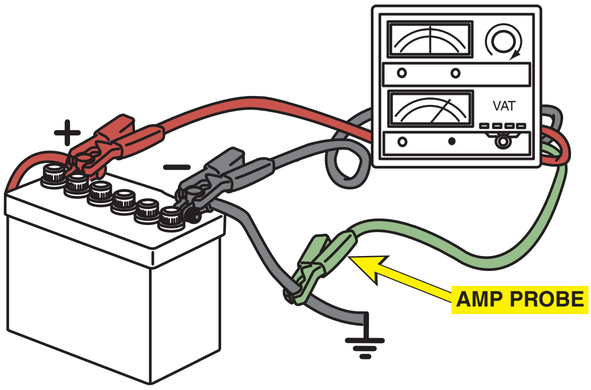

FIGURE 50–5 A starter amperage tester uses an amp probe around the positive or negative battery cables.

TECH TIP

Watch the Dome Light

When diagnosing any starter-related problem, open the door of the vehicle and observe the brightness of the dome or interior light(s).

The brightness of any electrical lamp is proportional to the voltage of the battery.

Normal operation of the starter results in a slight dimming of the dome light.

If the light remains bright, the problem is usually an open in the control circuit.

If the light goes out or almost goes out, there could be a problem with the following:

- A shorted or grounded armature of field coils inside the starter
- Loose or corroded battery connections or cables
- Weak or discharged battery

Excessive current draw may indicate one or more of the following:

1. Binding of starter armature as a result of worn bushings
2. Oil too thick (viscosity too high) for weather conditions
3. Shorted or grounded starter windings or cables
4. Tight or seized engine
5. Shorted starter motor (usually caused by fault with the field coils or armature)

CASE STUDY

The Case of the No-Crank Camaro

The owner of a Camaro SS equipped with a 6.2 liter V-8 and a six-speed manual transmission had the car towed to a shop for a no crank, no start condition. The technician used a scan tool and was able to retrieve a stored diagnostic trouble code (DTC) P0807. This code indicated a fault with the clutch pedal position (CPP) sensor. The clutch pedal position sensor was removed and it was found to be internally shorted. A new sensor was installed and the technician performed a relearn procedure as specified in service information. The car was then able to crank and start and verified that no codes were present.

Summary:

Complaint—The customer stated that the engine would not crank or start.
Cause—A shorted clutch pedal position (CPP) sensor.
Correction—The clutch pedal position sensor was replaced and a relearn procedure was performed.

Lower amperage draw and slow or no cranking may indicate one or more of the following:

- Dirty or corroded battery connections
- High internal resistance in the battery cable(s)
- High internal starter motor resistance
- Poor ground connection between the starter motor and the engine block

STARTER REMOVAL

PROCEDURE After testing has confirmed that a starter motor may need to be replaced, most vehicle manufacturers recommend the following general steps and procedures:

STEP 1 Disconnect the negative battery cable.

STEP 2 Hoist the vehicle safely.

NOTE: This step may not be necessary. Check service information for the specified procedure for the vehicle being serviced. Some starters are located under the intake manifold. ● **SEE FIGURE 50–6.**

STEP 3 Remove the starter retaining bolts and lower the starter to gain access to the wire(s) connection(s) on the starter.

STEP 4 Disconnect and label the wire(s) from the starter and remove the starter.

STEP 5 Inspect the flywheel (flexplate) for ring gear damage. Also check that the mounting holes are clean and the mounting flange is clean and smooth. Service as needed.

BENCH TESTING

Every starter should be tested before installation in a vehicle. **Bench testing** is the usual method and involves clamping the starter in a vise to prevent rotation during operation and connecting heavy-gauge jumper wires (minimum 4 gauge) to both a

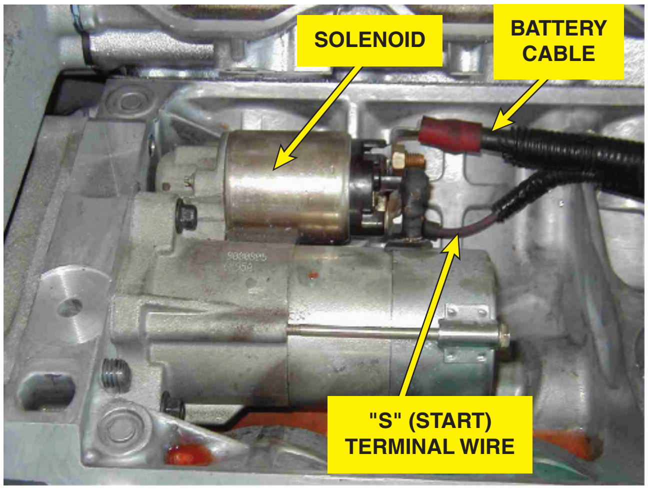

FIGURE 50–6 The starter is located under the intake manifold on this Cadillac Northstar engine.

good battery and the starter. The starter motor should rotate as fast as specifications indicate and not draw more than the free-spinning amperage permitted. A typical amperage specification for a starter being tested on a bench (not installed in a vehicle) usually ranges from 60 to 100 amperes.

STARTER INSTALLATION

After verifying that the starter assembly is functioning correctly, verify that the negative battery cable has been disconnected. Then safely hoist the vehicle, if necessary. The following are the usual steps to install a starter. Be sure to check service information for the exact procedures to follow for the vehicle being serviced.

STEP 1 Check service information for the exact wiring connections to the starter and/or the solenoid.

STEP 2 Verify that all electrical connections on the starter motor and/or the solenoid are correct for the vehicle and that they are in good condition.

NOTE: Be sure that the locking nuts for the studs are tight. Often, the retaining nut that holds the wire to the stud is properly tightened, but if the stud itself is loose, cranking problems can occur.

STEP 3 Attach the power and control wires.

STEP 4 Install the starter, and torque all the fasteners to factory specifications and tighten evenly.

STEP 5 Perform a starter amperage draw test and check for proper engine cranking.

CAUTION: Be sure to install all factory heat shields to help ensure problem-free starter operation under all weather and driving conditions.

STARTING SYSTEM SYMPTOM GUIDE

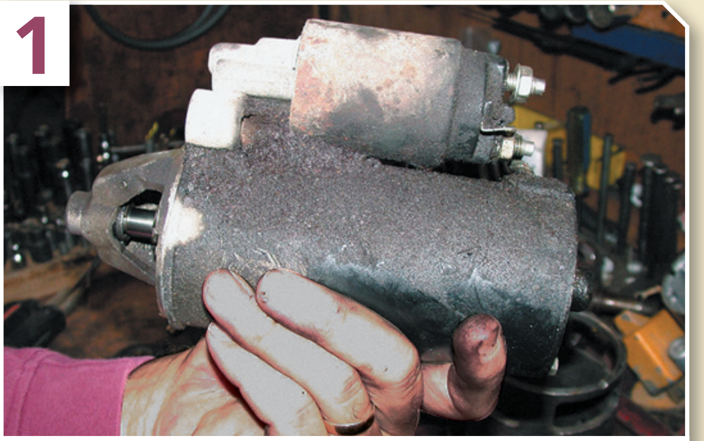
The following list assists technicians in troubleshooting starting systems:

Problem	**Possible Causes**
1. Starter motor whines	1. Possible defective starter drive; worn starter drive engagement yoke; defective flywheel; improper starter drive to flywheel clearance
2. Starter rotates slowly	2. Possible high resistance in the battery cables or connections; possible defective or discharged battery; possible worn starter bushings, causing the starter armature to drag on the field coils; possible worn starter brushes or weak brush springs; possible defective (open or shorted) field coil
3. Starter fails to rotate	3. Possible defective ignition switch or neutral safety switch, or open in the starter motor control circuit; theft deterrent system fault; possible defective starter solenoid
4. Starter produces grinding noise	4. Possible defective starter drive unit; possible defective flywheel; possible incorrect distance between the starter pinion and the flywheel; possible cracked or broken starter drive-end housing; worn or damaged flywheel or ring gear teeth
5. Starter clicks when engaged	5. Low battery voltage; loose or corroded battery connections

STARTER OVERHAUL

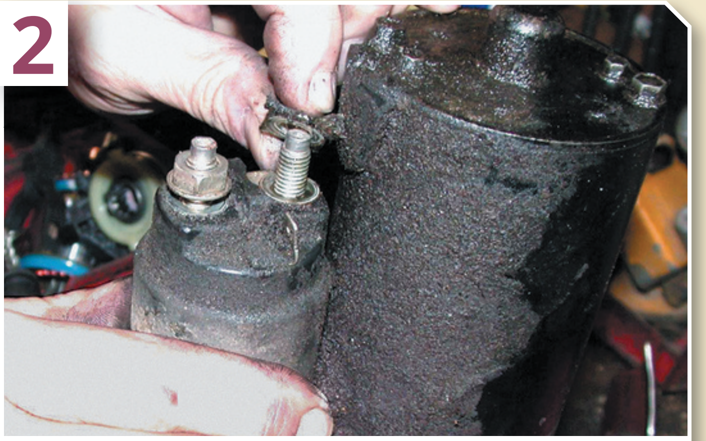
STEP BY STEP

1



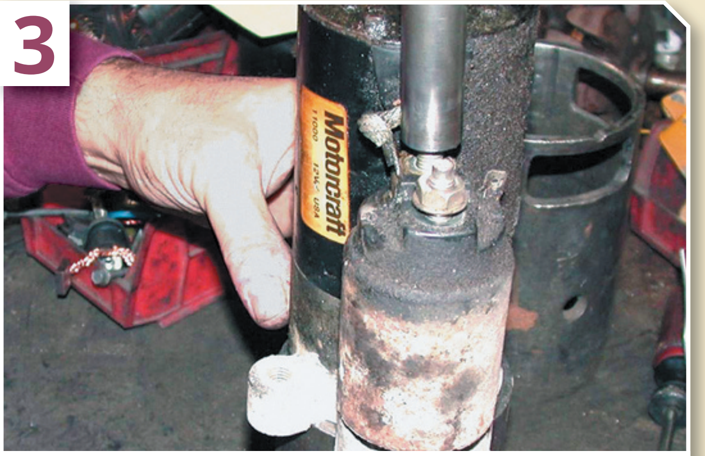
This dirty and greasy starter can be restored to useful service.

2



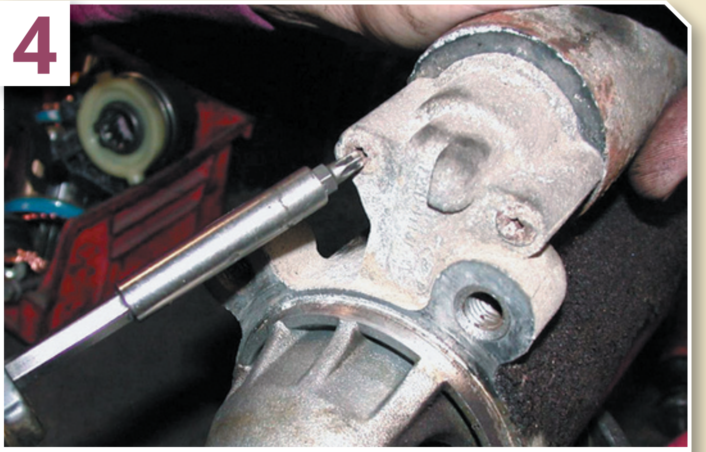
The connecting wire between the solenoid and the starter is removed.

3



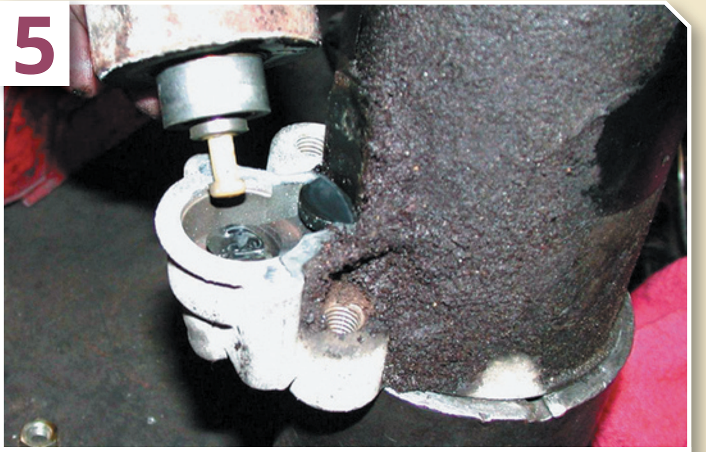
An old starter field housing is being used to support the drive-end housing of the starter as it is being disassembled. This rebuilder is using an electric impact wrench to remove the solenoid fasteners.

4



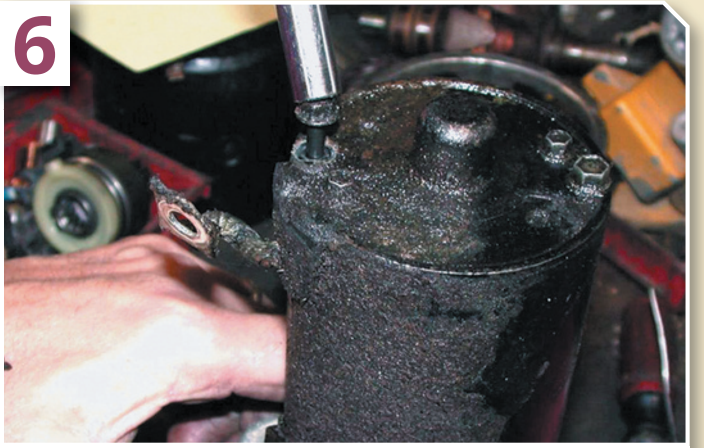
A Torx driver is used to remove the solenoid attaching screws.

5



After the retaining screws have been removed, the solenoid can be separated from the starter motor. This rebuilder always replaces the solenoid.

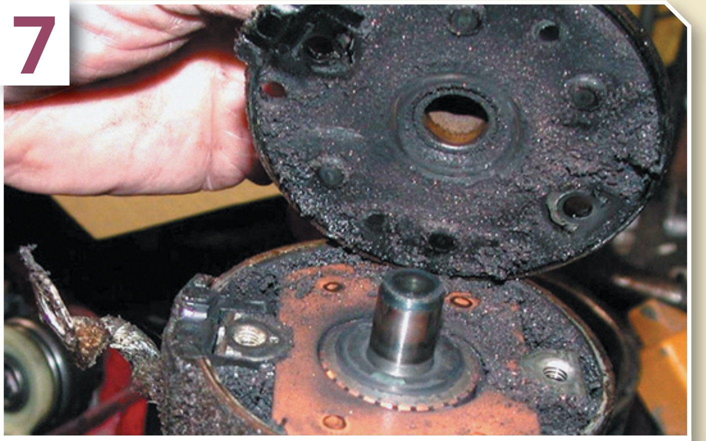
6



The through bolts are being removed.

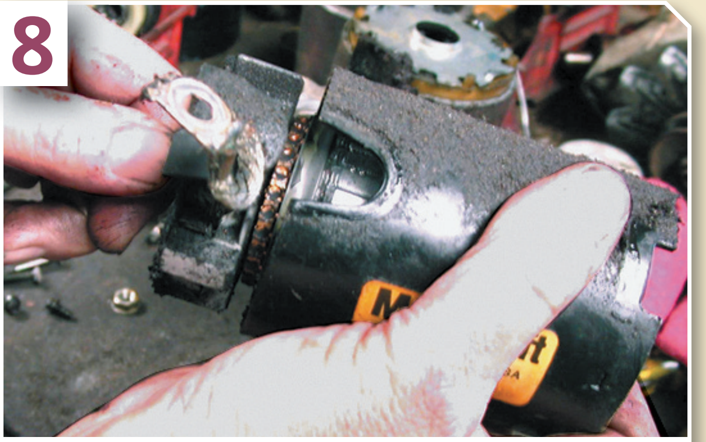
STARTER OVERHAUL

7



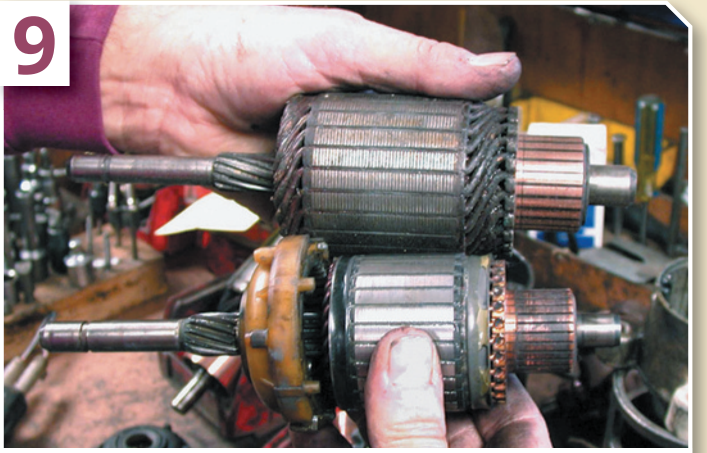
The brush end plate is removed.

8



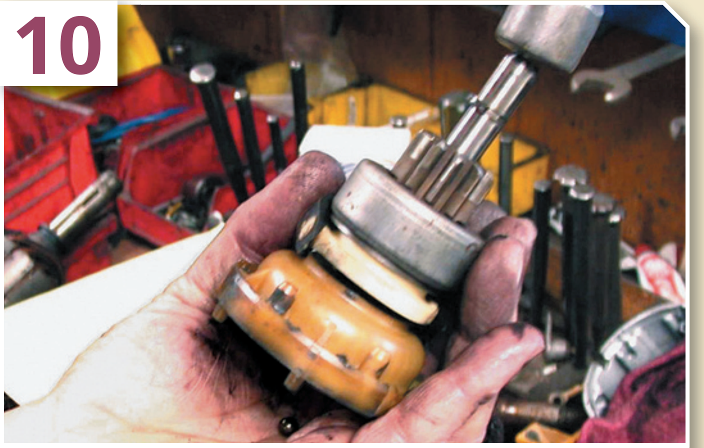
The armature assembly is removed from the field frame.

9



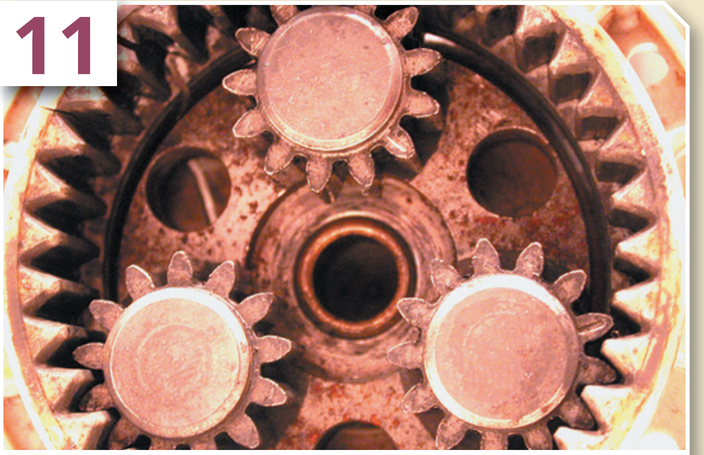
Notice that the length of a direct-drive starter armature (top) is the same length as the overall length of a gear-reduction armature, except smaller in diameter.

10



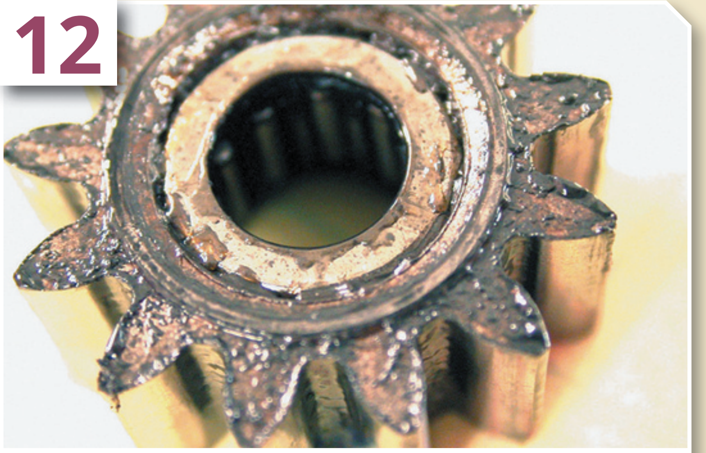
A light tap with a hammer dislodges the armature thrust ball (in the palm of the hand) from the center of the gear-reduction assembly.

11



This figure shows the planetary ring gear and pinion gears.

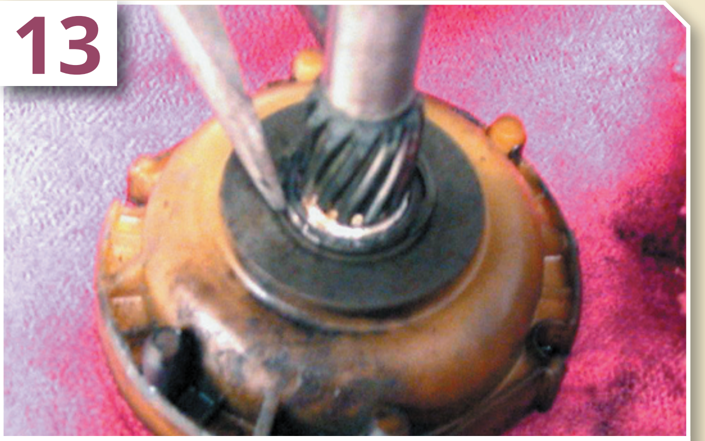
12



A close-up of one of the planetary gears, which shows the small needle bearings on the inside.

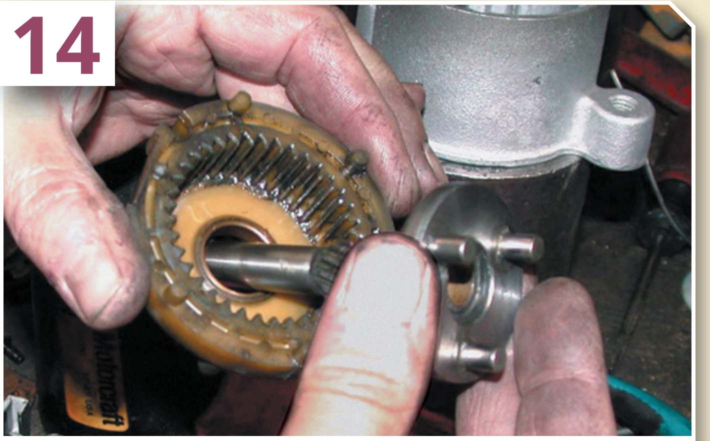
STEP BY STEP

13



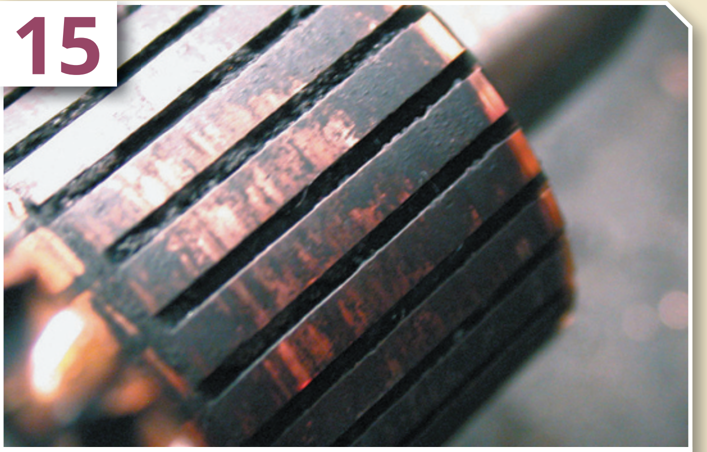
The clip is removed from the shaft so the planetary gear assembly can be separated and inspected.

14



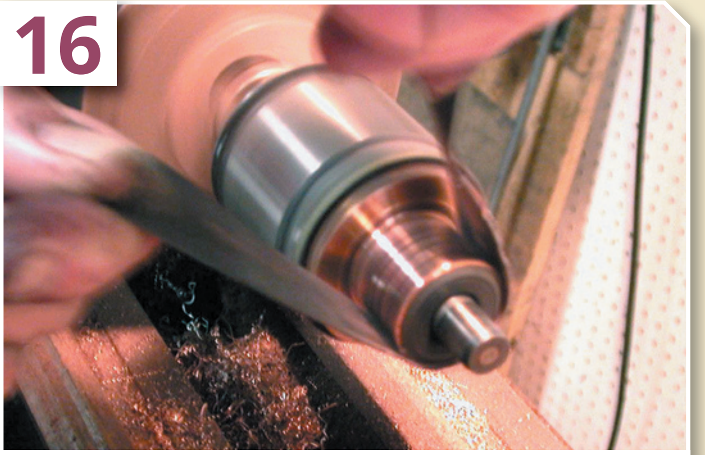
The shaft assembly is being separated from the stationary gear assembly.

15



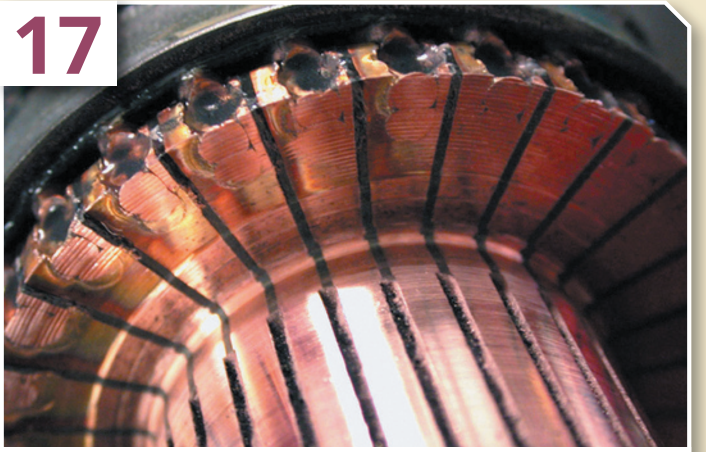
The commutator on the armature is discolored and the brushes may not have been making good contact with the segments.

16



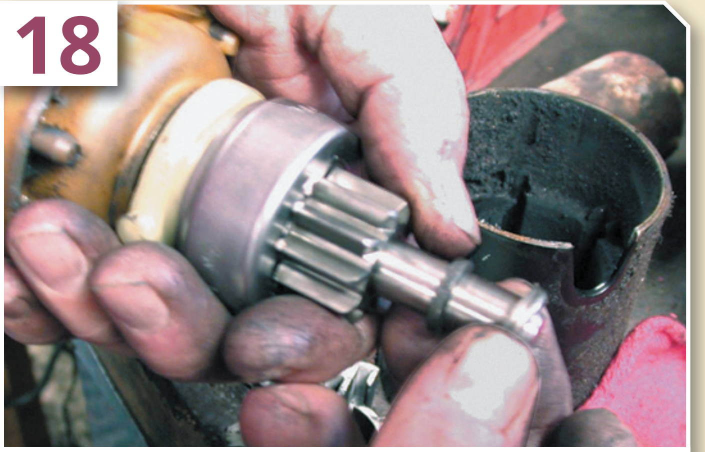
All of the starter components are placed in a tumbler with water-based cleaner. The armature is installed in a lathe and the commutator is resurfaced using emery cloth.

17



The finished commutator looks like new.

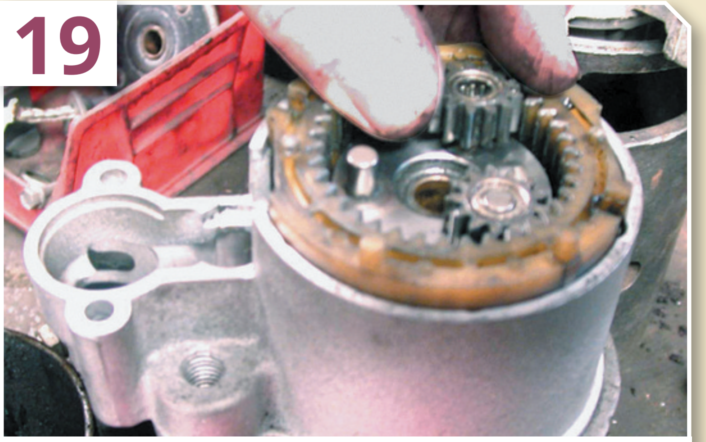
18



Starter reassembly begins by installing a new starter drive on the shaft assembly. The stop ring and stop ring retainer are then installed.

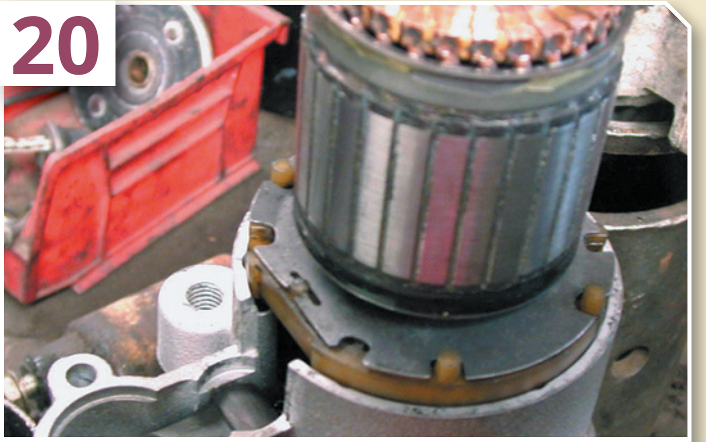
STARTER OVERHAUL

19



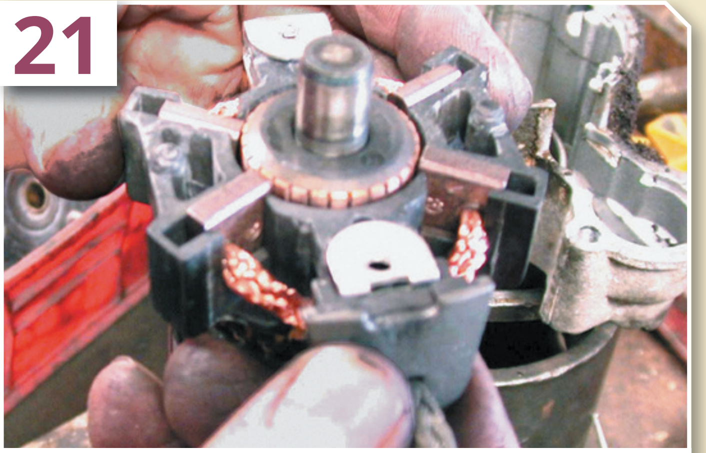
The gear-reduction assembly is positioned along with the shift fork (drive lever) into the cleaned drive-end housing.

20



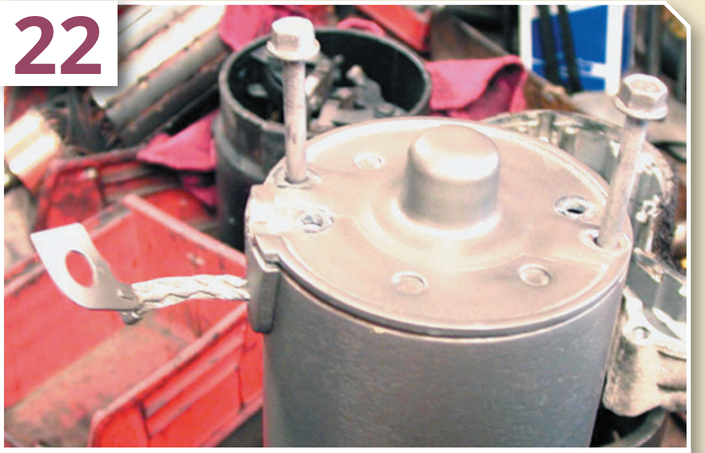
After gear retainer has been installed over the gear-reduction assembly, the armature is installed.

21



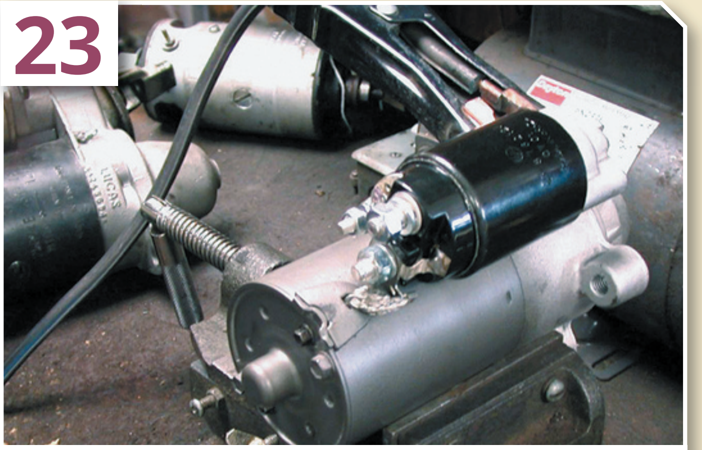
New brushes are being installed into the brush holder assembly.

22



The brush end plate and the through bolts are installed, being sure that the ground connection for the brushes is clean and tight.

23



This starter was restored to useful service by replacing the solenoid, the brushes, and the starter drive assembly, plus a thorough cleaning and attention to detail in the reassembly.

REVIEW QUESTIONS

1. What are the steps involved in the diagnosis of a fault in the cranking circuit?
2. What are the steps taken to perform a voltage drop test of the cranking circuit?
3. What are the steps necessary to replace a starter?
4. What are typical starter amperage draw for four-, six-, and eight-cylinder engines?
5. What could be the cause of excessive starter current draw?

CHAPTER QUIZ

1. Which one of these would NOT be a diagnostic step when diagnosing a "no crank" customer concern?
   - **a.** Check the condition of the engine oil
   - **b.** Check operation of the theft deterrent systems
   - **c.** Check the battery with a load test
   - **d.** Test for proper operation of the starter enable relay
2. Two technicians are discussing what could be the cause of slow cranking and excessive current draw. Technician A says that an engine mechanical fault could be the cause. Technician B says that the starter motor could be binding or defective. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
3. A V-6 is being checked for starter amperage draw. The initial surge current was about 210 amperes and about 160 amperes during cranking. Technician A says the starter is defective and should be replaced because the current flow exceeds 200 amperes. Technician B says this is normal current draw for a starter motor on a V-6 engine. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
4. What is the first step for removing a starter?
   - **a.** Hoist the vehicle
   - **b.** Disconnect the battery positive cable
   - **c.** Disconnect the battery negative cable
   - **d.** Remove the battery cable from the starter
5. Technician A says that a discharged battery (lower than normal battery voltage) can cause solenoid clicking. Technician B says that a discharged battery or dirty (corroded) battery cables can cause solenoid clicking. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
6. Slow cranking by the starter can be caused by all of these EXCEPT ____________.
   - **a.** a low or discharged battery
   - **b.** corroded or dirty battery cables
   - **c.** engine mechanical problems
   - **d.** an open neutral safety switch
7. Bench testing of a starter should be done ____________.
   - **a.** after reassembling an old starter
   - **b.** before installing a new starter
   - **c.** after removing the old starter
   - **d.** Both a and b
8. What is the symptom of an engine mechanical fault that can cause a slow-crank or a no-crank condition?
   - **a.** Excessive current draw
   - **b.** Low current draw and rapidly spinning starter motor
   - **c.** Starter solenoid clicking
   - **d.** Any of the above
9. A technician connects one lead of a digital voltmeter to the positive (+) terminal of the battery and the other meter lead to the battery terminal (B) of the starter solenoid and then cranks the engine. During cranking, the voltmeter displays a reading of 878 millivolts. Technician A says that this reading indicates that the positive battery cable resistance is too high. Technician B says that this reading indicates that the starter is defective. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
10. After installing the starter, the technician should perform which of the following?
    - **a.** Attach the negative battery cable
    - **b.** Check the starter for proper operation
    - **c.** Perform a starter voltage drop test before starting the engine
    - **d.** Both a and b

Chapter

51

CHARGING SYSTEM PARTS AND OPERATION

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain why an alternator generates an AC and changes it to DC.
- Describe an alternator's construction, including overrunning pulleys.
- Describe the components and operation of an alternator.
- Discuss how an alternator works.
- List the factors determining an alternator's output voltage and current.
- Explain how the voltage of an alternator is regulated.
- Explain how the heat produced by an alternator is regulated.
- Discuss computer-controlled alternators.

KEY TERMS:

Alternator 582 • Claw poles 584 • Delta winding 587 • Diodes 586 • Drive-end (DE) housing 582 • Duty cycle 590 • EPM 590 • OAD 584 • OAP 583 • Rotor 584 • Slip-ring-end (SRE) housing 582 • Stator 585 • Thermistor 589

PRINCIPLE OF ALTERNATOR OPERATION

PURPOSE AND FUNCTION It is the purpose and function of the charging system to keep the battery fully charged. The Society of Automotive Engineers (SAE) term for the unit that generates electricity is *generator.* The term **alternator** is most commonly used in the trade and is used here as well.

PRINCIPLES All electrical alternators use the principle of electromagnetic induction to generate electrical power from mechanical power. Electromagnetic induction involves the generation of electric current in a conductor when the conductor is moved through a magnetic field. The amount of current generated can be increased by the following factors:

1. Increasing the *speed* of the conductors through the magnetic field
2. Increasing the *number* of conductors passing through the magnetic field
3. Increasing the *strength* of the magnetic field

CHANGING AC TO DC An alternator generates an alternating current (AC) because the current changes polarity during the alternator's rotation. However, a battery cannot "store" AC; therefore, this AC is changed to direct current (DC) by diodes inside the alternator. Diodes are one-way electrical check valves that permit current to flow in only one direction.

ALTERNATOR CONSTRUCTION

HOUSING An alternator is constructed using a two-piece cast aluminum housing. Aluminum is used because of its lightweight, nonmagnetic properties, and heat transfer properties needed to help keep the alternator cool. A front ball bearing is pressed into the front housing, called the **drive-end (DE) housing**, to provide the support and friction reduction necessary for the belt-driven rotor assembly. The rear housing, or the **slip-ring-end (SRE) housing**, usually contains either a roller bearing or ball bearing support for the rotor and mounting for the brushes, diodes, and internal voltage regulator (if so equipped). ● **SEE FIGURES 51–1 AND 51–2**.

FIGURE 51–1 A typical alternator on a Chevrolet V-8 engine that is driven by the accessory drive belt at the front of the engine.

ALTERNATOR OVERRUNNING PULLEYS Many alternators are equipped with an **overrunning alternator pulley (OAP)**, also called an *overrunning clutch pulley* or an *alternator clutch pulley*. The purpose of this pulley is to help eliminate noise and vibration in the accessory drive belt system, especially when the engine is at idle speed. At idle, engine impulses are transmitted to the alternator through the accessory drive belt. The mass of the rotor of the alternator tends to want to keep spinning, but the engine crankshaft speeds up and slows down slightly due to the power impulses. Using a one-way clutch in the alternator pulley allows the belt to apply power to the alternator in only one direction, thereby reducing fluctuations in the belt. ● **SEE FIGURES 51–3 AND 51–4**.

A conventional drive pulley attaches to the alternator (rotor) shaft with a nut and lock washer. In the overrunning clutch pulley, the inner race of the clutch acts as the nut as it screws on to the shaft. Special tools are required to remove and install this type of pulley.

TECH TIP

Alternator Horsepower and Engine Operation

Many technicians are asked how much power certain accessories require. A 100 ampere alternator requires about 2 horsepower from the engine. One horsepower is equal to 746 watts. Watts are calculated by multiplying amperes times volts.

$$\textbf{Power in watts} = \textbf{100 A} \times \textbf{14.5 V} = \textbf{1,450 W}$$
$$\textbf{1 hp} = \textbf{746 W}$$

Therefore, 1,450 watts is about 2 horsepower.

Allowing about 20% for mechanical and electrical losses adds another 0.4 horsepower. Therefore, when someone asks how much power it takes to produce 100 amperes from an alternator, the answer is 2.4 horsepower.

Many alternators delay the electrical load to prevent the engine from stumbling when a heavy electrical load is applied. The voltage regulator or vehicle computer is capable of gradually increasing the output of the alternator over a period of several minutes. Even though 2 horsepower does not sound like much, a sudden demand for 2 horsepower from an idling engine can cause the engine to run rough or stall. The difference in part numbers of various alternators is often an indication of the time interval over which the load is applied. Therefore, using the wrong replacement alternator could cause the engine to stall!

Another type of alternator pulley uses a dampener spring inside, plus a one-way clutch. These units have the following names. ● **SEE FIGURES 51–5**.

- Isolating Decoupler Pulley (IDP)
- Active Alternator Pulley (AAP)

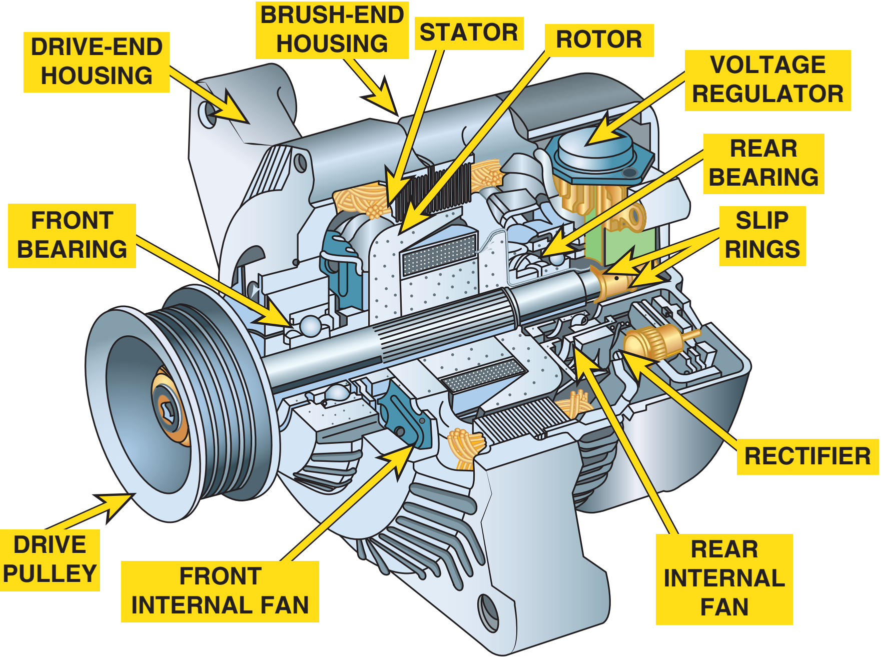


FIGURE 51–2 The end frame toward the drive belt is called the drive-end housing and the rear section is called the slip-ring-end housing.

- **Overrunning Alternator Dampener (OAD)** (most common term)

FREQUENTLY ASKED QUESTION

Can I Install an OAP or an OAD to My Alternator?

Usually, no. An alternator needs to be equipped with the proper shaft to allow the installation of an OAP or OAD. This also means that a conventional pulley often cannot be used to replace a defective overrunning alternator pulley or dampener. Check service information for the exact procedure to follow.

ALTERNATOR COMPONENTS AND OPERATION

ROTOR CONSTRUCTION The **rotor** is the rotating part of the alternator and is driven by the accessory drive belt. The rotor creates the magnetic field of the alternator and produces a current by electromagnetic induction in the stationary stator windings. The rotor is constructed of many turns of copper wire coated with a varnish insulation wound over an iron core. The iron core is attached to the rotor shaft.

At both ends of the rotor windings are heavy-gauge metal plates bent over the windings with triangular fingers called **claw poles**. These pole fingers do not touch, but alternate or interlace, as shown in ● **FIGURE 51–6**.

HOW ROTORS CREATE MAGNETIC FIELDS The two ends of the rotor winding are connected to the rotor's slip rings. Current

FRONT BEARING

FIGURE 51–6 A cutaway of an alternator, showing the rotor and cooling fan that is used to force air through the unit to remove the heat created when it is charging the battery and supplying electrical power for the vehicle.

for the rotor flows from the battery into one brush that rides on one of the slip rings, then flows through the rotor winding, then exits the rotor through the other slip ring and brush. One alternator brush is considered to be the "positive" brush and one is considered to be the "negative" or "ground" brush. The voltage regulator controls the field current through the rotor that controls the output of the alternator.

If current flows through the rotor windings, the metal pole pieces at each end of the rotor become electromagnets. Because the pole pieces are attached to each end of the rotor, one pole piece is a north pole magnet. The other pole piece is on the opposite end of the rotor, creating a south pole. Therefore, the rotor fingers are alternating north and south magnetic poles. These individual magnetic fields produce a current by electromagnetic induction in the stationary stator windings. ● **SEE FIGURE 51–7**.

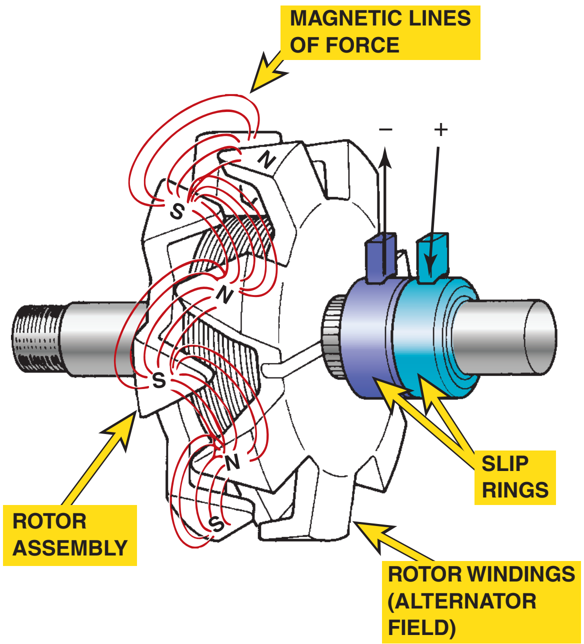

FIGURE 51–7 Rotor assembly of a typical alternator. Current through the slip rings causes the "fingers" of the rotor to become alternating north and south magnetic poles. As the rotor revolves, these magnetic lines of force induce a current in the stator windings.

ROTOR CURRENT The current necessary for the field (rotor) windings is conducted through slip rings with carbon brushes. The maximum rated alternator output in amperes depends on the number and gauge of the rotor windings.

The current for the field is controlled by the voltage regulator and is conducted to the slip rings through carbon brushes. The brushes conduct only the field current, which is usually between 2 and 5 amperes.

STATOR CONSTRUCTION The **stator** consists of the stationary coil windings inside the alternator. The stator is supported between the two halves of the alternator housing, with three copper wire windings that are wound on a laminated metal core.

As the rotor revolves, its moving magnetic field induces a current in the stator windings. ● **SEE FIGURE 51–8**.

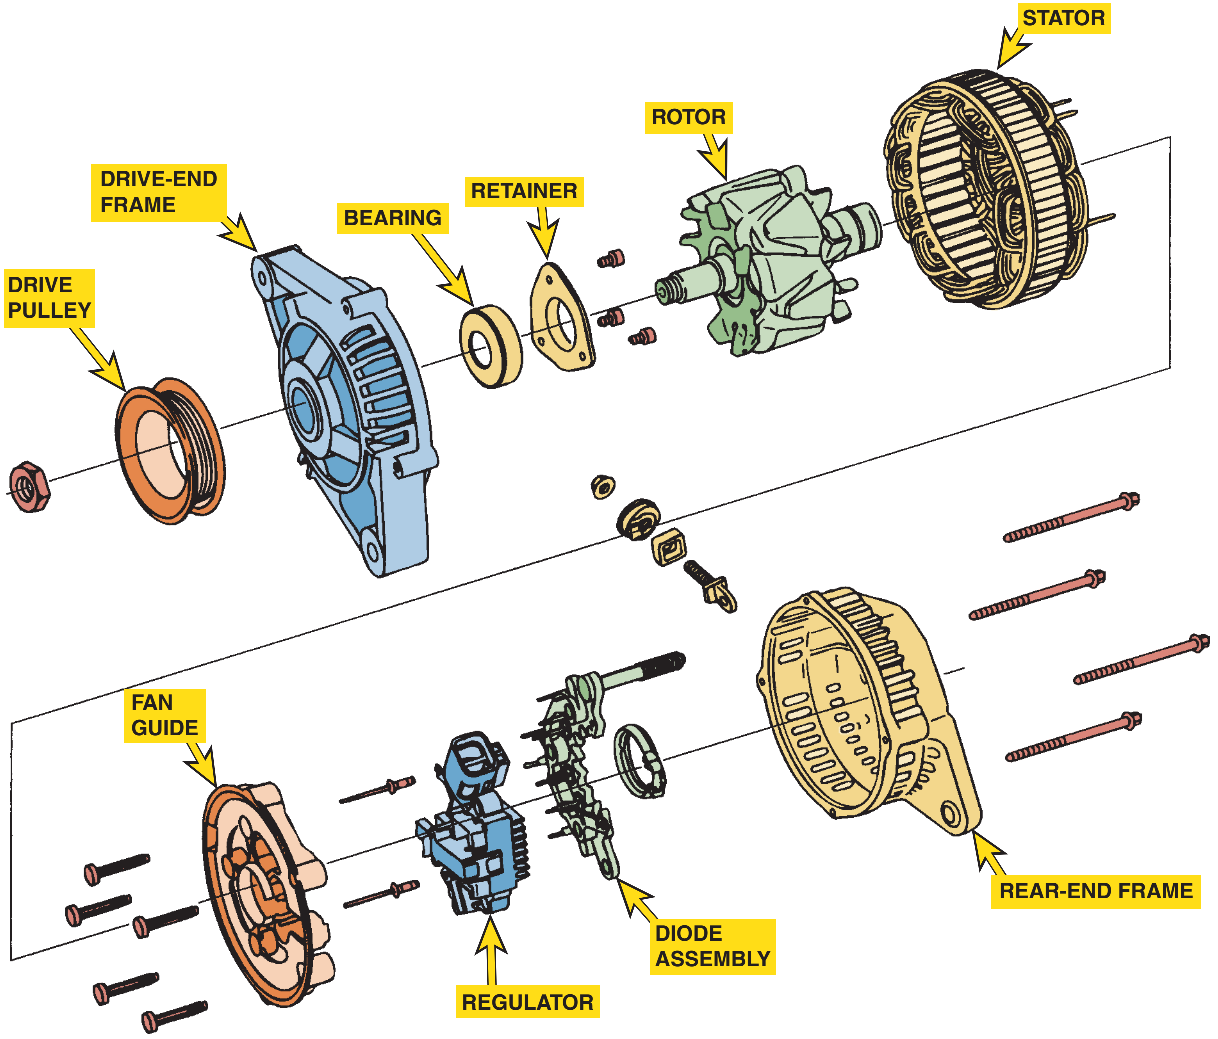

FIGURE 51–8 An exploded view of a typical alternator showing all of its internal parts including the stator windings.

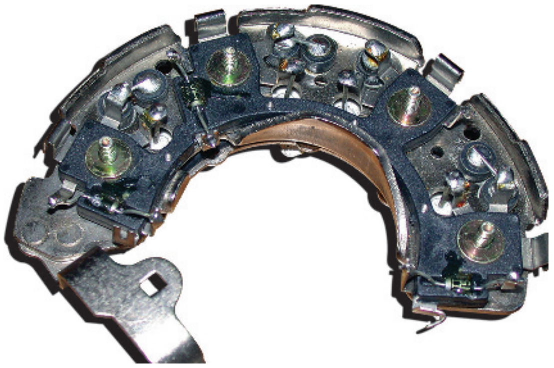

FIGURE 51–9 A rectifier usually includes six diodes in one assembly and is used to rectify AC voltage from the stator windings into DC voltage suitable for use by the battery and electrical devices in the vehicle.

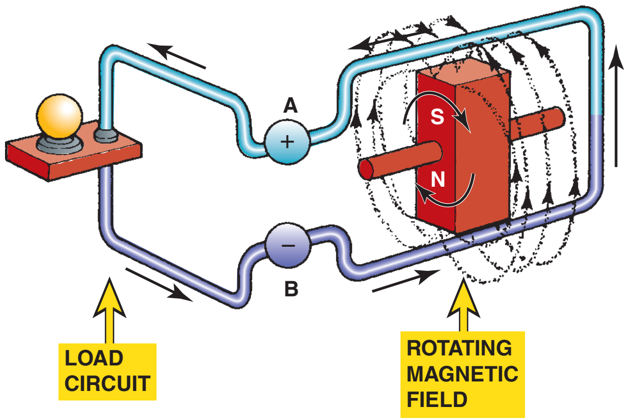

FIGURE 51–10 Magnetic lines of force cutting across a conductor induce a voltage and current in the conductor.

DIODES **Diodes** are constructed of a semiconductor material (usually silicon) and operate as a one-way electrical check valve that permits the current to flow in only one direction. Alternators often use six diodes (one positive and one negative set for each of the three stator windings) to convert alternating current to direct current.

Diodes used in alternators are included in a single part called a rectifier, or *rectifier bridge*. A rectifier includes not only the diodes (usually six), but also the cooling fins and connections for the stator windings and the voltage regulator. ● **SEE FIGURE 51–9**.

DIODE TRIO Some alternators are equipped with a diode trio that supplies current to the brushes from the stator windings. A diode trio uses three diodes in one housing, with one diode for each of the three stator windings and then one output terminal.

HOW AN ALTERNATOR WORKS

FIELD CURRENT IS PRODUCED A rotor inside an alternator is turned by a belt and drive pulley that are turned by the engine. Field current flowing through the slip rings to the rotor creates an alternating north and south pole on the rotor, with a magnetic field between each finger of the rotor. The magnetic field of the rotor generates a current in the stator windings by electromagnetic induction. ● **SEE FIGURE 51–10**.

CURRENT IS INDUCED IN THE STATOR The induced current in the stator windings is an alternating current because of the alternating magnetic field of the rotor. The induced current starts to increase as the magnetic field starts to induce current in each winding of the stator. The current then peaks when the magnetic field is the strongest and starts to decrease as the magnetic field moves away from the stator winding. Therefore, the current generated is described as being of a sine wave or alternating current pattern. ● **SEE FIGURE 51–11**.

As the rotor continues to rotate, this sine wave current is induced in each of the three windings of the stator.

Because each of the three windings generates a sine wave current, as shown in ● **FIGURE 51–12**, the resulting currents combine to form a three-phase voltage output.

The current induced in the stator windings connects to diodes (one-way electrical check valves) that permit the alternator output current to flow in only one direction, thereby changing AC voltage to DC voltage. All alternators contain at

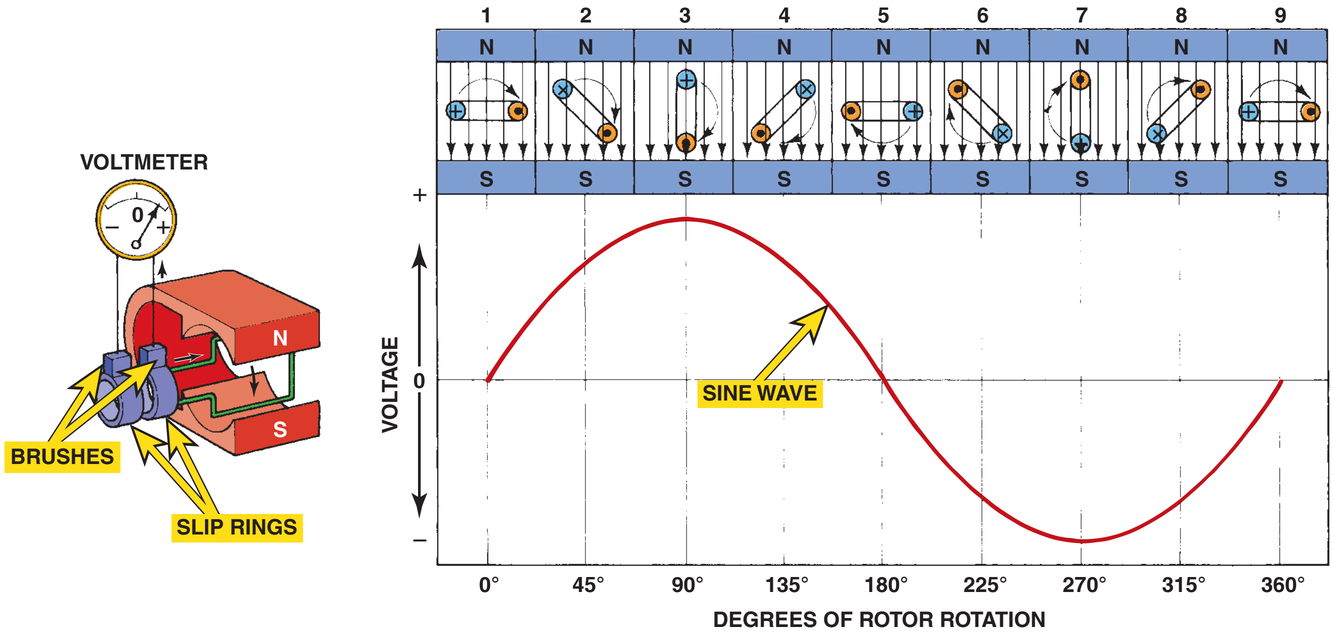

FIGURE 51–11 A sine wave (shaped like the letter *S* on its side) voltage curve is created by one revolution of a winding as it rotates in a magnetic field.

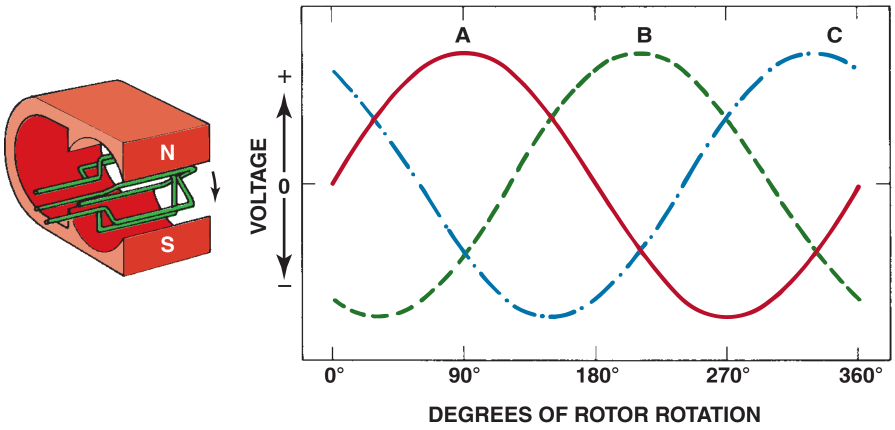

FIGURE 51–12 When three windings (A, B, and C) are present in a stator, the resulting current generation is represented by the three sine waves. The voltages are 120 degrees out of phase. The connection of the individual phases produces a three-phase alternating voltage.

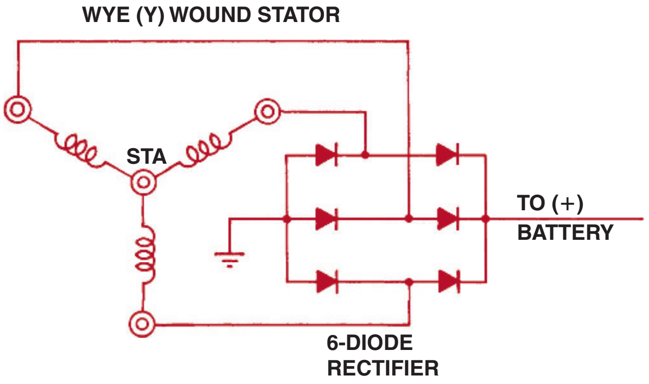

FIGURE 51–13 Wye-connected stator winding.

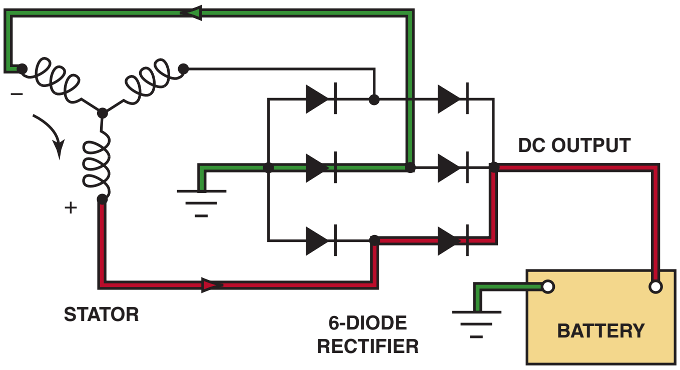

FIGURE 51–14 As the magnetic field, created in the rotor, cuts across the windings of the stator, a current is induced. Notice that the current path includes passing through one positive (+) diode on the way to the battery and one negative (–) diode as a complete circuit is completed through the rectifier and stator. It is the flow of current through the diodes that converts the AC voltage produced in the stator windings to DC voltage available at the output terminal of the alternator.

least six diodes, one pair (a positive and a negative diode) for each of the three stator windings. Some alternators contain eight diodes with another pair connected to the center connection of a wye-type stator.

WYE-CONNECTED STATORS The Y (pronounced "wye" and generally so written) type or star pattern is the most commonly used alternator stator winding connection. ● **SEE FIGURE 51–13.**

The output current with a wye-type stator connection is constant over a broad alternator speed range.

Current is induced in each winding by electromagnetic induction from the rotating magnetic fields of the rotor. In a wye-type stator connection, the currents must combine because two windings are always connected in series. ● **SEE FIGURE 51–14.**

The current produced in each winding is added to the other windings' current and then flows through the diodes to the alternator output terminal. One-half of the current produced is available at the neutral junction (usually labeled "STA" for stator).

DELTA-CONNECTED STATORS The **delta winding** is connected in a triangular shape. Delta is a Greek letter shaped like a triangle. ● **SEE FIGURE 51–15.**

Current induced in each winding flows to the diodes in a parallel circuit. More current can flow through two parallel circuits than can flow through a series circuit (as in a wye-type stator connection).

Delta-connected stators are used on alternators where high output at high-alternator revolutions per minute (RPM) is required. The delta-connected alternator can produce 73% more current than the same alternator with wye-type stator connections. For example, if an alternator with a wye-connected stator can produce 55 amperes, the *same* alternator with delta-connected stator windings can produce 73% more current, or 95 amperes (55 × 1.73 = 95). The delta-connected alternator, however, produces lower current at low speed and must be operated at high speed to produce its maximum output.

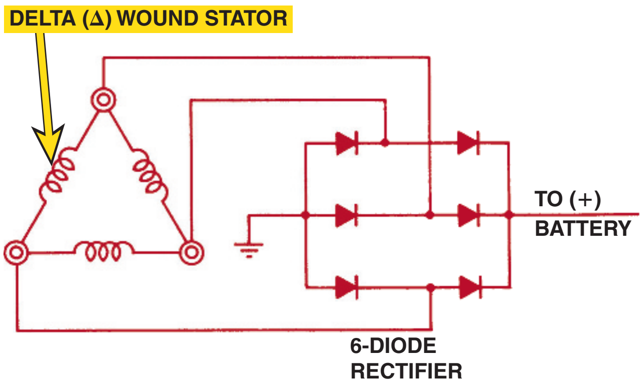

FIGURE 51–15 Delta-connected stator winding.

ALTERNATOR OUTPUT FACTORS

The output voltage and current of an alternator depend on the following factors:

1. **Speed of rotation.** Alternator output is increased with alternator rotational speed up to the alternator's maximum possible ampere output. Alternators normally rotate at a speed two to three times faster than engine speed, depending on the relative pulley sizes used for the belt drive. For example, if an engine is operating at 5,000 RPM, the alternator is rotating at about 15,000 RPM.
2. **Number of conductors.** A high-output alternator contains more turns of wire in the stator windings. Stator winding connections (whether wye or delta) also affect the maximum alternator output. ● **SEE FIGURE 51–16** for an example of a stator that has six, rather than three windings, which greatly increase the amperage output of the alternator.
3. **Strength of the magnetic field.** If the magnetic field is strong, a high output is possible because the current generated by electromagnetic induction is dependent on the number of magnetic lines of force that are cut.
    - **a.** The strength of the magnetic field can be increased by increasing the number of turns of conductor wire wound on the rotor. A higher output alternator rotor has more turns of wire than an alternator rotor with a low-rated output.
    - **b.** The strength of the magnetic field also depends on the current through the field coil (rotor). Because magnetic field strength is measured in ampere-turns, the greater the amperage or the number of turns, or both, the greater the alternator output.

ALTERNATOR VOLTAGE REGULATION

PRINCIPLES An automotive alternator must be able to produce electrical pressure (voltage) higher than battery voltage to charge the battery. Excessively high voltage can damage the battery, electrical components, and the lights of a vehicle. Basic principles include the following:

- If no (zero) amperes of current exists throughout the field coil of the alternator (rotor), alternator output is zero, because without field current, a magnetic field does not exist.

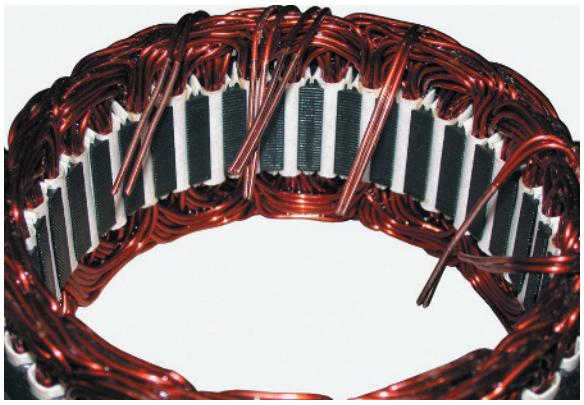

FIGURE 51–16 A stator assembly with six, rather than the normal three, windings.

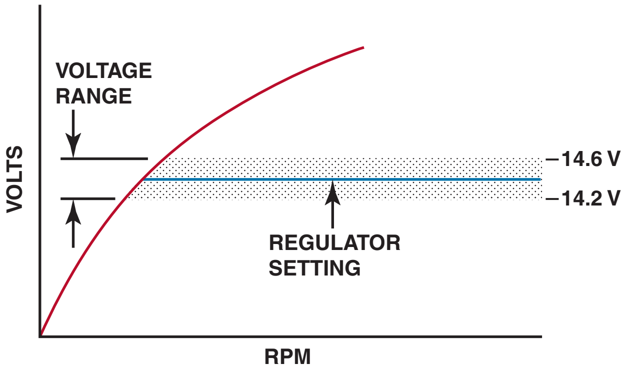

FIGURE 51–17 Typical voltage regulator range.

- The field current required by most automotive alternators is less than 3 amperes. It is the *control* of the *field* current that controls the output of the alternator.
- Current for the rotor flows from the battery positive post, through the rotor positive brush, into the rotor field winding, and exits the rotor winding through the rotor ground brush. Most voltage regulators control field current by controlling the amount of field current through the ground brush.
- The voltage regulator simply opens the field circuit if the voltage reaches a predetermined level, then closes the field circuit again, as necessary, to maintain the correct charging voltage. ● **SEE FIGURE 51–17**.
- The electronic circuit of the voltage regulator cycles between 10 and 7,000 times per second, as needed, to accurately control the field current through the rotor and, therefore, control the alternator output.

REGULATOR OPERATION

- The control of the field current is accomplished by opening and closing the *ground* side of the field circuit through the rotor on most alternators.
- The zener diode is a major electronic component that makes voltage regulation possible. A zener diode blocks current flow until a specific voltage is reached, then it permits current to flow. Alternator voltage from the stator and diodes is first sent through a thermistor, which changes resistance with temperature, and then to a zener diode. When the upper-limit voltage is reached, the zener diode conducts current to a transistor, which then opens the field (rotor) circuit. The electronics are usually housed in a separate part inside the alternator. ● **SEE FIGURES 51–18 AND 51–19**.

BATTERY CONDITION AND CHARGING VOLTAGE If the automotive battery is discharged, its voltage is lower than the voltage of a fully charged battery. The alternator supplies charging current, but it may not reach the maximum charging voltage. For example, if a vehicle is jump started and run at a fast idle (2,000 RPM), the charging voltage may be only 12 volts. In this case, the following may occur:

- As the battery becomes charged and the battery voltage increases, the charging voltage also increases, until the voltage regulator limit is reached.

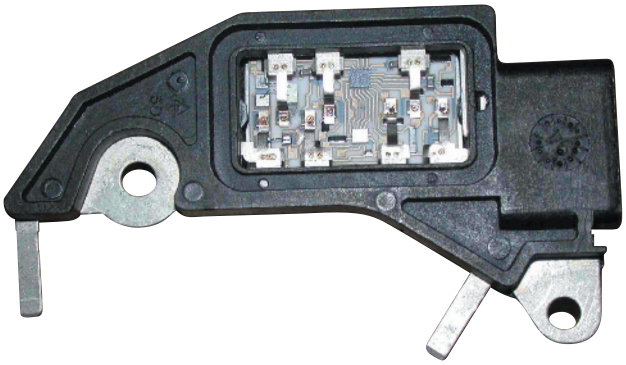

FIGURE 51–18 A typical electronic voltage regulator with the cover removed showing the circuits inside.

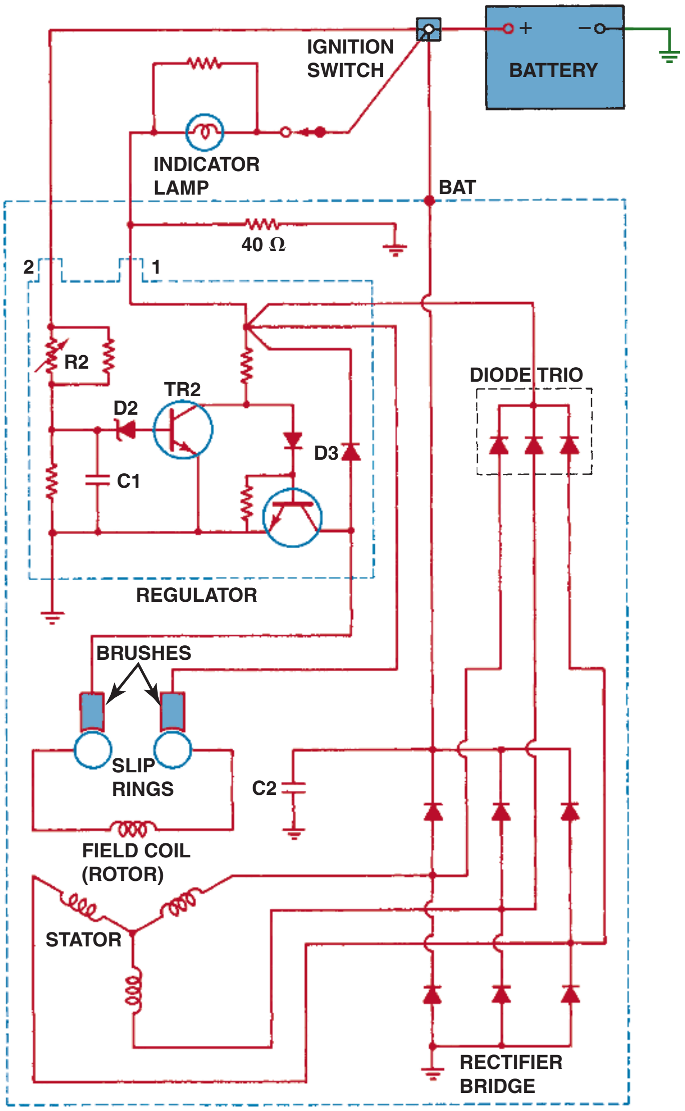

FIGURE 51–19 Typical General Motors SI-style alternator with an integral voltage regulator. Voltage present at terminal 2 is used to reverse bias the zener diode (D2) that controls TR2. The positive brush is fed by the ignition current (terminal 1) plus current from the diode trio.

- Then, the voltage regulator starts to control the charging voltage. A good, but discharged, battery should be able to convert into chemical energy all the current the alternator can produce. As long as alternator voltage is higher than battery voltage, current flows from the alternator (high voltage) to the battery (lower voltage).
- Therefore, if a voltmeter is connected to a discharged battery with the engine running, it may indicate charging voltage that is lower than normally acceptable.

In other words, the condition and voltage of the battery *do* determine the charging rate of the alternator. It is often stated that the battery is the true "voltage regulator" and that the voltage regulator simply acts as the upper-limit voltage control. This is the reason why all charging system testing *must* be performed with a reliable and known to be good battery, at least 75% charged, to be assured of accurate test results. If a discharged battery is used during charging system testing, tests could mistakenly indicate a defective alternator and/or voltage regulator.

TEMPERATURE COMPENSATION All voltage regulators (mechanical or electronic) provide a method for increasing the charging voltage slightly at low temperatures and for lowering the charging voltage at high temperatures. A battery requires a higher charging voltage at low temperatures because of the resistance to chemical reaction changes. However, the battery is overcharged if the charging voltage is not reduced during warm weather. Electronic voltage regulators use a temperature-sensitive resistor in the regulator circuit. This resistor, called a **thermistor**, provides lower resistance as the temperature increases. A thermistor is used in the electronic circuits of the voltage regulator to control charging voltage over a wide range of underhood temperatures.

NOTE: Voltmeter test results may vary according to temperature. Charging voltage tested at 32°F (0°C) is higher than for the same vehicle tested at 80°F (27°C) because of the temperature-compensation factors built into voltage regulators.

ALTERNATOR COOLING

Alternators create heat during normal operation and this heat must be removed to protect the components inside, especially the diodes and voltage regulator. The types of cooling include the following:

- External fan
- Internal fan(s)
- Both an external fan and an internal fan
- Coolant cooled (● **SEE FIGURE 51–20**)

COMPUTER-CONTROLLED CHARGING SYSTEMS

ADVANTAGES Computer control of the charging system has the following advantages:

1. The computer controls the field of the alternator, which can pulse it on or off, as needed, for maximum efficiency, thereby saving fuel.

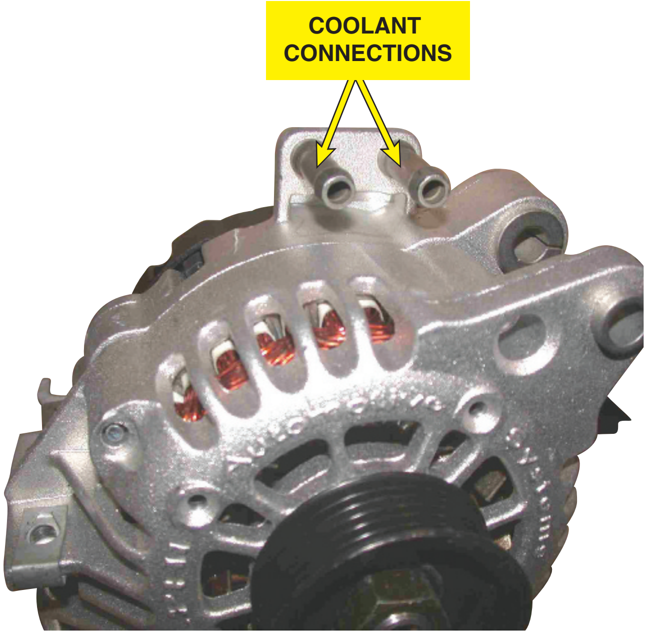

FIGURE 51–20 A coolant-cooled alternator showing the hose connections where coolant from the engine flows through the rear frame of the alternator.

NOTE: Some vehicle manufacturers, such as Honda/ Acura, use an electronic load control (ELC), which turns on the alternator when decelerating, where the additional load on the engine is simply used to help slow the vehicle. This allows the battery to be charged without placing a load on the engine, helping to increase fuel economy.

2. Engine idle can also be improved by turning on the alternator slowly, rather than all at once, if an electrical load is switched on, such as the air-conditioning system.
3. Most computers can also reduce the load on the electrical system if the demand exceeds the capacity of the charging system, by reducing fan speed, shutting off rear window defoggers, or increasing engine speed to cause the alternator to increase the amperage output.

NOTE: A commanded higher-than-normal idle speed may be the result of the computer compensating for an abnormal electrical load. This higher idle speed could indicate a defective battery or other electrical system faults.

4. The computer can monitor the charging system and set diagnostic trouble codes (DTCs) if a fault is detected. Many systems allow the service technician to control the charging of the alternator using a scan tool.
5. Because the charging system is computer controlled, it can be checked using a scan tool. Some vehicle systems allow the scan tool to activate the alternator field and then monitor the output to help detect fault locations. Always follow the vehicle manufacturer's diagnostic procedure.

TYPES OF SYSTEMS Computers can interface with the charging system in three ways.

1. The computer can *activate* the charging system by turning on and off the field current to the rotor. In other words, the computer, usually the powertrain control module (PCM), controls the field current to the rotor.
2. The computer can *monitor* the operation of the alternator and increase engine speed, if needed, during conditions when a heavy load is demanded by the alternator.
3. The computer can *control* the alternator by controlling alternator output to match the needs of the electrical system. This system detects the electrical needs of the vehicle and commands the alternator to charge only when needed to improve fuel economy.

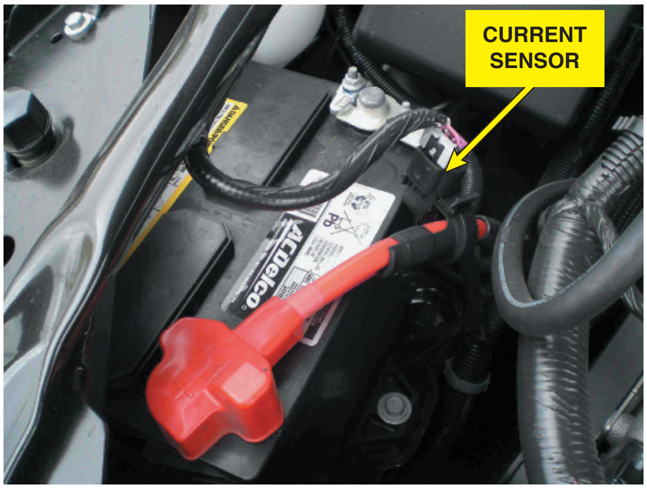

FIGURE 51–21 A Hall-effect current sensor attached to the positive battery cable is used as part of the EPM system.

GM ELECTRICAL POWER MANAGEMENT SYSTEM A typical system used on some General Motors vehicles is called **electrical power management (EPM)**. It uses a Hall-effect sensor attached to the negative or positive battery cable to measure the current leaving and entering the battery. ● **SEE FIGURE 51–21**.

The engine control module (ECM) controls the alternator by changing the on-time of the current through the rotor. ● **SEE FIGURE 51–22**.

The on-time, called **duty cycle**, varies from 5% to 95%. ● **SEE CHART 51–1**.

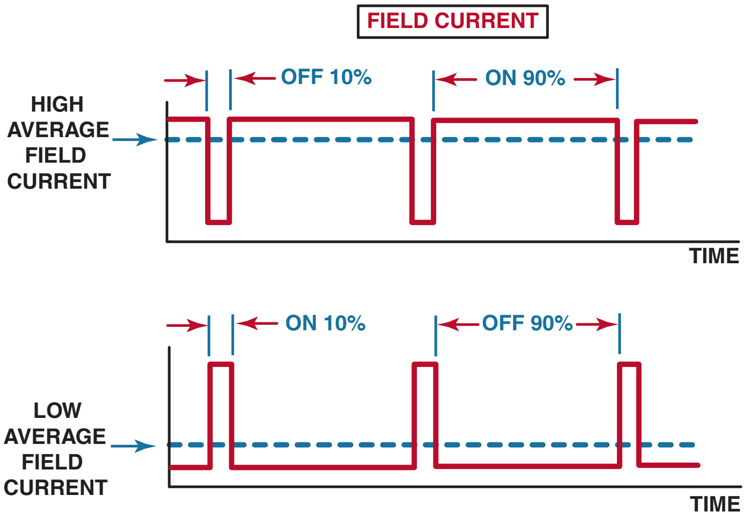

FIGURE 51–22 The amount of time current flowing through the field (rotor) determines the alternator output.

COMMAND DUTY CYCLE	ALTERNATOR OUTPUT VOLTAGE
10%	11.0 V
20%	11.6 V
30%	12.1 V
40%	12.7 V
50%	13.3 V
60%	13.8 V
70%	14.4 V
80%	14.9 V
90%	15.5 V

CHART 51–1

The output voltage is controlled by varying the duty cycle as controlled by the PCM.

This system has six modes of operation.

1. **Charge mode.** The charge mode is activated when any of the following occurs:
   - Electric cooling fans are on high speed.
   - Rear window defogger is on.
   - Battery state of charge (SOC) is less than 80%
   - Outside (ambient) temperature is less than 32°F (0°C).
2. **Fuel economy mode.** This mode reduces the load on the engine from the alternator for maximum fuel economy. This mode is activated when the following conditions are met:
   - Ambient temperature is above 32°F (0°C).
   - The SOC of the battery is 80% or higher.
   - The cooling fans and rear defogger are off.

   The target voltage is 13 volts and returns to the charge mode, if needed.
3. **Voltage reduction mode.** This mode is commanded to reduce the stress on the battery during low-load conditions. This mode is activated when the following conditions are met:
   - Ambient temperature is above 32°F (0°C).
   - Battery discharge rate is less than 7 amperes.
   - Rear defogger is off.
   - Cooling fans are on low or off.
   - Target voltage is limited to 12.7 volts.
4. **Start-up mode.** This mode is selected after engine start and commands a charging voltage of 14.5 volts for 30 seconds. After 30 seconds, the mode is changed, depending on conditions.
5. **Battery sulfation mode.** This mode is commanded if the output voltage is less than 13.2 volts for 45 minutes, which can indicate that sulfated plates could be the cause. The target voltage is 13.9 to 15.5 volts for three minutes. After three minutes, the system returns to another mode, based on conditions.
6. **Headlight mode.** This mode is selected when the headlights are on and the target voltage is 14.5 volts.

TECH TIP

The Voltage Display Can Be a Customer Concern

A customer may complain that the voltmeter reading on the dash fluctuates up and down. This may be normal as the computer-controlled charging system commands various modes of operation based on the operating conditions. Follow the vehicle manufacturer's recommended procedures to verify proper operation.

REVIEW QUESTIONS

1. How can a small electronic voltage regulator control the output of a typical 100 ampere alternator?
2. What are the component parts of a typical alternator?
3. How is the computer used to control an alternator?
4. How is AC voltage inside the alternator changed to DC voltage at the output terminal?
5. What is the purpose of an OAP or OAD?

CHAPTER QUIZ

1. Technician A says that the diodes regulate the alternator output voltage. Technician B says that the field current can be computer controlled. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. A magnetic field created in the ____________ is used to induce a voltage in the ____________.
   a. stator; rear housing
   b. diodes; stator
   c. rotor; stator
   d. drive-end frame; OAD
3. How is the AC voltage produced in the alternator changed to DC voltage?
   a. Mechanical switches
   b. Alternating brushes
   c. Slip ring rotation
   d. Diodes inside the alternator
4. Technician A says that two diodes are required for each stator winding lead. Technician B says that diodes change alternating current into direct current. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

5. The alternator output current is produced in the ___________.
   - **a.** stator
   - **b.** rotor
   - **c.** brushes
   - **d.** diodes (rectifier bridge)
6. The output of an alternator can be increased by increasing the ______________ of the alternator.
   - **a.** speed of rotation
   - **b.** number of conductors in the starter
   - **c.** current in the rotor
   - **d.** Any of these would increase the output
7. How much current flows through the alternator brushes?
   - **a.** All of the alternator output flows through the brushes
   - **b.** 25 to 35 amperes, depending on the vehicle
   - **c.** 10 to 15 amperes
   - **d.** Less than 3 amperes
8. Technician A says that an alternator overrunning pulley is used to reduce vibration and noise. Technician B says that an overrunning alternator pulley or dampener uses a one-way clutch. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
9. What is/are used to help control the heat created in the alternator?
   - **a.** External fan
   - **b.** Internal fan
   - **c.** Coolant cooled
   - **d.** Any of the above
10. How does the computer interface with the alternator?
    - **a.** The computer can actuate the charging system
    - **b.** The computer can monitor the operation of the alternator
    - **c.** The computer can control the operation of the alternator
    - **d.** Any of the above

Chapter 52

CHARGING SYSTEM DIAGNOSIS AND SERVICE

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss the various methods to test the charging system.
- Describe how to inspect and replace the drive belts.
- Describe the AC ripple voltage check.
- Describe how to test AC ripple current.
- Describe charging system voltage drop testing.
- Discuss the alternator output test.
- Discuss minimum required alternator output.
- Explain how to remove an alternator.
- Explain how to install an alternator.

KEY TERMS:

AC ripple voltage 597 • Charging voltage test 593

CHARGING SYSTEM TESTING AND SERVICE

BATTERY STATE OF CHARGE The charging system can be tested as part of a routine vehicle inspection or to determine the reason for a no-charge or reduced charging circuit performance. The battery *must* be at least 75% charged before testing the alternator and the charging system. A weak or defective battery causes inaccurate test results. If in doubt, replace the battery with a known good shop battery for testing.

CHARGING VOLTAGE TEST The **charging voltage test** is the easiest way to check the charging system voltage at the battery. Use a digital multimeter to check the voltage, as follows:

STEP 1 Select DC volts.

STEP 2 Connect the red meter lead to the positive (+) terminal of the battery and the black meter lead to the negative (−) terminal of the battery.

NOTE: The polarity of the meter leads is not too important when using a digital multimeter. If the meter leads are connected backward on the battery, the resulting readout simply has a negative (−) sign in front of the voltage reading.

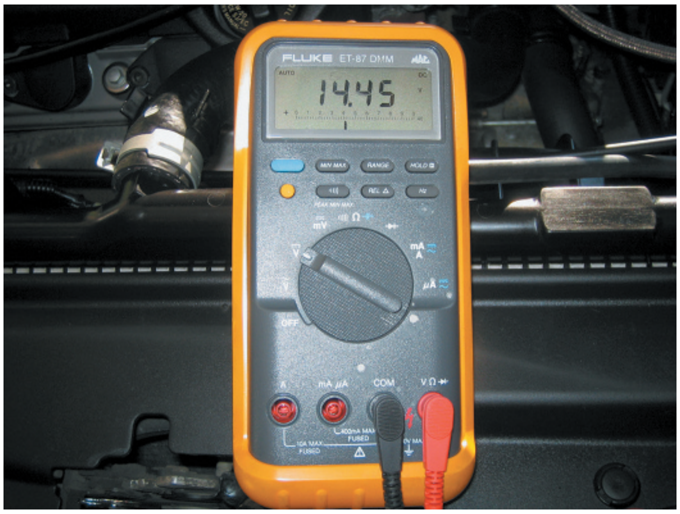

FIGURE 52–1 The digital multimeter should be set to read DC volts, with the red lead connected to the positive (+) battery terminal and the black meter lead connected to the negative (−) battery terminal.

STEP 3 Start the engine and increase the engine speed to about 2,000 RPM (fast idle) and record the charging voltage. ● **SEE FIGURE 52–1**.

Specifications for charging voltage = 13.5 to 15 volts

- If the voltage is too high, check that the alternator is properly grounded.
- If the voltage is lower than specifications, then there is a fault with the wiring or the alternator.
- If the wiring, fuses, and the connections are okay, then additional testing is required to help pinpoint the root cause. Replacement of the alternator and/or battery is often required if the charging voltage is not within factory specifications.
- If the alternator is computer-controlled, a defective current sensor or PCM could be the reason for a no-charge condition.

SCAN TESTING THE CHARGING CIRCUIT Most vehicles that use a computer-controlled charging system can be diagnosed using a scan tool. Not only can the charging voltage be monitored, but also, in many vehicles, the field circuit can be controlled and the output voltage monitored to check that the system is operating correctly. ● **SEE FIGURE 52–2.**

NOTE: Some charging systems, such as those on many Honda/Acura vehicles, use an electronic load detection circuit that energizes the field circuit only when an electrical load is detected. For example, if the engine is running and there are no accessories on, the voltage read at the battery may be 12.6 volts, which could indicate that the charging system is not operating. In this situation, turning on the headlights or an accessory should cause the computer to activate the field circuit, and the alternator should produce normal charging voltage.

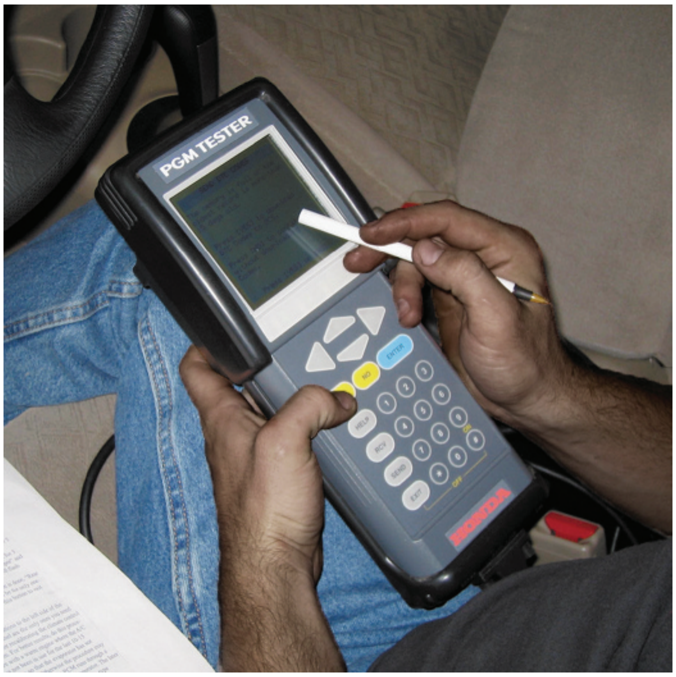

FIGURE 52–2 A scan tool can be used to diagnose charging system problems.

CASE STUDY

The Case of the Overcharging Chevrolet Truck

The owner of a Chevrolet Silverado 2500 HD, equipped with a 6.6 L diesel V8, stated that the ABS, Battery, and many other dash warning lights would come on when accelerating hard. The technician retrieved a C0800 diagnostic trouble code. (The module detects that the system voltage is greater than 16 volts.) The technician measured the voltage at the battery terminal with the engine operating above the idle speed and recorded a reading of a 17.7 volts. Because the voltage output of the alternator is controlled by the voltage regulator and it is built in the alternator, the technician replaced the alternator. The technician checked the charging voltage and it was now within factory specification. The diagnostic trouble code was cleared and the vehicle returned to the customer.

Summary:

Complaint—Customer asked to check the engine light and stated that several other warning lights would come on when accelerating rapidly.
Cause—The voltage regulator inside the alternator was not working as designed.
Correction—The alternator was replaced which corrected the customer concern.

FREQUENTLY ASKED QUESTION

What Is a Full-Fielding Test?

Full fielding is a procedure used on older noncomputerized vehicles for bypassing the voltage regulator that could be used to determine if the alternator is capable of producing its designed output. This test is no longer performed for the following reasons:

- The voltage regulator is built into the alternator, requiring that the entire assembly be replaced even if just the regulator is defective.
- When the regulator is bypassed, the alternator can produce a high voltage (over 100 volts in some cases), which could damage all of the electronic circuits in the vehicle.

Always follow the vehicle manufacturer's recommended testing procedures.

DRIVE BELT INSPECTION AND REPLACEMENT

BELT VISUAL INSPECTION It is generally recommended that all belts be inspected regularly and replaced as needed. Replace any serpentine belt that has more than three cracks in any one

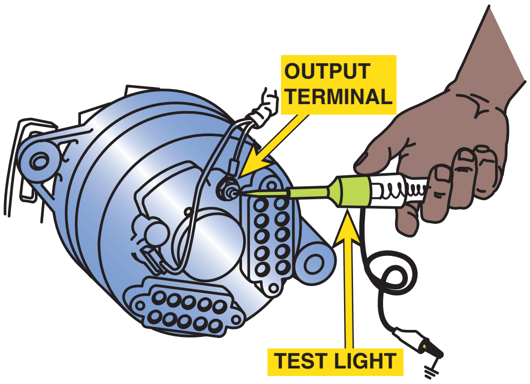

FIGURE 52–3 Before replacing an alternator, the wise technician checks that battery voltage is present at the output and battery voltage sense terminals. if no voltage is detected, then there is a fault in the wiring.

TECH TIP

Use a Test Light to Check for a Defective Fusible Link

Most alternators use a fusible link or mega fuse between the output terminal and the positive (+) terminal of the battery. If this fusible link or fuse is defective (blown), then the charging system does not operate at all. Many alternators have been replaced repeatedly because of a blown fusible link that was not discovered until later. A quick test that checks whether the fusible link is okay is to touch a test light to the output terminal with the other end of the test light attached to a good ground. The fusible link or mega fuse is okay if the light comes on. This test confirms that the circuit between the alternator and the battery has continuity. ● **SEE FIGURE 52–3**.

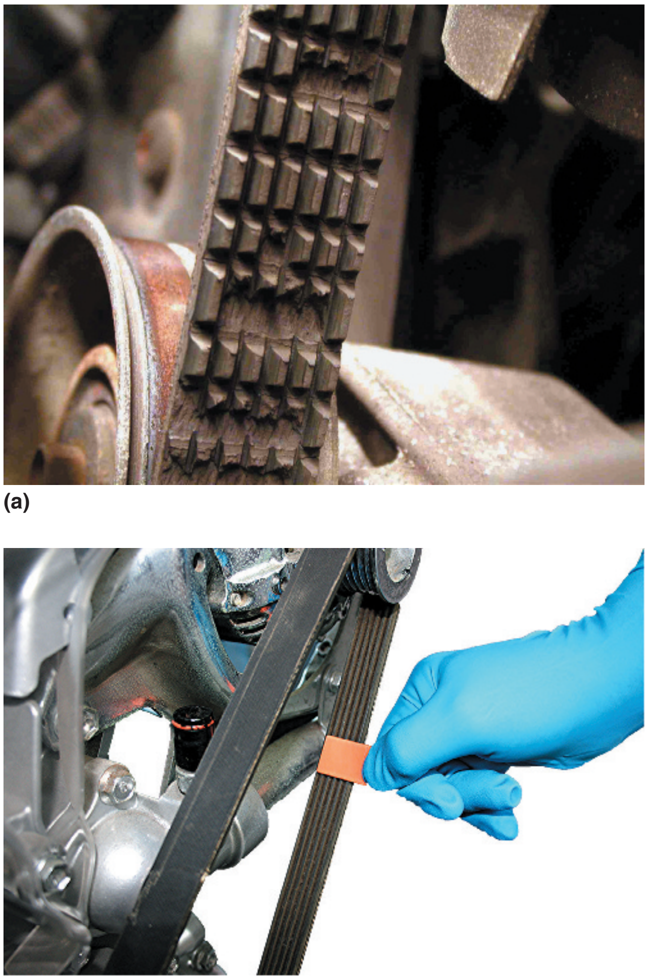
rib that appears in a 3 inch span. Check service information for the specified procedure and recommended replacement interval. ● **SEE FIGURE 52–4**.

BELT REPLACEMENT If the belt needs replacement, first make note of the belt routing. There may be a diagram under the hood. Use a tool to release the tensioner and then remove the belt. ● **SEE FIGURE 52–5**. Install the new belt and check it for the proper tension.

BELT TENSION MEASUREMENT If the vehicle does not use a belt tensioner, then a belt tension gauge is needed to achieve the specified belt tension. Install the belt and operate the engine with all of the accessories turned on to "run-in" the belt for at least five minutes. Adjust the tension of the accessory drive belt to factory specifications or use the following table for an example of the proper tension based on the size of the belt.

There are four ways that vehicle manufacturers specify that the belt tension is within factory specifications:

1. **Belt tension gauge.** A belt tension gauge is needed to determine if it is at the specified belt tension. Install the belt and operate the engine with all of the accessories turned on to "run-in" the belt for at least five minutes. Adjust the tension of the accessory drive belt to factory specifications, or see ● **CHART 52–1** for an example of the proper tension based on the size of the belt.



(a)
(b)

FIGURE 52–4 (a) This accessory drive belt is worn and requires replacement. Newer belts are made from ethylene propylene diene monomer (EPDM). This rubber does not crack like older belts and may not show wear, even though the ribs do wear and can cause slippage. (b) A belt wear gauge being used to check a belt. It should fit tightly but if it is able to be moved side to side, then the belt is worn and should be replaced.

SERPENTINE BELTS	
NUMBER OF RIBS USED	**TENSION RANGE (LB)**
3	45–60
4	60–80
5	75–100
6	90–125
7	105–145
V-BELTS	
V-BELT TOP WIDTH (IN.)	**TENSION RANGE (LB)**
1/4	45–65
5/16	60–85
25/64	85–115
31/64	105–145

CHART 52–1

Typical belt tension for various widths of belts. Tension is the force needed to depress the belt as displayed on a belt tension gauge.

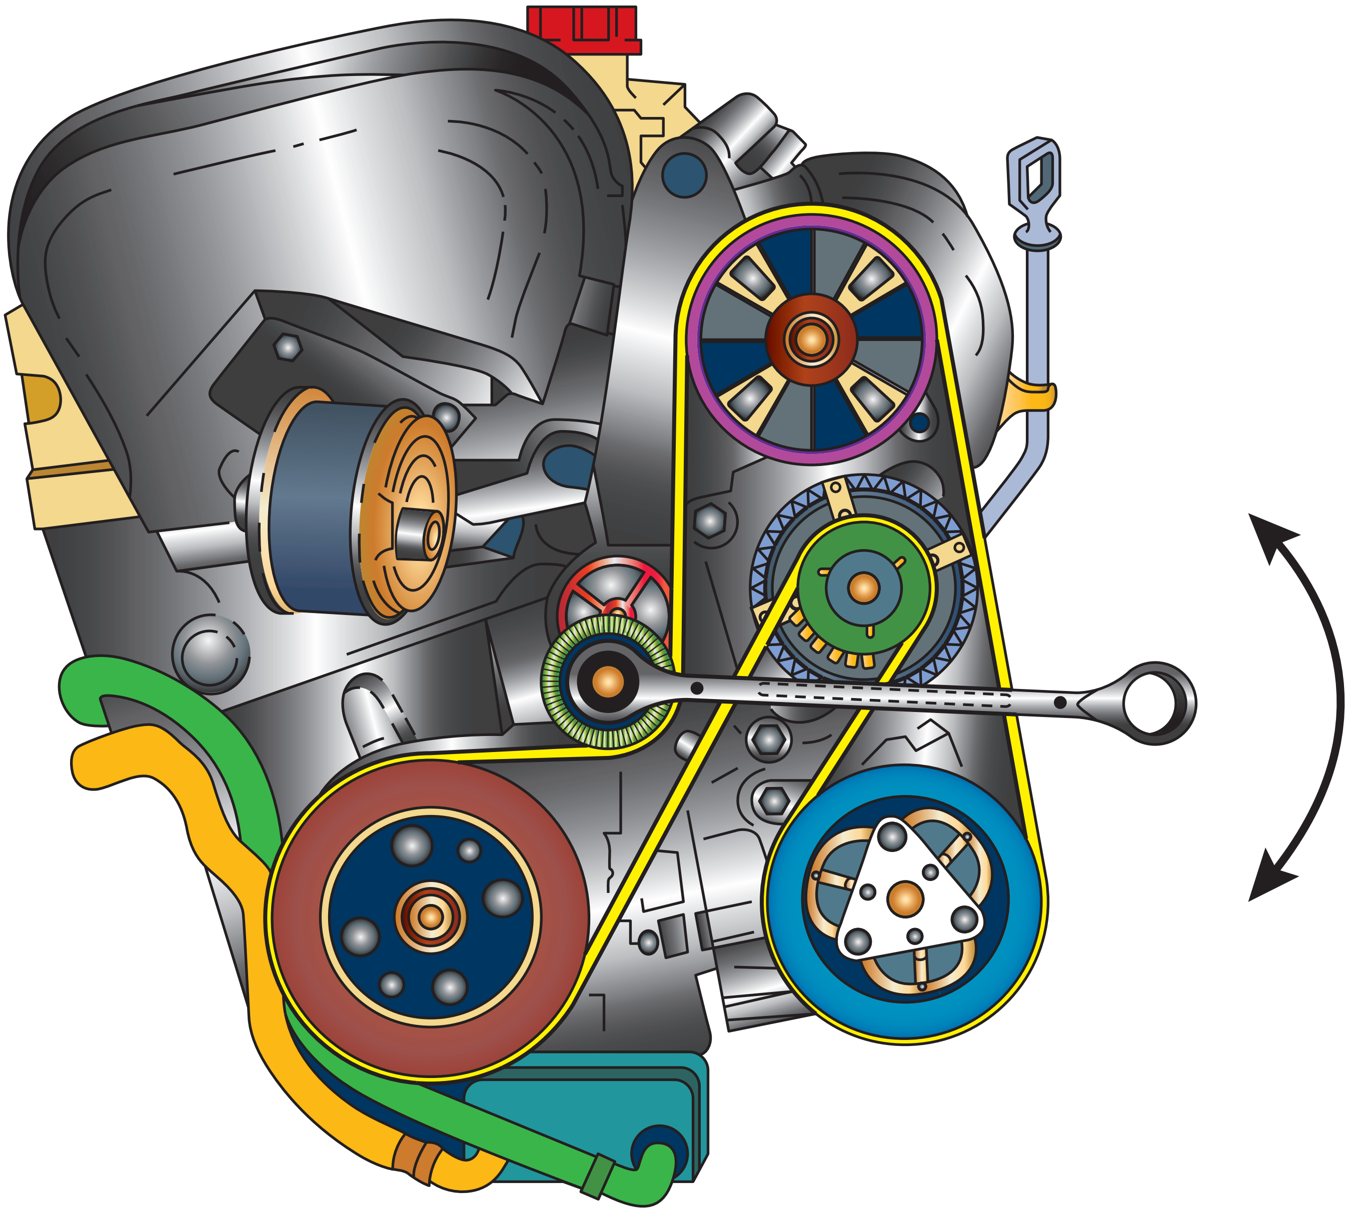


FIGURE 52–5 A wrench, breaker bar, or ratchet is used to release tension on the accessory drive belt, often called the front engine accessory drive (FEAD). Many experts recommend replacing the tensioner at the same time as the accessory drive belt.

2. **Marks on a tensioner.** Many tensioners have marks that indicate the normal operating tension range for the accessory drive belt. Check service information for the preferred location of the tensioner mark. ● **SEE FIGURE 52–6**.
3. **Torque wrench reading.** Some vehicle manufacturers specify that a beam-type torque wrench be used to determine the torque needed to rotate the tensioner. If the torque reading is below specifications, the tensioner must be replaced.
4. **Deflection.** Depress the belt between the two pulleys that are the farthest apart; the flex or deflection should be 1/2 inch (13 mm).

OVERRUNNING CLUTCH If low or no alternator output is found, remove the alternator drive belt and check the overrunning alternator pulley (OAP) or overrunning alternator dampener (OAD) for proper operation. Both types of overrunning clutches use a one-way clutch. Therefore, the pulley should freewheel in

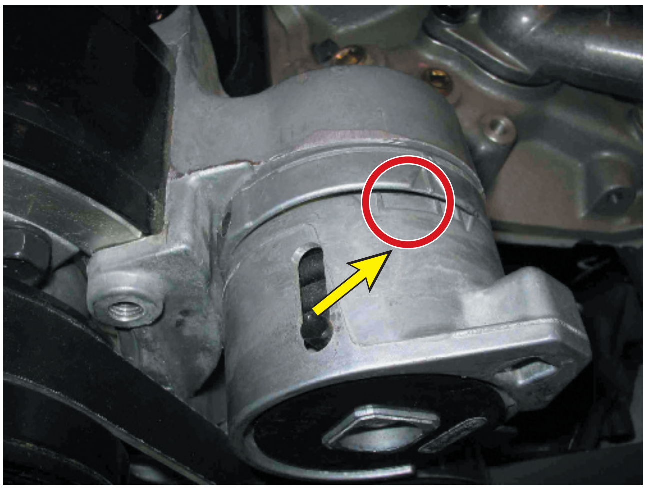

FIGURE 52–6 Check service information for where the tensioner marks should be located for proper belt tension.

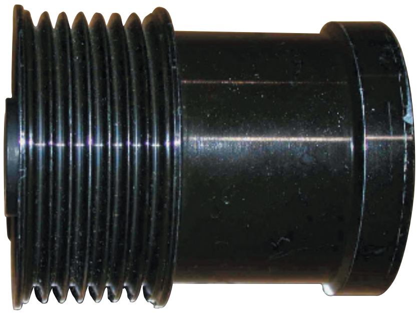

FIGURE 52–7 This overrunning alternator dampener (OAD) is longer than an overrunning alternator pulley (OAP) because it contains a dampener spring, as well as a one-way clutch. Be sure to check that it locks in one direction.

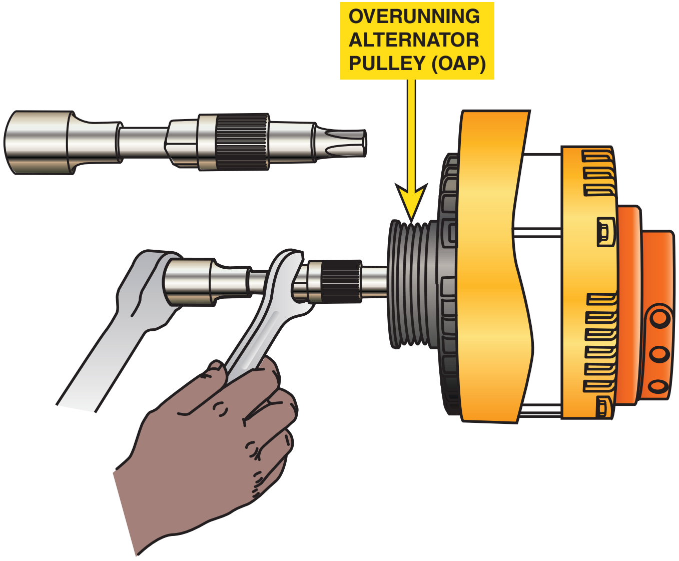

FIGURE 52–8 A special tool is needed to remove and install overrunning alternator pulleys or dampeners.

one direction and rotate the alternator rotor when rotated in the opposite direction. ● **SEE FIGURE 52–7.**

A special tool, such as Lisle No. 57650 or Gates No. 91024, is needed to repair the alternator. ● **SEE FIGURE 52–8.**

AC RIPPLE VOLTAGE CHECK

PRINCIPLES A good alternator should produce very little AC voltage or current output. It is the purpose of the diodes in the alternator to rectify or convert most AC voltage into DC voltage. While it is normal to measure some AC voltage from an alternator, excessive AC voltage, called AC ripple, is undesirable and indicates a fault with the rectifier diodes or stator windings inside the alternator.

TESTING AC RIPPLE VOLTAGE The procedure to check for **AC ripple voltage** includes the following steps:

STEP 1 Set the digital meter to read AC volts.

STEP 2 Start the engine and operate it at 2,000 RPM (fast idle).

MEASURING THE AC RIPPLE FROM THE ALTERNATOR TELLS A LOT ABOUT ITS CONDITION. IF THE AC RIPPLE IS ABOVE 500 MILLIVOLTS, OR 0.5 VOLT, LOOK FOR A PROBLEM IN THE DIODES OR STATOR. IF THE RIPPLE IS BELOW 500 MILLIVOLTS, CHECK THE ALTERNATOR OUTPUT TO DETERMINE ITS CONDITION.

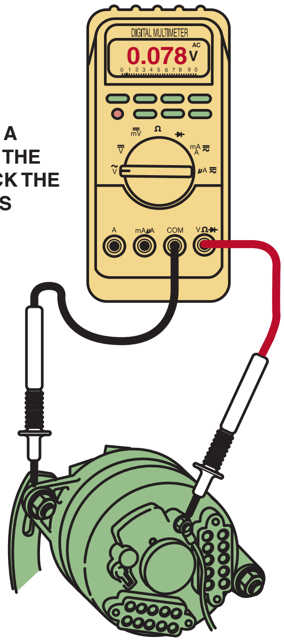

FIGURE 52–9 Testing AC ripple at the output terminal of the alternator is more accurate than testing at the battery due to the resistance of the wiring between the alternator and the battery. The reading shown on the meter, set to AC volts, is only 78 millivolts (0.078 volt), far below what the reading is if a diode is defective.

STEP 3 Connect the voltmeter leads to the positive and negative battery terminals.

STEP 4 Turn on the headlights to provide an electrical load on the alternator.

NOTE: A more accurate reading can be obtained by touching the meter lead to the output or "battery" terminal of the alternator. ● **SEE FIGURE 52–9.**

The results should be interpreted as follows: If the rectifier diodes are good, the voltmeter should read *less* than 400 millivolts (0.4 volt) AC. If the reading is over 500 millivolts (0.5 volt) AC, the rectifier diodes are defective.

NOTE: Many conductance testers, such as Midtronic and Snap-On, automatically test for AC ripple.

TECH TIP

The Lighter Plug Trick

Battery voltage measurements can be read through the lighter socket. Simply construct a test tool using a lighter plug at one end of a length of two-conductor wire and the other end connected to a double banana plug. The double banana plug fits most meters in the common (COM) terminal and the volt terminal of the meter. This is handy to use while road testing the vehicle under real-life conditions. Both DC voltage and AC ripple voltage can be measured. ● **SEE FIGURE 52–10.**

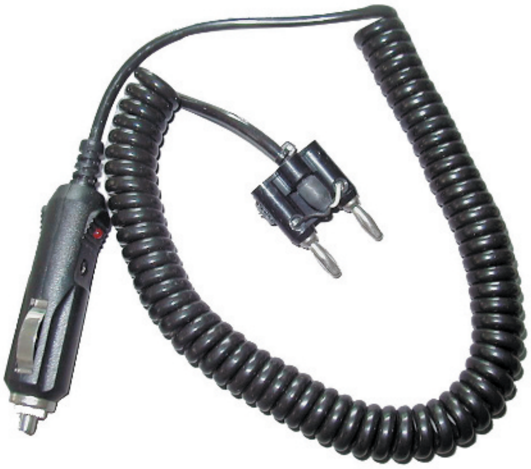

FIGURE 52–10 Charging system voltage can be easily checked at the lighter plug by connecting a lighter plug to the voltmeter through a double banana plug.

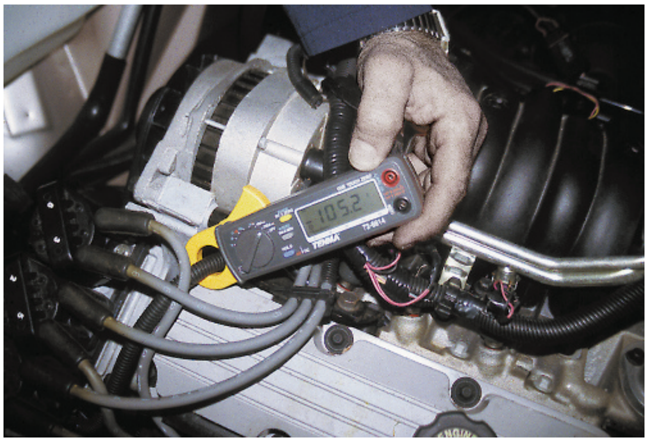

FIGURE 52–11 A mini clamp-on meter can be used to measure alternator output, as shown here (105.2 amperes). Then the meter can be used to check AC ripple by selecting AC amps on the rotary dial. AC ripple should be less than 10% of the DC output.

TESTING AC RIPPLE CURRENT

All alternators should create direct current (DC) if the diodes and stator windings are functioning correctly. A mini clamp-on meter capable of measuring AC amperes can be used to check the alternator. A good alternator should produce less than 10% of its rated amperage output in AC ripple amperes. For example, an alternator rated at 100 amperes should not produce more than 10 amperes AC ripple ($100 \times 10\% = 10$). It is normal for a good alternator to produce 3 or 4 amperes of AC ripple current to the battery. Only if the AC ripple current exceeds 10% of the rating of the alternator should the alternator be repaired or replaced.

TEST PROCEDURE To measure the AC current to the battery, perform the following steps:

STEP 1 Start the engine and turn on the lights to create an electrical load on the alternator.

STEP 2 Using a mini clamp-on digital multimeter, place the clamp around either all of the positive (+) battery cables or all of the negative (–) battery cables.

An AC/DC current clamp adapter can also be used with a conventional digital multimeter set on the DC millivolts scale.

STEP 3 To check for AC current ripple, switch the meter to read AC amperes and record the reading. Read the meter display.

STEP 4 The results should be less than 10% of the specified alternator rating. A reading of greater than 10 amperes AC indicates defective alternator diodes. ● **SEE FIGURE 52–11**.

CHARGING SYSTEM VOLTAGE DROP TESTING

ALTERNATOR WIRING For the proper operation of any charging system, there must be good electrical connections between the battery positive terminal and the alternator output terminal. The alternator must also be properly grounded to the engine block.

Many manufacturers of vehicles run the lead from the output terminal of the alternator to other connectors or junction blocks that are electrically connected to the positive terminal of the battery. If there is high resistance (a high voltage drop) in these connections or in the wiring itself, the battery is not properly charged.

VOLTAGE DROP TEST PROCEDURE When there is a suspected charging system problem (with or without a charge indicator light on), simply follow these steps to measure the voltage drop of the insulated (power-side) charging circuit.

STEP 1 Start the engine and run it at a fast idle (about 2,000 engine RPM).

STEP 2 Turn on the headlights to ensure an electrical load on the charging system.

STEP 3 Using any voltmeter set to read DC volts, connect the positive test lead (red) to the output terminal of the alternator. Attach the negative test lead (black) to the positive post of the battery.

The results should be interpreted as follows:

1. If there is less than a 0.4 volt (400 millivolts) reading, then all wiring and connections are satisfactory.
2. If the voltmeter reads higher than 0.4 volt, there is excessive resistance (voltage drop) between the alternator output terminal and the positive terminal of the battery.
3. If the voltmeter reads battery voltage (or close to battery voltage), there is an open circuit between the battery and the alternator output terminal.

To determine whether the alternator is correctly grounded, maintain the engine speed at 2,000 RPM with the headlights on. Connect the positive voltmeter lead to the case of the alternator and the negative voltmeter lead to the negative terminal of the battery. The voltmeter should read less than 0.2 volt (200 millivolts) if the alternator is properly grounded. If the reading is over 0.2 volt, connect one end of an auxiliary ground wire to the case of the alternator and the other end to a good engine ground. ● **SEE FIGURE 52–12**.

TECH TIP

Use a Fused Jumper Wire as a Diagnostic Tool

When diagnosing an alternator charging problem, try using a fused jumper wire to connect the positive and negative terminals of the alternator directly to the positive and negative terminals of the battery. If a definite improvement is noticed, the problem is in the wiring of the vehicle. High resistance, due to corroded connections or loose grounds, can cause low alternator output, repeated regulator failures, slow cranking, and discharged batteries. A voltage drop test of the charging system can also be used to locate excessive resistance (high voltage drop) in the charging circuit, but using a fused jumper wire is often faster and easier.

ALTERNATOR OUTPUT TEST

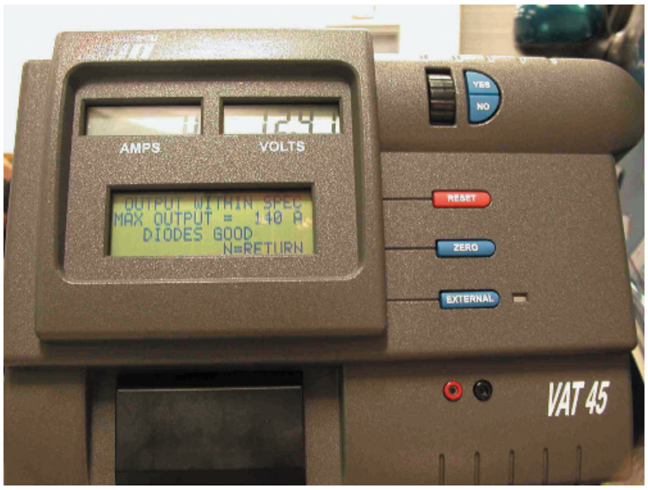
PRELIMINARY CHECKS An alternator output test measures the current (amperes) of the alternator. A charging circuit may be able to produce correct charging circuit voltage, but not be able to produce adequate amperage output. If in doubt about charging system output, first check the condition of the alternator drive belt. With the engine off, attempt to rotate the fan of the alternator by hand. Replace or tighten the drive belt if the alternator fan can be rotated this way.

CARBON PILE TEST PROCEDURE A carbon pile tester uses plates of carbon to create an electrical load. A carbon pile test is used to load test a battery and/or an alternator. ● **SEE FIGURE 52–13**.

The testing procedure for alternator output is as follows:

STEP 1 Connect the starting and charging test leads according to the manufacturer's instructions, which usually include installing the amp clamp around the output wire near the alternator.

STEP 2 Turn off all electrical accessories to be sure that the tester is measuring the true output of the alternator.



AMPS
VOLTS

MAX OUTPUT = 140 A
DIODES GOOD
N=RETURN
YES
NO
RESET
ZERO
EXTERNAL
VAT 45

FIGURE 52–13 A typical tester used to test batteries as well as the cranking and charging system. Always follow the operating instructions.

STEP 3 Start the engine and operate it at 2,000 RPM (fast idle). Turn the load increase control slowly to obtain the highest reading on the ammeter scale. Do not allow the voltage to drop below 12.6 volts. Note the ampere reading.

STEP 4 Add 5 to 7 amperes to the reading because this amount of current is used by the ignition system to operate the engine.

STEP 5 Compare the output reading to factory specifications. The rated output may be stamped on the alternator or can be found in service information.

CAUTION: *NEVER* disconnect a battery cable with the engine running. All vehicle manufacturers warn not to do this, because this was an old test, before alternators, to see if a generator could supply current to operate the ignition system without a battery. When a battery cable is removed, the alternator (or PCM) loses the battery voltage sense signal. Without a battery voltage sense circuit, the alternator does one of two things, depending on the make and model of vehicle:

- **The alternator output can exceed 100 volts. This high voltage may damage not only the alternator, but also electrical components in the vehicle, including the PCM and all electronic devices.**
- **The alternator stops charging as a fail-safe measure to protect the alternator and all of the electronics in the vehicle from being damaged due to excessively high voltage.**

MINIMUM REQUIRED ALTERNATOR OUTPUT

PURPOSE All charging systems must be able to supply the electrical demands of the electrical system. If lights and accessories are used constantly and the alternator cannot supply the necessary ampere output, the battery is drained. To determine the minimum electrical load requirements, connect an inductive ammeter probe around either battery cable or the alternator output cable. ● **SEE FIGURE 52–14.**

TECH TIP

Bigger Is Not Always Better

Many technicians are asked to install a higher output alternator to allow the use of emergency equipment or other high-amperage equipment, such as a high-wattage sound system.

Although many higher output units can be physically installed, it is important not to forget to upgrade the wiring and the fusible link(s) in the alternator circuit. Failure to upgrade the wiring could lead to overheating. The usual failure locations are at junctions or electrical connectors.

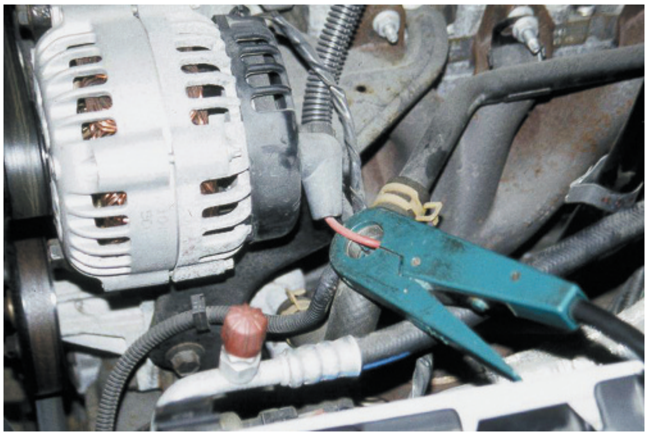

FIGURE 52–14 The best place to install a charging system tester amp probe is around the alternator output terminal wire, as shown in the figure.

NOTE: If using an inductive pickup ammeter, be certain that the pickup is over *all* the wires leaving the battery terminal.

Failure to include the small body ground wire from the negative battery terminal to the body or the small positive wire (if testing from the positive side) *greatly decreases* the current flow readings.

PROCEDURE After connecting an ammeter correctly in the battery circuit, continue as follows:

1. Start the engine and operate to about 2,000 RPM (fast idle).
2. Turn the heat selector to air-conditioning (if the vehicle is so equipped).
3. Turn the blower motor to high speed.
4. Turn the headlights on bright.
5. Turn on the rear defogger.
6. Turn on the windshield wipers.
7. Turn on any other accessories that may be used continuously (do not operate the horn, power door locks, or other units that are not used for more than a few seconds).
8. Observe the ammeter. The current indicated is the electrical load that the alternator is able to exceed to keep the battery fully charged.

TEST RESULTS The minimum acceptable alternator output is 5 amperes greater than the accessory load. A negative (discharge) reading indicates that the alternator is not capable of supplying the current (amperes) that may be needed.

ALTERNATOR REMOVAL

After diagnosis of the charging system has determined that there is a fault with the alternator, it must be removed safely from the vehicle. Always check service information for the exact procedure to follow on the vehicle being serviced. A typical removal procedure includes the following steps:

STEP 1 Disconnect the negative (–) terminal from the battery. (Use a memory saver to maintain radio, memory seats, and other functions.)

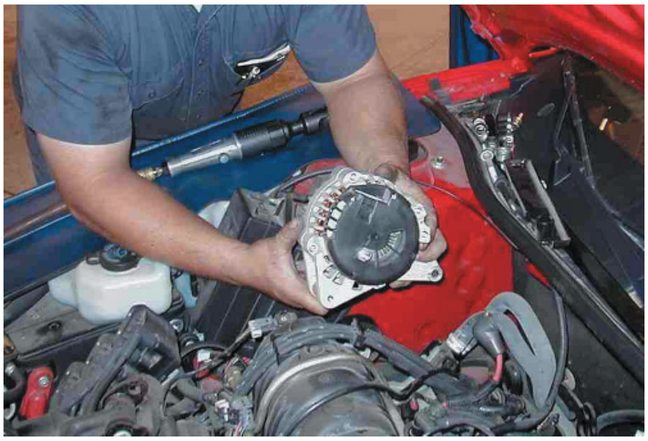

FIGURE 52–15 Replacing an alternator is not always as easy as it is from a Buick with a 3800 V-6, where the alternator is easy to access. Many alternators are difficult to access and require the removal of other components.

STEP 2 Remove the accessory drive belt that drives the alternator.

STEP 3 Remove electrical wiring, fasteners, spacers, and brackets, as necessary, and remove the alternator from the vehicle. ● **SEE FIGURE 52–15**.

ALTERNATOR INSTALLATION

Before installing a replacement alternator, check service information for the exact procedure to follow for the vehicle being serviced. A typical installation procedure includes the following steps:

STEP 1 Verify that the replacement alternator is the correct unit for the vehicle.

STEP 2 Install the alternator wiring on the alternator and install the alternator.

STEP 3 Check the condition of the drive belt and replace, if necessary. Install the drive belt over the drive pulley.

STEP 4 Properly tension the drive belt.

STEP 5 Tighten all fasteners to factory specifications.

STEP 6 Double-check that all fasteners are correctly tightened and remove all tools from the engine compartment area.

STEP 7 Reconnect the negative battery cable.

STEP 8 Start the engine and verify proper charging circuit operation.

CASE STUDY

The Two-Minute Alternator Repair

A Chevrolet pickup truck was brought to a shop for routine service. The customer stated that the battery required a jump start after a weekend of sitting. The technician tested the battery and the charging system voltage using a small handheld digital multimeter. The battery voltage was 12.4 volts (about 75% charged), but the charging voltage was also 12.4 volts at 2,000 RPM. Because normal charging voltage should be 13.5 to 15 volts, it was obvious that the charging system was not operating correctly.

The technician checked the dash and found that the "charge" light was *not* on. Before removing the alternator for service, the technician checked the wiring connection on the alternator. When the connector was removed, it was discovered to be rusty. After the contacts were cleaned, the charging system was restored to normal operation. The technician had learned that the simple things should always be checked first before tearing into a big or expensive repair.

Summary:

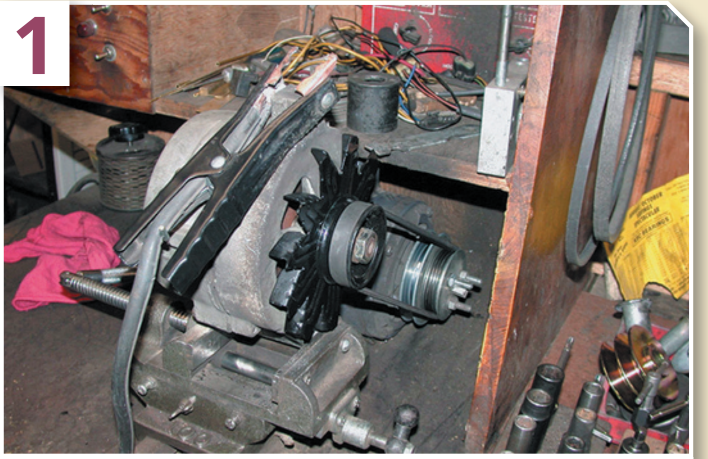
Complaint—Customer stated that the truck battery had to be jump-started after sitting for a weekend.

Cause—Tests confirmed that the alternator was not charging and a rusty connection at the alternator was found during a visual inspection.

Correction—Cleaning the electrical terminals at the alternator restored proper operation of the charging system.

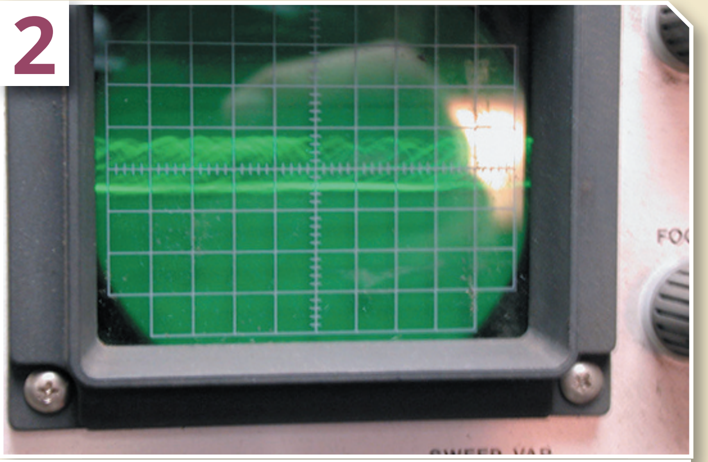
ALTERNATOR OVERHAUL

1



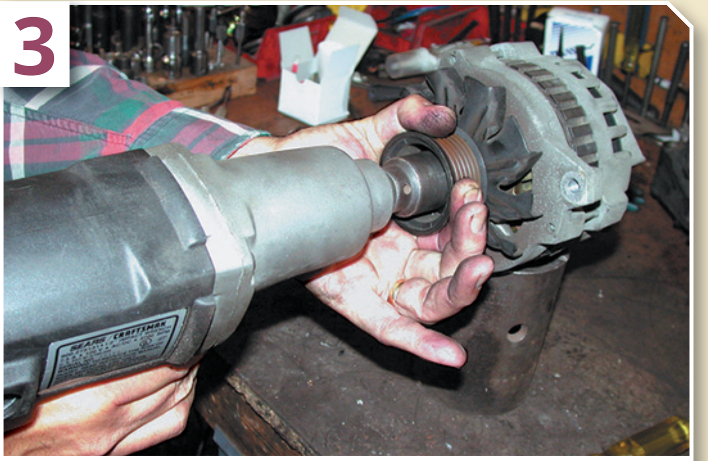
Before the alternator is disassembled, it is spin tested and connected to a scope to check for possible defective components.

2



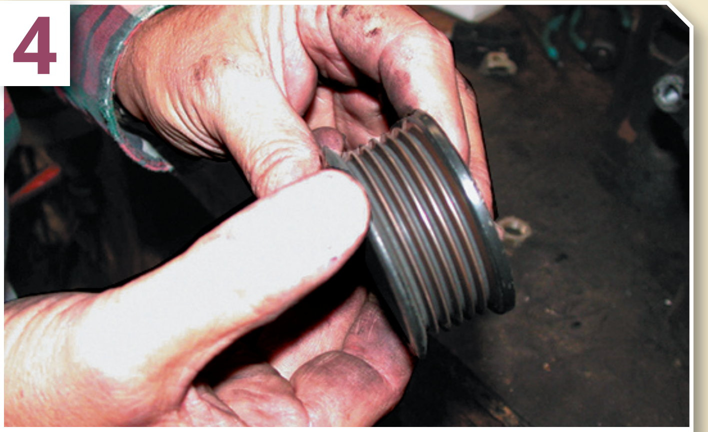
The scope pattern shows that the voltage output is far from being a normal pattern. This pattern indicates serious faults in the rectifier diodes.

3



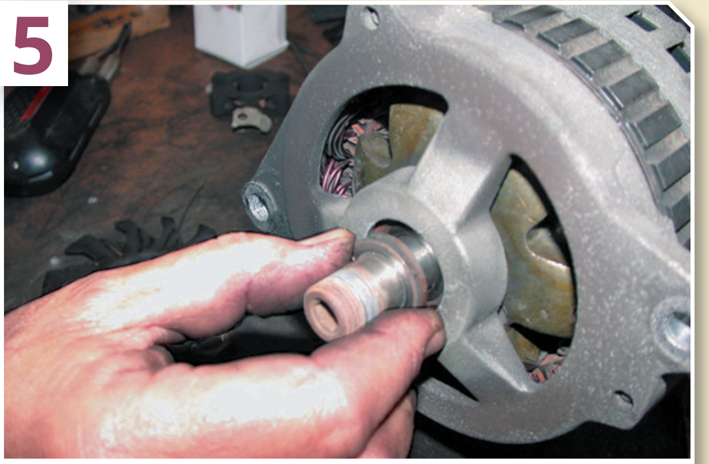
The first step is to remove the drive pulley. This rebuilder is using an electric impact wrench to accomplish the task.

4



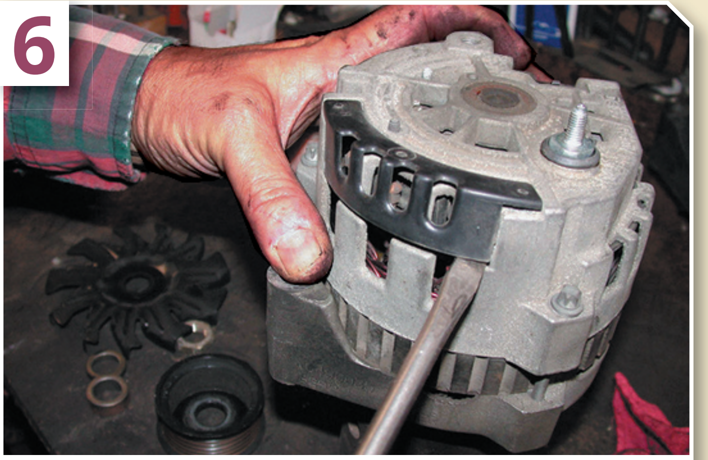
Carefully inspect the drive galley for damage of embedded rubber from the drive belt. The slightest fault can cause a vibration, noise, or possible damage to the alternator.

5



Remove the external fan (if equipped) and then the spacers, as shown.

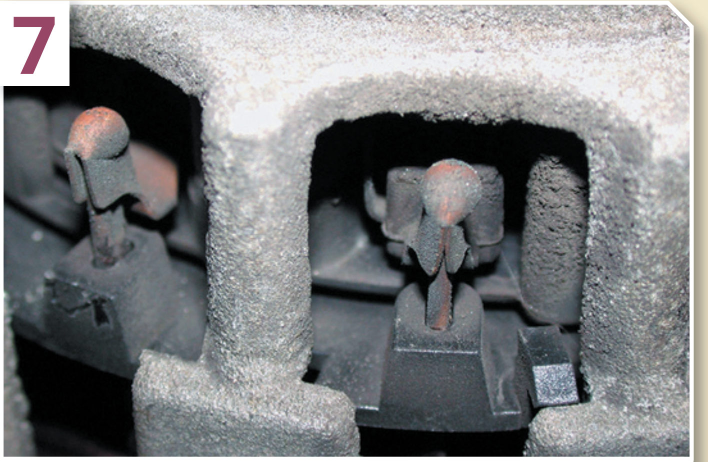
6



Next pop off the plastic cover (shield) covering the stator/rectifier connection.

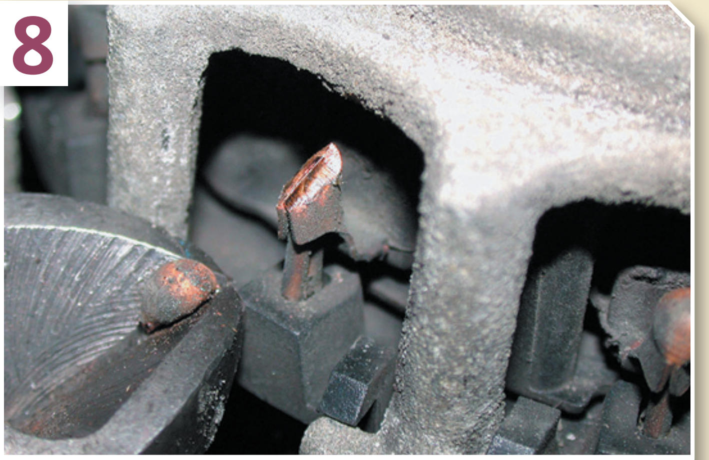
STEP BY STEP

7



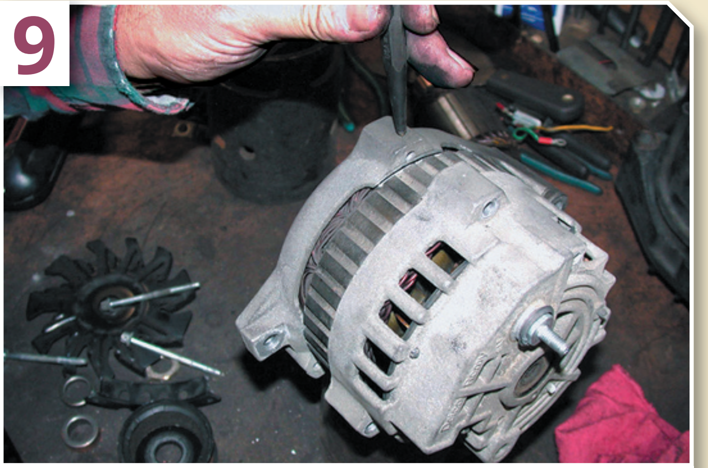
After the cover has been removed, the stator connections to the rectifier can be seen.

8



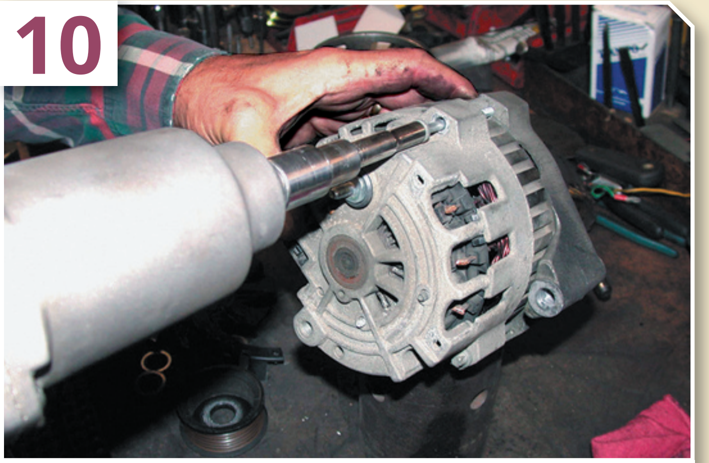
Using a diagonal cutter, cut the weld to separate the stator from the rectifier.

9



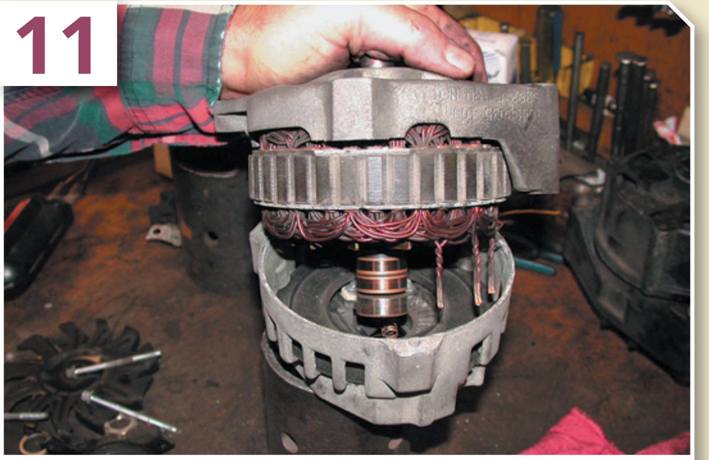
Before separating the halves of the case, this technician uses a punch to mark both halves.

10



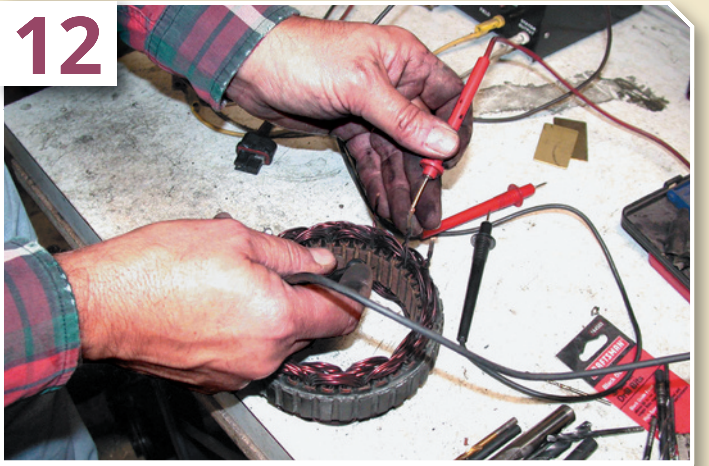
After the case has been marked, the through bolts are removed.

11



The drive-end (DE) housing and the stator are being separated from the rear (slip-ring-end) housing.

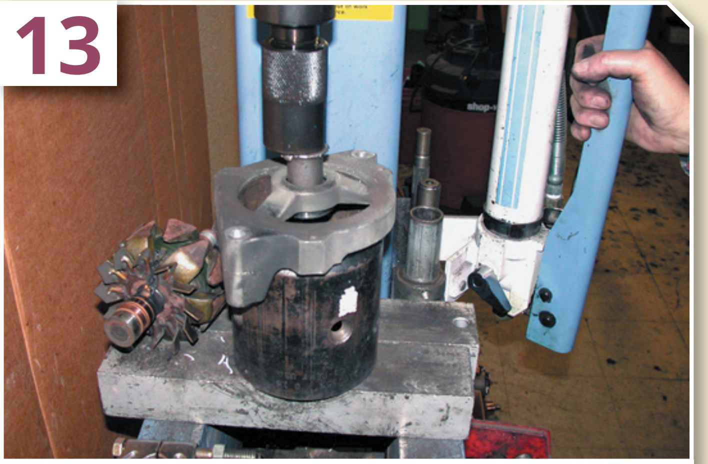
12



The stator is checked by visual inspection for discoloration or other physical damage, and then checked with an ohmmeter to see if the windings are shorted-to-ground.

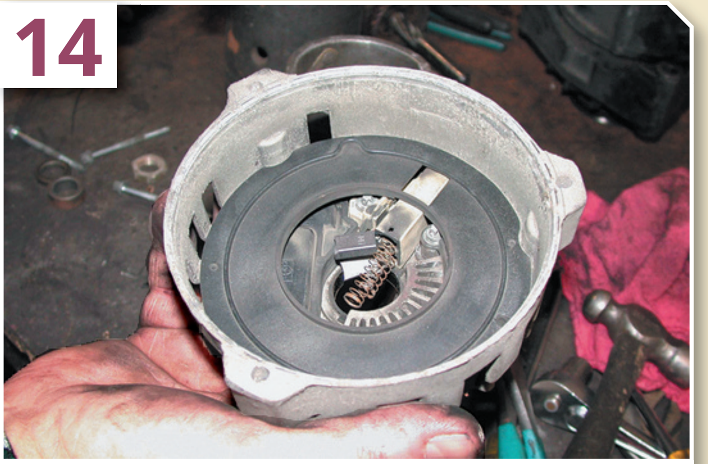
ALTERNATOR OVERHAUL

13



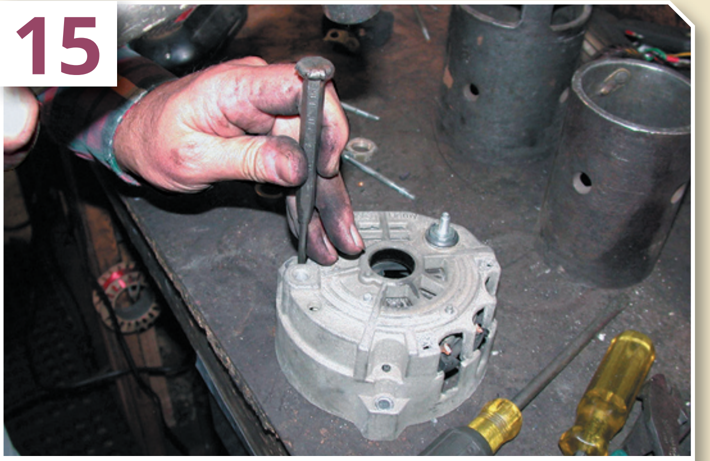
The front bearing is removed from the drive-end housing using a press.

14



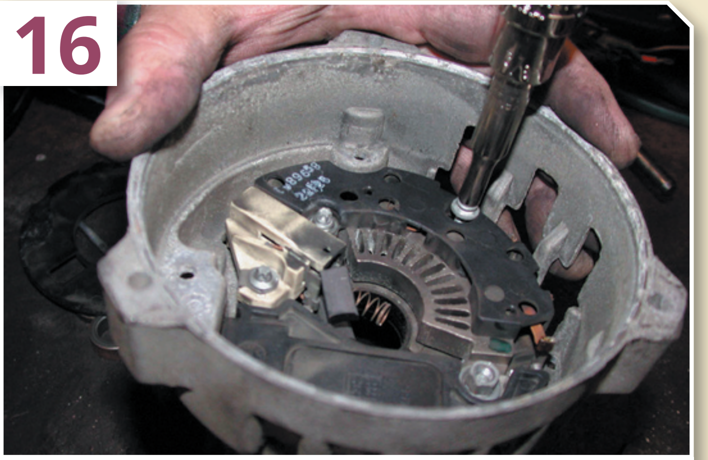
A view of the slip-ring-end (SRE) housing showing the black plastic shield, which helps direct air flow across the rectifier.

15



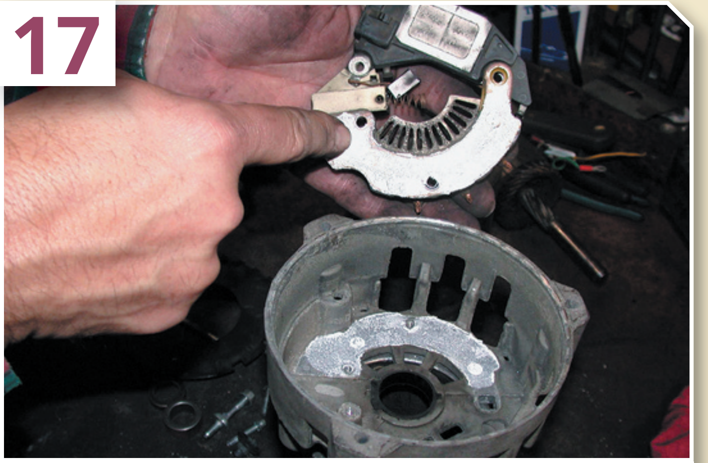
A punch is used to dislodge the plastic shield retaining clips.

16



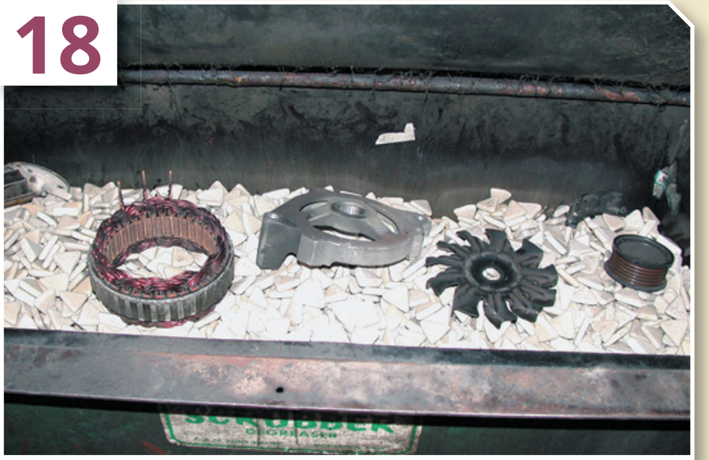
After the shield has been removed, the rectifier, regulator, and brush holder assembly can be removed by removing the retaining screws.

17



The heat transfer grease is visible when the rectifier assembly is lifted out of the rear housing.

18

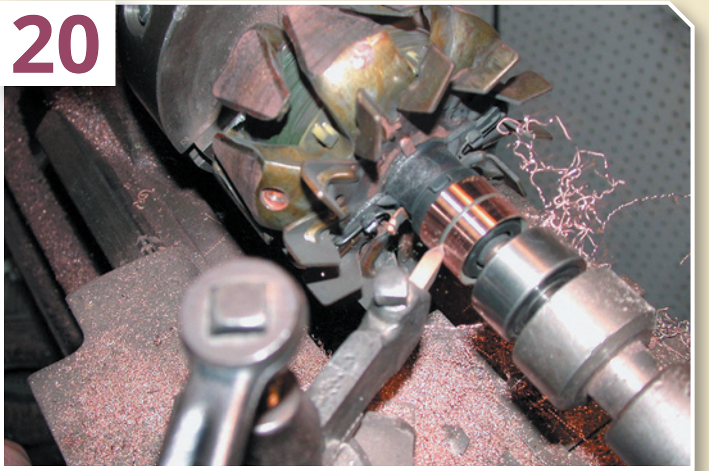


The parts are placed into a tumbler where ceramic stones and a water-based solvent are used to clean the parts.

19

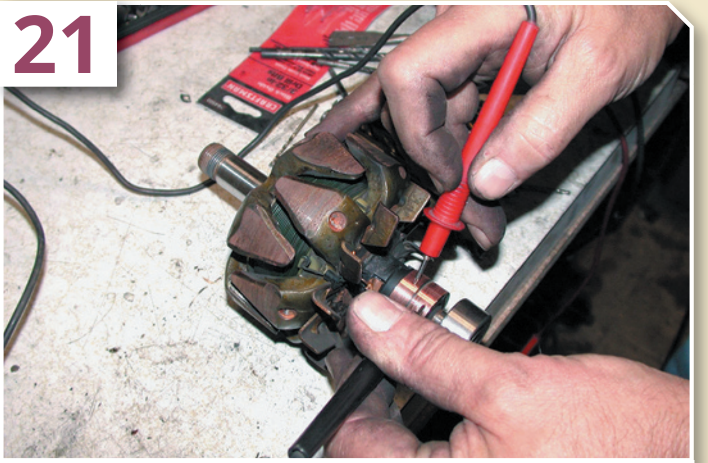
This rebuilder is painting the housing using a high-quality industrial grade spray paint to make the rebuilt alternator look like new.

20



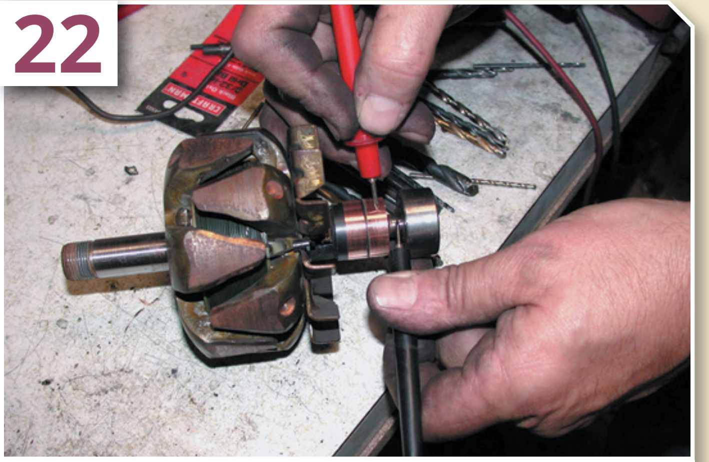
The slip rings on the rotor are being machined on a lathe.

21



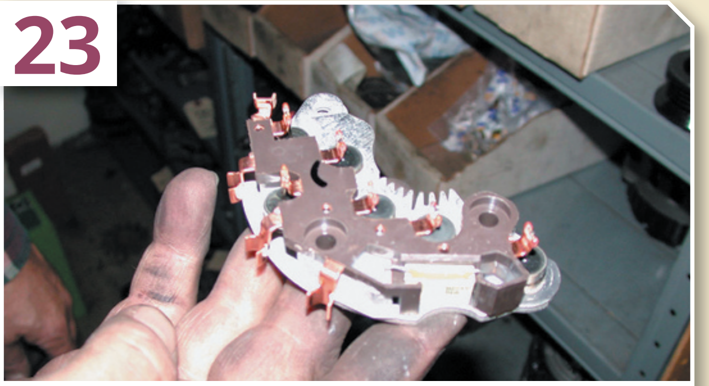
The rotor is being tested using an ohmmeter. The specifications for the resistance between the slip rings on the CS-130 are 2.2 to 3.5 ohms.

22



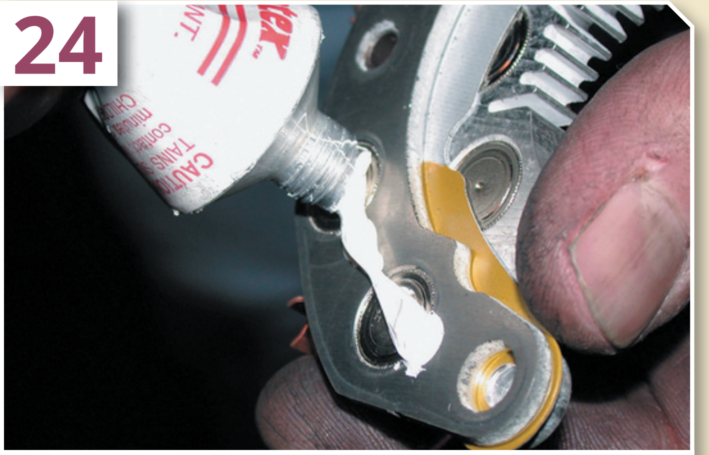
The rotor is also tested between the slip ring and the rotor shaft. This reading should be infinity.

23



A new rectifier. This replacement unit is significantly different than the original but is designed to replace the original unit and meets the original factory specifications.

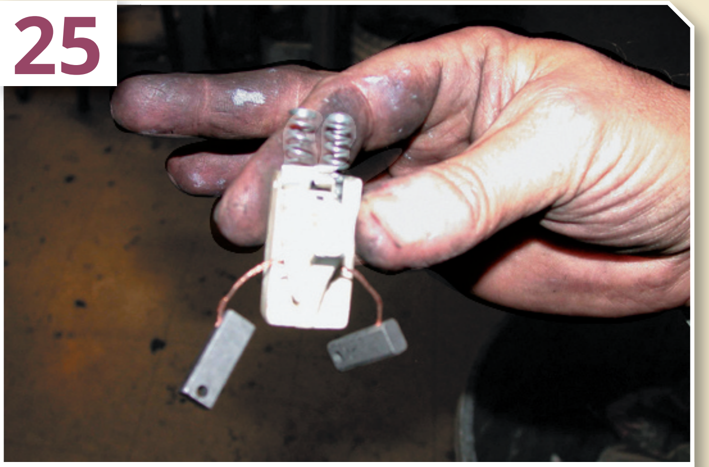
24



Silicone heat transfer compound is applied to the heat sink of the new rectifier.

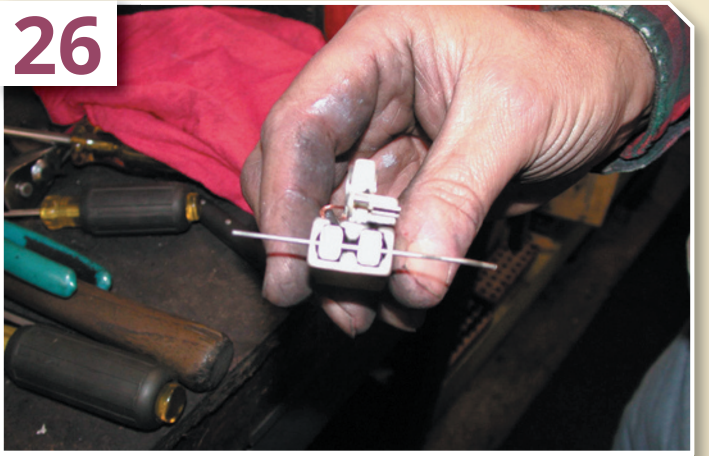
ALTERNATOR OVERHAUL

25



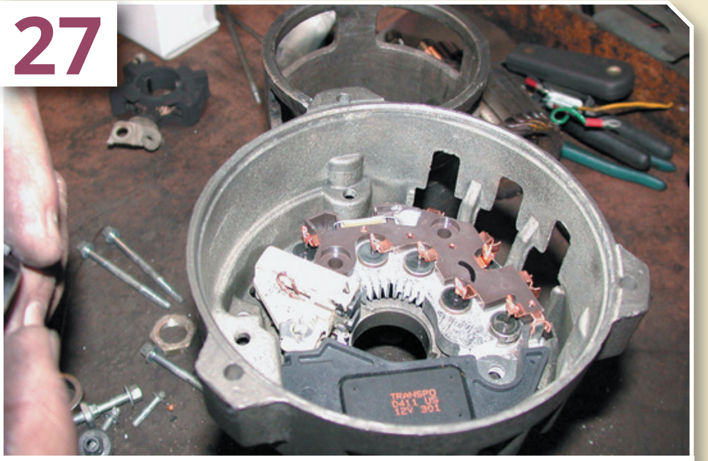
Replacement brushes and springs are assembled into the brush holder.

26



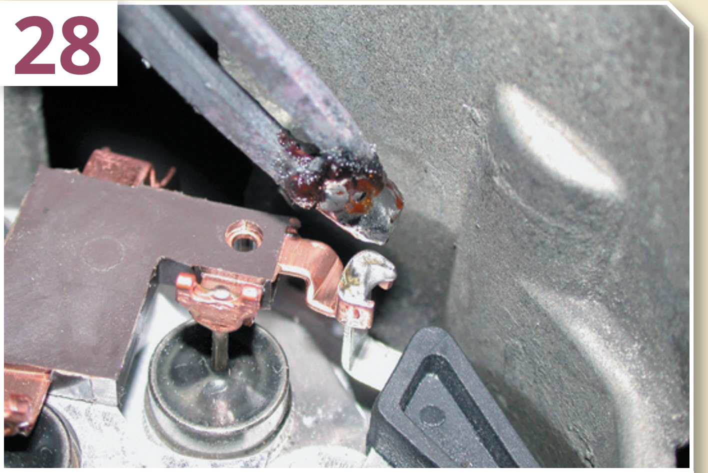
The brushes are pushed into the brush holder and retained by a straight wire, which extends through the rear housing of the alternator. This wire is then pulled out when the unit is assembled.

27



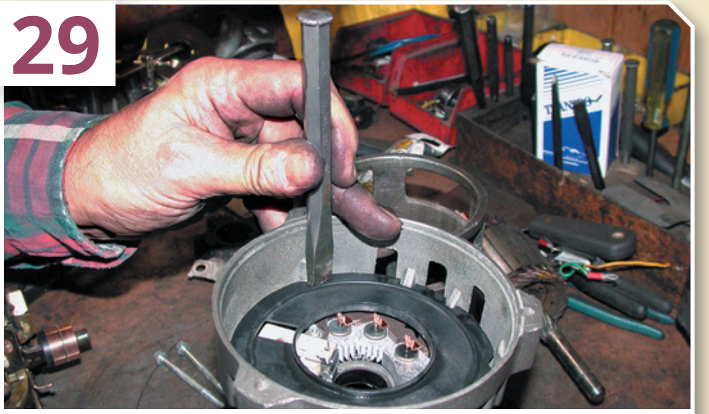
Here is what the CS alternator looks like after installing the new brush holder assembly, rectifier bridge, and voltage regulator.

28



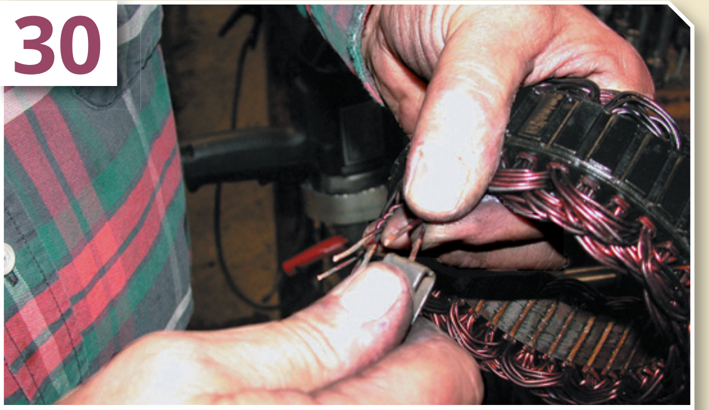
The junction between the rectifier bridge and the voltage regulator is soldered.

29



The plastic deflector shield is snapped back into location using a blunt chisel and a hammer. This shield directs the airflow from the fan over the rectifier bridge and voltage regulator.

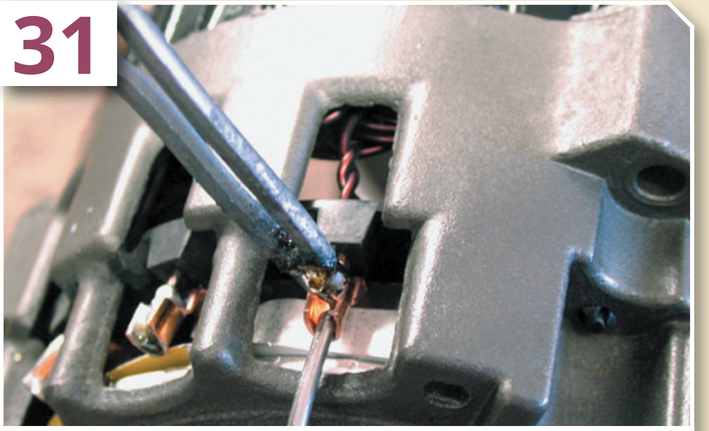
30



Before the stator windings can be soldered to the rectifier bridge, the varnish insulation is removed from the ends of the leads.

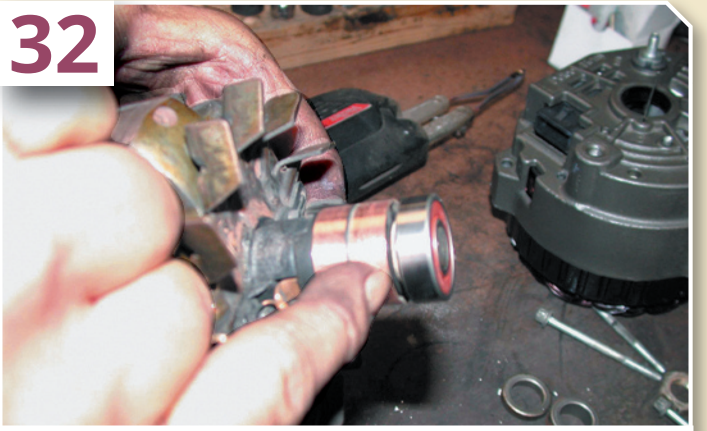
STEP BY STEP

31



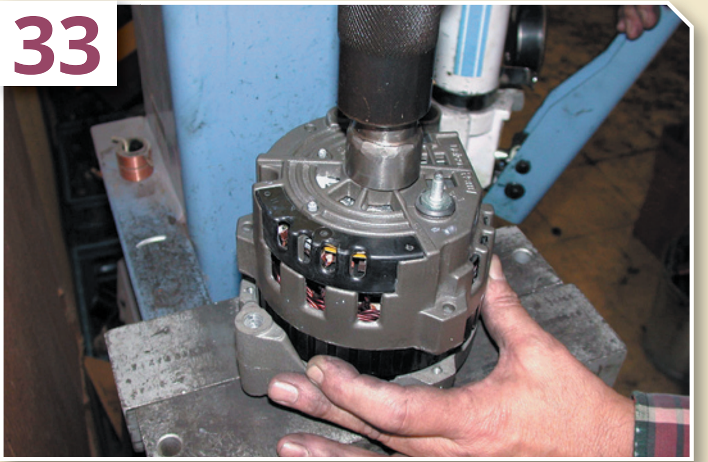
After the stator has been inserted into the rear housing, the stator leads are soldered to the copper lugs of the rectifier bridge.

32



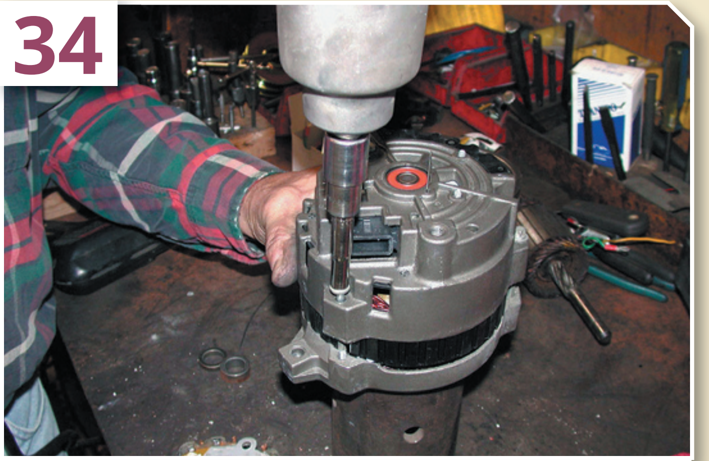
New bearings are installed. A spacer is placed between the bearing and the slip rings to help prevent the possibility that the bearing could move on the shaft and short against the slip ring.

33



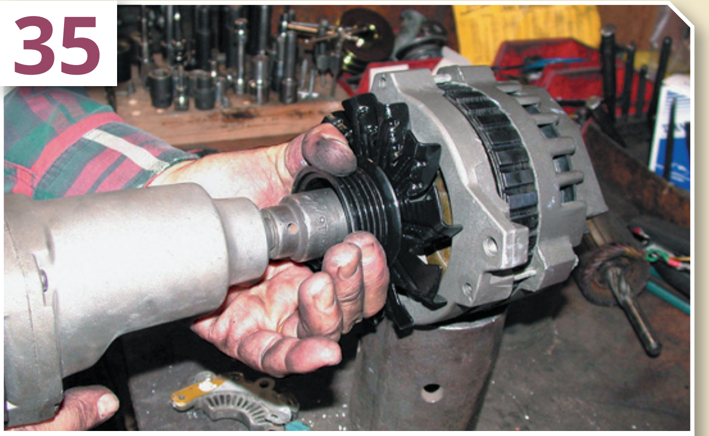
The slip-ring-end housing is aligned with the marks made during disassembly and is pressed into the drive-end housing.

34



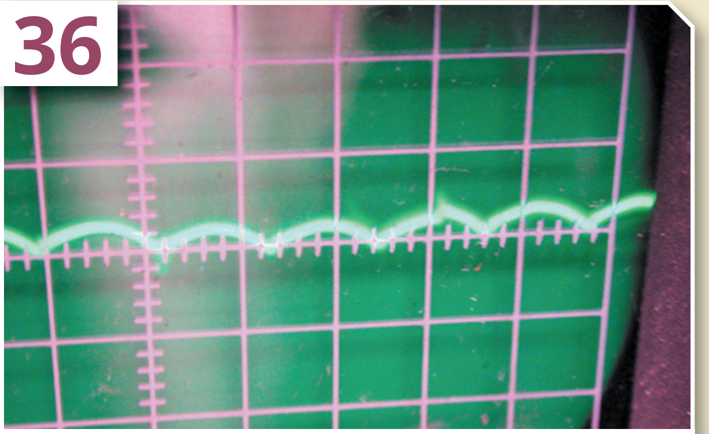
The retaining bolts, which are threaded into the drive-end housing from the back of the alternator, are installed.

35



The external fan and drive pulley are installed and the retaining nut is tightened on the rotor shaft.

36



The scope pattern shows that the diodes and stator are functioning correctly and voltage check indicates that the voltage regulator is also functioning correctly.

REVIEW QUESTIONS

1. How does a technician test the voltage drop of the charging circuit?
2. How does a technician measure the amperage output of an alternator?
3. What tests can be performed to determine whether a diode or stator is defective before removing the alternator from the vehicle?
4. Why could a defective overrunning alternator pulley (OAP) or dampener (OAD) cause a lack of proper charging?
5. What is procedure for replacing an alternator?

CHAPTER QUIZ

1. To check the charging voltage, connect a digital multimeter (DMM) to the positive (+) and the negative (–) terminals of the battery and select __________.
   - **a.** DC volts
   - **b.** AC volts
   - **c.** DC amps
   - **d.** AC amps
2. To check for ripple voltage from the alternator, connect a digital multimeter (DMM) and select __________ .
   - **a.** DC volts
   - **b.** AC volts
   - **c.** DC amps
   - **d.** AC amps
3. Which of the following would NOT be used to check drive belt wear?
   - **a.** Groove color change
   - **b.** A tension gauge
   - **c.** A belt wear gauge
   - **d.** Belt deflection between two pulleys
4. When performing an alternator output test, which tool should the technician choose?
   - **a.** An electronic torque wrench
   - **b.** An ohmmeter
   - **c.** A load tester
   - **d.** A vacuum gauge
5. An acceptable AC ripple current is __________ .
   - **a.** less than 100 amperes
   - **b.** 10 amperes or more
   - **c.** less than 10% of the rated output
   - **d.** None of the above
6. If the overrunning alternator pulley were to fail, what is the likely result?
   - **a.** Over charging
   - **b.** The alternator would not charge at all
   - **c.** The drive belt will become loose
   - **d.** Both a and c
7. Technician A says that a voltage drop test of the charging circuit should only be performed when current is flowing through the circuit. Technician B says to connect the leads of a voltmeter to the positive and negative terminals of the battery to measure the voltage drop of the charging system. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
8. When testing an alternator minimum required output, what is the acceptable reading?
   - **a.** 2 to 5 amperes
   - **b.** Five amperes greater than the accessory load
   - **c.** Over 100 amperes higher than the accessory load
   - **d.** Less than 3 amperes
9. What action should be performed when replacing an alternator?
   - **a.** Disconnect the negative battery cable.
   - **b.** Disconnect the positive battery cable.
   - **c.** Remove the drive belt.
   - **d.** Both a and c
10. What action should be performed when installing a replacement alternator?
    - **a.** Verify that the replacement alternator is the correct part.
    - **b.** Check the condition of the drive belt and replace if needed.
    - **c.** Tighten all fasteners to factory specifications.
    - **d.** All of the above

Chapter

LIGHTING AND SIGNALING CIRCUITS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain lighting systems in an automobile.
- List the advantages of using LED lights.
- Read and interpret a bulb chart.
- Discuss the operation of brake lights.
- Discuss the operation of turn signals.
- Describe daytime running lights.
- Describe headlights.
- Describe high-intensity discharge headlights.
- Describe LED headlights.
- Describe adaptive front lighting systems.
- Describe automatic headlights.
- Describe the headlight high-/low-beam switch.
- Describe auto-dimming headlights.
- Describe how to aim headlights.
- Describe fog lights and driving lights.
- Describe automatic dimming mirrors.
- Describe courtesy lights.
- Describe illuminated entry.
- Explain the procedures to inspect and troubleshoot the headlight system.
- Explain the procedures to diagnose the lighting and signaling system.

KEY TERMS:

Adaptive front lighting system (AFS) 619 • Automatic headlights 620 • Composite headlight 616 • Courtesy lights 623 • Daytime running lights (DRLs) 615 • Hazard warning 615 • High-intensity discharge (HID) 617 • Kelvin (K) 618 • Light-emitting diode (LED) 610 • Trade number 612 • Troxler effect 622

LIGHTING SYSTEMS

CIRCUITS INVOLVED A vehicle has many different lighting and signaling systems, each with its own specific components and operating characteristics. The major light-related circuits and systems covered in this chapter include the following:

- Exterior lighting
- Headlights
- Brake lights
- Turn signals and flasher units
- Courtesy lights
- Light-dimming rearview mirrors

NON-COMPUTER-CONTROLLED LIGHTING Older vehicles used the headlight switch to operate all the lights, including

1. Headlights
2. Taillights
3. Side-marker lights
4. Front parking lights
5. Dash lights
6. Interior (dome) light(s)

The headlight switch assembly on older vehicles carried a heavy current and was mechanical. Most contained a built-in circuit breaker for circuit protection. ● **SEE FIGURE 53–1**.

BODY CONTROL MODULE-CONTROLLED LIGHTING The **Body Control Module (BCM)** is often referred to as a *central organizational module*. Using a BCM results in the following benefits:

1. It simplifies the manufacturing and troubleshooting aspects of electronic modules.
2. It coordinates the operating functions of many related items, as well as security features.

All recent vehicles use a controller, usually the body control module (BCM), to control the lights. The switches to turn on the lights are simply a request from the switch to the BCM to turn

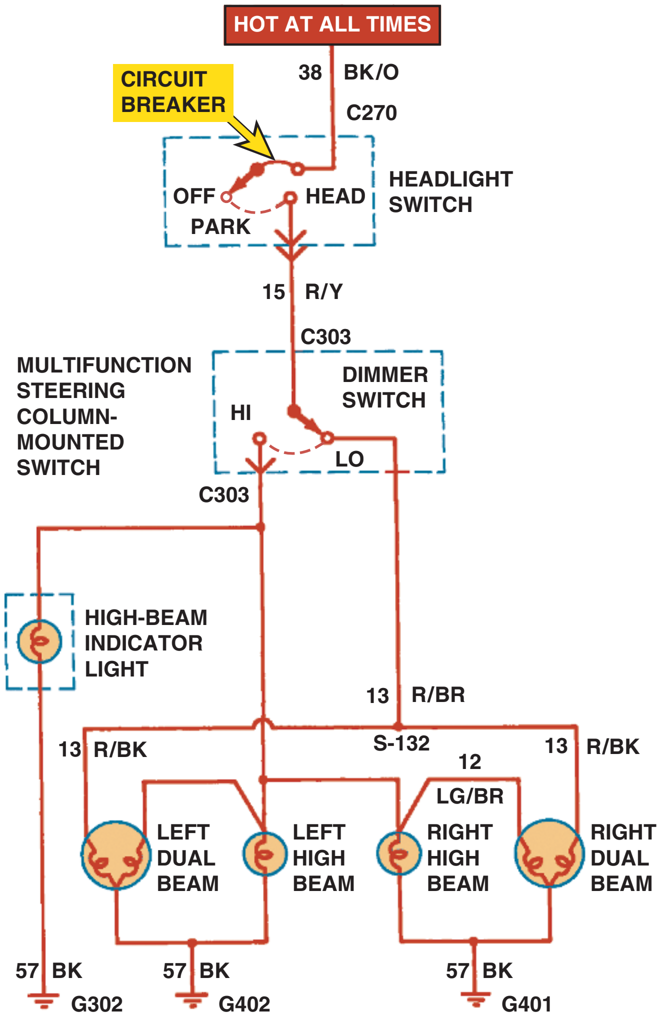

FIGURE 53–1 A typical headlight circuit diagram on an older vehicle that does not use a controller, such as the body control module (BCM) to control the operation of the lights. Note that the headlight switch is represented by a dotted outline indicating that other circuits (such as dash lights) also operate from the switch.

on the lights. The communication between the switches and the BCM is over serial data lines. Many vehicles use front and rear lighting modules, so the BCM sends a message over the data lines to the front or rear lighting module to turn on the commanded lights. The controller can control either the power side or the ground side of the circuit and performs the following:

- Monitors the current flow through the circuit and turns on a bulb failure warning light if it detects an open bulb or a fault in the circuit.
- After the ignition has been turned off, the modules turn off the lights after a time delay to prevent the battery from being drained.
- In the event of a communication failure, most module-controlled exterior lighting systems default to on position for safety.

Many electronic components are controlled by the BCM, including the following lighting circuits:

- Brake lights
- Courtesy lamps
- Dome lamps
- Exterior and interior lamps
- Fog lamps
- Hazard warning lamps
- Low- and high-beam head lamps
- Parking lamps
- Turn-signal lamps

● **SEE FIGURE 53–2.**

LED LIGHTING

PARTS AND OPERATION A **light-emitting diode (LED)** is a two-lead semiconductor light source. An LED is a P–N junction diode that emits light when a suitable voltage is applied to the leads. The electrons are able to recombine with electron holes within the device, releasing energy in the form of photons. ● **SEE FIGURE 53–3.**

LED FEATURES LED lights are frequently used in newer vehicles for the following reasons:

1. **Faster illumination.** Using LEDs in brake lights light up 200 ms faster than an incandescent bulb, which requires some time to heat the filament before it is hot enough to create light. This faster illumination, when used in brake lights, can mean the difference in stopping distances at 60 MPH 60 MPH (100 km/h) by about 18 feet (6 m) due to the reduced reaction time for the driver of the vehicle behind.
2. **Longer service life.** LEDs are solid-state devices that do not use a filament to create light. As a result, they are less susceptible to vibration and often last the life of the vehicle.
3. **Lower current draw.** LEDs draw less current compared to incandescent bulbs and the result is less electrical drain from the charging system to operate all the lights in the vehicle. This helps improve fuel economy and lowers exhaust emissions by reducing the electrical load created by the alternator on the engine.

NOTE: Aftermarket replacement LED bulbs that are used to replace conventional bulbs may require the use of a different type of flasher unit due to the reduced current draw of the LED bulbs. ● **SEE FIGURE 53–4.**

TESTING BULBS Bulbs can be tested using two basic tests.

1. Perform a visual inspection of any bulb. Many faults, such as a shorted filament, a corroded connector, or moisture, can cause weird problems that are often thought to be wiring issues.
2. Bulbs can be tested using an ohmmeter and checking the resistance of the filament(s). Most bulbs read low resistance, between 0.5 and 20 ohms (incandescent bulbs), at room temperature, depending on the bulb. Test results include the following:
    - Normal resistance. The bulb is good. Check both filaments if it is a two-filament bulb.
    - Zero ohms. It is unlikely, but possible for the bulb filament to be shorted.
    - OL (electrically open). The reading indicates that the bulb filament is broken.

NOTE: If testing LED lights, check service information for the specified testing procedure.

BULB NUMBERS

TRADE NUMBER The number used on automotive bulbs is called the bulb **trade number**, as recorded with the American National Standards Institute (ANSI). The number is the same regardless of the manufacturer. ● **SEE FIGURE 53–5.**

The amount of light produced by a bulb is determined by the resistance of the filament wire, which also affects the amount of current (in amperes) required by the bulb. The correct trade number of a bulb should always be used for replacement to prevent circuit or component damage. Check service information or the owner's manual for the exact replacement bulb to use. ● **SEE CHART 53–1**.

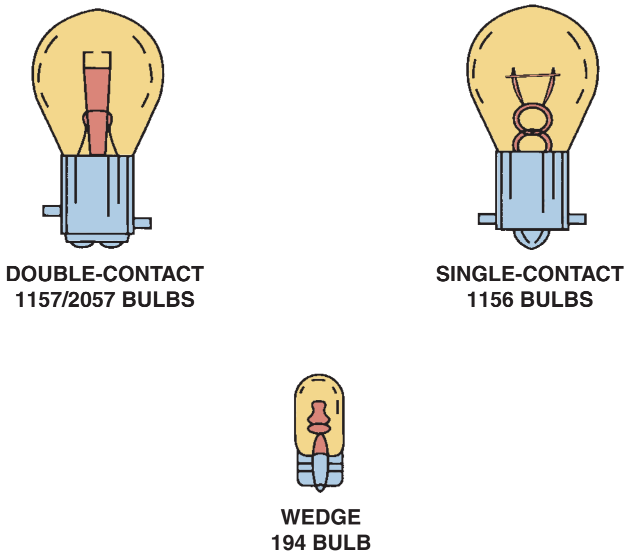

FIGURE 53–5 Dual-filament (double-contact) bulbs contain both a low-intensity filament for taillights or parking lights, and a high-intensity filament for brake lights and turn signals. Bulbs come in a variety of shapes and sizes. The numbers shown are the trade numbers.

BULB NUMBER	FILAMENTS	AMPERAGE	WATTAGE
1156	1	2.1	26.9
1157	2	0.6/2/1	8.3/26.9
2057	2	0.5/2.1	6.9/26.9
3057	2	0.5/2.1	6.7/26.9
4157	2	0.6/2/1	8.3/26.9
7440	1	1.8	21.0
7443	2	0.4/1.8	5.0/21.0
67	1	0.6	8.0
161	1	0.2	2.7
168	1	0.4	4.9
192	1	0.3	4.3
194	1	0.3	3.8
585	1	0.04	1.1
921	1	1.4	18
9003	2	4.6/5.0	55.0/60.0
9006	1	4.3	55.0

CHART 53–1

Some automotive bulb trade numbers with their amperage and wattage rating. Check service information for the exact bulb to use.

BULB NUMBER SUFFIXES Many bulbs have suffixes that indicate some feature of the bulb, while keeping the same size and light output specifications. Typical bulb suffixes include the following:

- A—amber (painted glass)
- B—blue
- G—green
- HD—heavy duty
- IF—inside frosted
- LL—long life
- NA—natural amber (amber glass)
- Q—quartz halogen
- R—red

● **SEE FIGURE 53–6.**

BRAKE LIGHTS

TERMINOLOGY Brake lights, also called *stop lights*, use the high-intensity filament of a double-filament bulb or LEDs. The brake lights are lit when the driver depresses the brake pedal. On older vehicles, the brake switch receives current from a fuse that is hot all the time. The brake light switch is a normally open (N.O.) switch, but is closed when the driver depresses the brake pedal. Newer brake switches have more than one set of contacts. In many cases, one set is normally open and the other set is normally closed.

- **One-Filament Stop/Turn Bulbs**—In some vehicles, the stop and turn signals are both provided by one filament.

7213157
7213157NA

FIGURE 53–6 Bulbs that have the same trade number have the same operating voltage and wattage. NA means that the bulb uses a natural amber glass ampoule with clear turn-signal lenses.

- **Two-Filament Stop/Turn Bulbs**—In systems using separate filaments for the stop and turn lamps, the brake and turn-signal switches are not connected.

All vehicles sold in the United States have a third brake light commonly referred to as the *center high-mounted stop light (CHMSL).* ● **SEE FIGURE 53–7**.

BCM-CONTROLLED BRAKE LIGHTS When the brake pedal is depressed, the signal is sent to the brake light controller, usually the BCM, which then signals the rear light module to actuate the brake lights. The input from the brake pedal switch or sensor is used by other systems in the vehicle as an input signal for the following systems:

1. **Shift interlock**—On vehicles equipped with an automatic transmission, the gear selector cannot be moved out of the park position unless the brake pedal is depressed.
2. **Push-button start**—Vehicles equipped with a push-button start do not start unless the brake pedal is depressed.
3. **Cruise control**—If the brake pedal is depressed, the cruise control function is disabled.

(TBC) MODULE

FIGURE 53–8 A schematic of the BCM-controlled brake light circuit that includes the brake pedal position (BPP) switch, which creates signals to the powertrain control module (PCM) with inputs labeled BPS (brake pedal position) and BOO (brake on-off).

4. **Antilock braking system (ABS)**—When the brake pedal is depressed, the ABS system is ready to intervene, if needed, to control wheel slippage.

On some vehicles, the key must be in the on position for all the brake lights to illuminate. This is particularly important to know when performing diagnostics. Check service information for the specified procedure to follow on the vehicle being tested. ● **SEE FIGURE 53–8**.

TURN SIGNALS

MECHANICAL SYSTEM OPERATION In older systems, the turn-signal circuit is supplied power from the flasher unit, which is powered from the ignition switch. When the turn-signal switch is moved in either direction, the corresponding turn-signal lamps receive current, and the flasher unit causes the current to start and stop.

A turn-signal flasher unit is a metal or plastic can, containing a switch that opens and closes the turn-signal circuit. It is often installed in a metal clip attached to the dash panel to allow the "clicking" noise of the flasher to be heard by the driver. ● **SEE FIGURE 53–9**.

BCM-CONTROLLED TURN SIGNALS Starting in the early 2000s, many vehicles use the turn signal as an input to the body control module (BCM). ● **SEE FIGURE 53–10**.

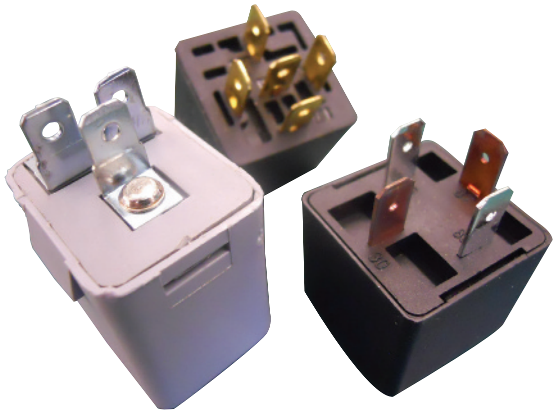

FIGURE 53–9 Three styles of flasher units.

The BCM sends a signal through the data lines to the lighting module(s) to flash the lights. With these systems, the BCM also sends a signal to the radio, which sends a clicking sound to the driver's side speaker, even if the radio is off.

BULB OUTAGE WARNING On some vehicles the lighting module, usually the BCM, monitors the current flow through all the lights. These circuits measure the current and, if there is a change that is not expected, they can turn on a warning light to warn the driver. If this current is below some threshold value, the bulb is assumed to be burned out. Some bulb failure

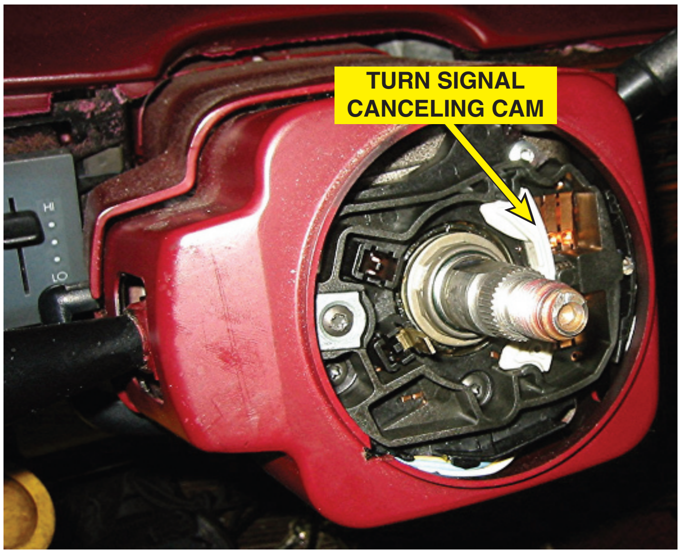

FIGURE 53–10 A steering column with the steering wheel removed, showing the turn signal canceling cam used to return the lever to the neutral position after a turn. The switches are an input to the body control module for left and right turn-signal operation.

systems work by sensing bulb resistances when the lamps are off. When diagnosing a bulb outage concern, perform the following steps:

STEP 1 Visually check the exterior lights for proper operation. Check all of the following:

- Backup light(s)
- Brake lights, including the center high-mounted stop light
- Driving lights, if equipped
- Fog lights, if equipped
- High-beam headlights
- License plate light(s)
- Low-beam headlights
- Park lights
- Puddle lights
- Side marker lights, front and rear, and left and right sides
- Taillights
- Turn signals front and rear

STEP 2 If one or more are not lighting, check or replace the bulb. Verify that the affected bulb is not an LED where a non-LED bulb is specified. ● **SEE FIGURE 53–11**.

STEP 3 If the warning lamp is still on, check the sockets for corrosion, proper voltage, and ground at the socket.

HAZARD WARNING LIGHTS

The **hazard warning**, also called *four-way flashers*, is a device installed in a vehicle lighting system with the primary function of causing both the left and right turn-signal lamps to flash when the hazard warning switch is activated. Secondary functions may include visible dash indicators for the hazard system and an audible signal to indicate when the flasher is operating. In older systems, a separate hazard warning flasher is used. Current vehicles use the BCM to operate all four turn-signal lights when the hazard (four-way) flasher switch is turned on by the driver.

DAYTIME RUNNING LIGHTS

PURPOSE AND FUNCTION

Daytime running lights (DRLs) are lights at the front of the vehicle that are on all the time the engine is running, unless they are turned off, or when the headlights are on. DRLs involve operation of the following:

- Front parking lights
- Separate DRL lamps
- Headlights (usually at reduced current and voltage) when the vehicle is running

Studies have shown that DRLs have reduced accidents where used. DRLs primarily use a control module that turns on either the low- or high-beam headlights wired in series or separate daytime running lights. The lights on some vehicles come on when the engine starts. Other vehicles turn on the lamps when the engine is running but delay their operation until a signal from the vehicle speed sensor indicates that the vehicle is moving. To avoid having the lights on during servicing, some systems turn off the headlights when the parking brake is applied, and the ignition switch is cycled off and then back on. Others only light the headlights when the vehicle is in a drive gear. ● **SEE FIGURE 53–12**.

The DRLs operate when the following conditions are met:

- The ignition is in the RUN or CRANK position
- The shift lever is out of the PARK position for vehicles equipped with automatic transmissions, or the parking brake is released for vehicles with manual transmissions
- The low- and high-beam headlamps are OFF

HEADLIGHTS

HEADLIGHT SWITCHES

Older vehicles use the headlight switch to operate the exterior and interior lights. On these systems, the headlight switch is connected directly to the battery

through a fusible link, and has continuous power or is "hot" all the time. ● **SEE FIGURE 53–13.**

HEADLIGHT SWITCH, BCM-CONTROLLED LIGHTING When the headlamp switch is placed in the HEAD or PARK position, a signal is sent to the body control module (BCM). The BCM responds by applying voltage to the park lamps, tail lamps, and license lamps control circuits illuminating the park, tail, and license lamps.

When the headlamp switch is placed in the HEADLAMP position, the BCM responds to the inputs by illuminating the park lamps and headlamps.

When placed in the AUTO position, the BCM monitors inputs from the ambient light sensor to determine whether headlamps are required or whether the daytime running lamps will be activated, based on outside lighting conditions.

COMPOSITE HEADLIGHTS Sealed beam headlights were used for many years and then, in the 1990s, were replaced with composite headlights. **Composite headlights** are constructed using a replaceable bulb and a fixed lens cover that is part of the vehicle. Composite headlights are the result of changes in the aerodynamic styling of vehicles where sealed beam lamps could no longer be used. ● **SEE FIGURE 53–14.**

The replaceable bulbs are usually bright halogen bulbs. Halogen bulbs get very hot during operation, between 500°F and 1,300°F (260°C and 704°C). It is important to never touch the glass of any halogen bulb with bare fingers because the natural oils of the skin on the glass bulb can cause the bulb to break when it heats during normal operation. ● **SEE FIGURE 53–15.**

BULB FAULTS Halogen bulbs can fail for various reasons. Some causes for halogen bulb failure and their indications include the following:

- **Gray color.** Low voltage to the bulb (check for corroded socket or connector)
- **White (cloudy) color.** Indication of an air leak
- **Broken filament.** Usually caused by excessive vibration
- **Blistered glass.** Indication that someone has touched the glass

FIGURE 53–13 A Typical headlight circuit diagram on an older vehicle that does not use a controller, such as the BCM, to control the operation of the lights. Note that the headlight switch is represented by a dotted outline, indicating that other circuits (such as dash lights) also operate from the switch.

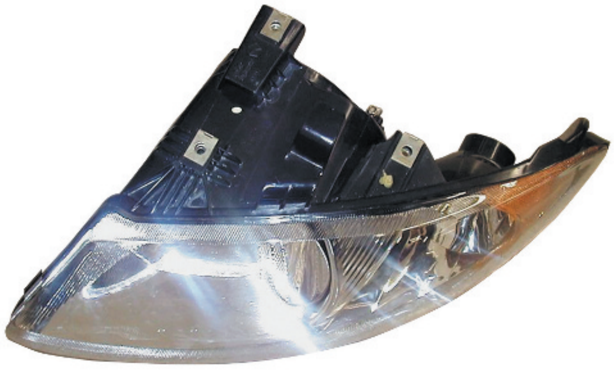

FIGURE 53–14 A typical composite headlamp assembly. The lens, housing, and bulb sockets are usually included as a complete assembly.

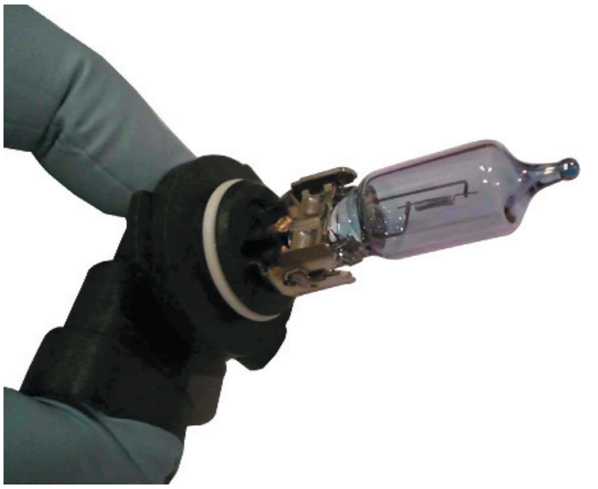

FIGURE 53–15 Handle a halogen bulb by the base to prevent the skin's oil from getting on the glass.

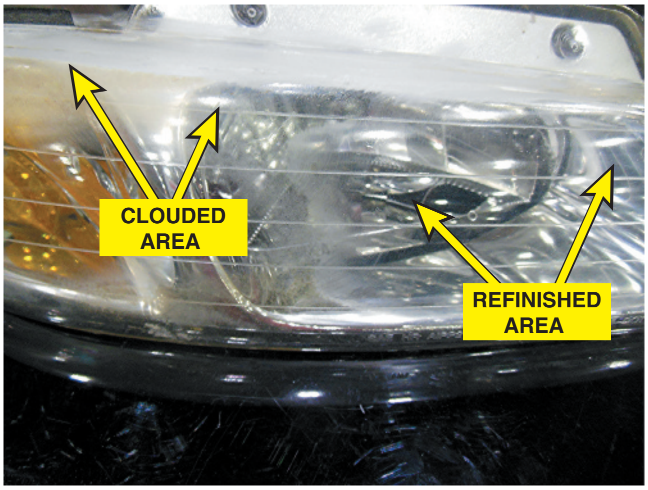

CLOUDED AREA
REFINISHED AREA

FIGURE 53–16 The right side of this headlight assembly has been restored, but still needs to be polished. The left side is cloudy and not yet restored.

CLOUDY HEADLIGHT RESTORATION The bulb covering of composite headlights is made from acrylic plastic. This material tends to fade, turn yellow, and discolor over a period of time due primarily to constant exposure to the sun's ultraviolet (UV) rays. The problem tends to be most serious in warmer, sunny climates. This clouding of the surface is more than a cosmetic issue because it can reduce the available light, reducing night vision. There are many brands and types of headlight restoration products available. Most products involve sanding the surface of the lens using fine sandpaper and applying a UV protectant to help prevent further damage to the plastic lens. Always follow the instructions for the product or procedure used to restore the headlights. ● **SEE FIGURE 53–16**.

HIGH-INTENSITY DISCHARGE HEADLIGHTS

PARTS AND OPERATION **High-intensity discharge (HID)** headlights produce light that is crisper, clearer, and brighter than light produced by a halogen headlight. HID lamps do not use a filament like conventional electrical bulbs, but contain two electrodes about 0.2 inch (5 mm) apart. A high-voltage pulse is sent to the bulb, which arcs across the tips of electrodes, producing light. It creates light from an electrical discharge between two electrodes in a gas-filled arc tube. A HID lamp produces twice

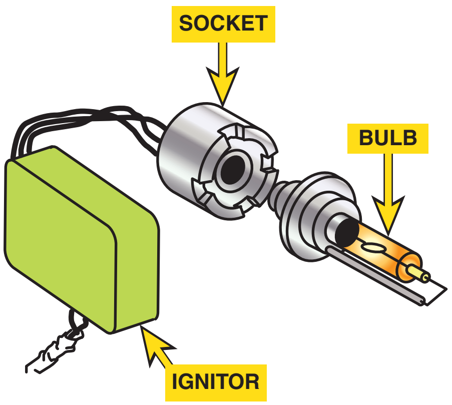

FIGURE 53–17 The igniter contains the ballast and transformer needed to provide high-voltage pulses to the arc-tube bulb.

the light with less electrical current (amperage) than conventional halogen bulbs. The HID lighting system consists of the discharge arc source, igniter, ballast, and headlight assembly. ● **SEE FIGURE 53–17**.

The two electrodes are contained in a tiny quartz capsule filled with xenon gas, mercury, and metal halide salts. HID headlights are also called *xenon* headlights. The lights and support electronics are expensive, but they should last the life of the vehicle, unless physically damaged. HID headlights produce a white light giving the lamp a blue-white color. The color of light is expressed in temperature using the Kelvin scale. **Kelvin (K)** temperature is the Celsius temperature plus 273 degrees. Typical color temperatures include the following:

- Daylight—5,400°K
- HID—4,100°K
- Halogen—3,200°K
- Incandescent (tungsten)—2,800°K

● **SEE FIGURE 53–18**.

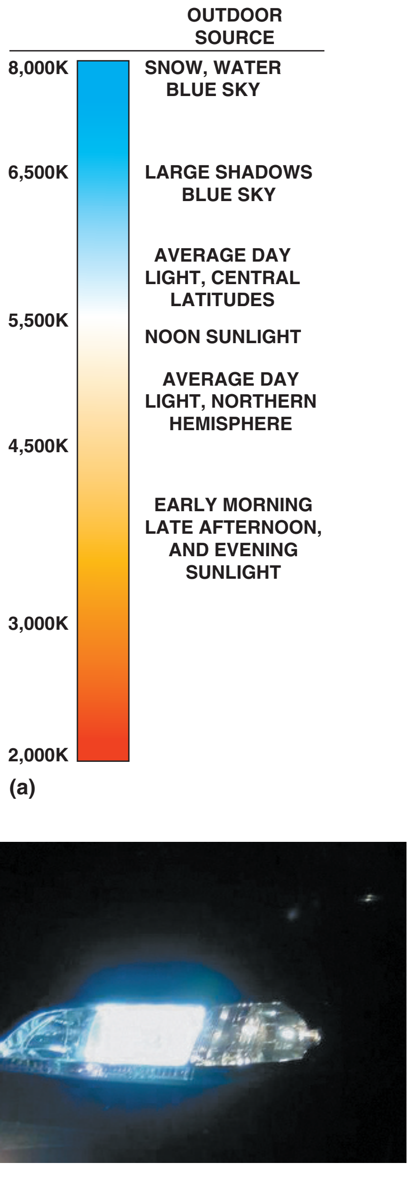

FIGURE 53–18 (a) The color of light is measured in degrees Kevin (K). The higher the temperature of the light, the bluer the appearance. (b) HID (xenon) headlights emit a whiter light than halogen headlights and usually look blue compared to halogen bulbs.

STAGES OF HID HEADLIGHT OPERATION The HID ballast is powered by voltage from the headlight switch or the BCM. The HID headlights operate in three stages or states:

1. **Start-up or stroke state**—When the headlight switch is turned to the on position, the ballast may draw up to 20 amperes at 12 volts. The ballast sends multiple high-voltage pulses to the arc tube to start the arc inside the bulb. The voltage provided by the ballast during the start-up state ranges from −600 to +600 volts, which is increased by a transformer to about 25,000 volts. The increased voltage is used to create an arc between the electrodes in the bulb.
2. **Run-up state**—After the arc is established, the ballast provides a higher-than-steady-state voltage to the arc tube to keep the bulb illuminated. On a cold bulb, this state could last as long as 40 seconds. On a hot bulb, the run-up state may last only 15 seconds. The current requirements during the run-up state are about 360 volts from the ballast and a power level of about 75 watts.
3. **Steady state**—The steady-state phase begins when the power requirement of the bulb drops to 35 watts. The ballast provides a minimum of 55 volts to the bulb during steady-state operation.

FREQUENTLY ASKED QUESTION

What Is the Difference between the Temperature of the Light and the Brightness of the Light?

The temperature of the light indicates the color of the light. The brightness of the light is measured in lumens. A standard 100 watt incandescent light bulb emits about 1,700 lumens. A typical halogen headlight bulb produces about 2,000 lumens, and a typical HID bulb produces about 2,800 lumens.

BI-XENON HEADLIGHTS Some vehicles are equipped with bi-xenon headlights, which use a shutter to block some of the

WARNING

Always adhere to all warnings because the high-voltage output of the ballast assembly can cause personal injury or death.

light during low-beam operation, and then mechanically move to expose more of the light from the bulb for high-beam operation. Because xenon lights are relatively slow to start working, vehicles equipped with bi-xenon headlights use two halogen lights for the "flash-to-pass" feature.

HID HEADLIGHT FAILURE SYMPTOMS The following symptoms indicate bulb failure.

- A light flickers
- Lights go out (caused when the ballast assembly detects repeated bulb restrikes)
- Color changes to a dim pink glow

Bulb failures are often intermittent and difficult to repeat. However, bulb failure is likely if the symptoms get worse over time. Always follow the vehicle manufacturer's recommended testing and service procedures.

DIAGNOSIS AND SERVICE HID headlights change slightly in color with age. This color shift is usually not noticeable unless one headlight arc-tube assembly has been replaced due to a collision repair, and then the difference in color may be noticeable. The difference in color gradually changes as the arc tube ages and should not be too noticeable by most customers. If the arc-tube assembly is near the end of its life, it may not light immediately if it is turned off and then back on immediately. This test is called a "hot restrike" and, if it fails, a replacement arc-tube assembly may be needed, or there is another fault, such as a poor electrical connection, that should be checked.

LED HEADLIGHTS

Many newer vehicles use LED headlights either as standard equipment or optional equipment. ● **SEE FIGURE 53–19**.

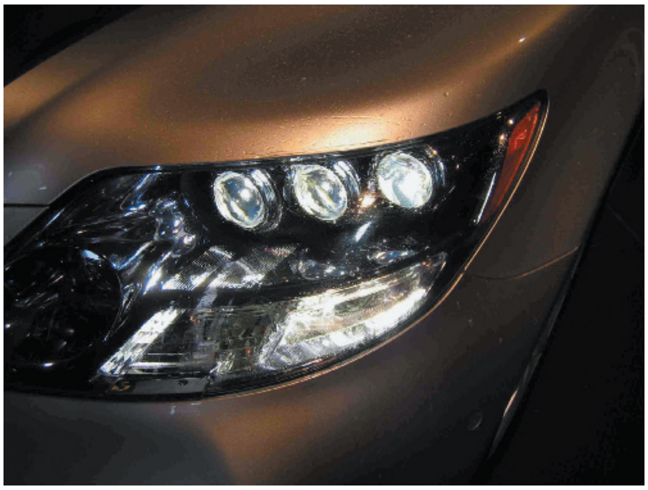

FIGURE 53–19 LED headlights usually require multiple units to provide the needed light, as seen on this Lexus LS600h.

The advantages of LED headlights compared to other types are as follows:

- Long service life
- Reduced electrical power required

The disadvantages of LED headlights are as follows:

- Higher cost
- Many small LEDs are required to create the necessary light output

ADAPTIVE FRONT LIGHTING SYSTEM

PURPOSE AND FUNCTION An **adaptive** (or **advanced**) **front lighting system**, or **AFS**, is a system that mechanically moves the headlights to follow the direction of the front wheels. The purpose is to provide improved lighting during cornering. The AFS headlights are usually capable of rotating 15 degrees to the left and 5 degrees to the right (some systems rotate 14 degrees and 9 degrees, respectively). Vehicles that use AFS include Lexus, Mercedes, and certain domestic models, usually as an extra cost option. ● **SEE FIGURE 53–20**.

AFS is often used in addition to self-leveling motors so that the headlights remain properly aimed, regardless of how the vehicle is loaded. Without self-leveling, headlights shine higher than normal if the rear of the vehicle is heavily loaded. ● **SEE FIGURE 53–21**.

NOTE: These angles are reversed on vehicles sold in countries that drive on the left side of the road, such as Great Britain, Japan, Australia, and New Zealand.

PARTS AND OPERATION The vehicle has to be moving above a predetermined speed, usually above 20 MPH (30 km/h), and the lights stop moving when the speed drops below about 3 MPH (5 km/h).

When a vehicle is equipped with an AFS, the lights are moved by the headlight controller outward and then inward, as well as up and down, as a test of the system. This action is quite noticeable to the driver and is a normal operation of the system.

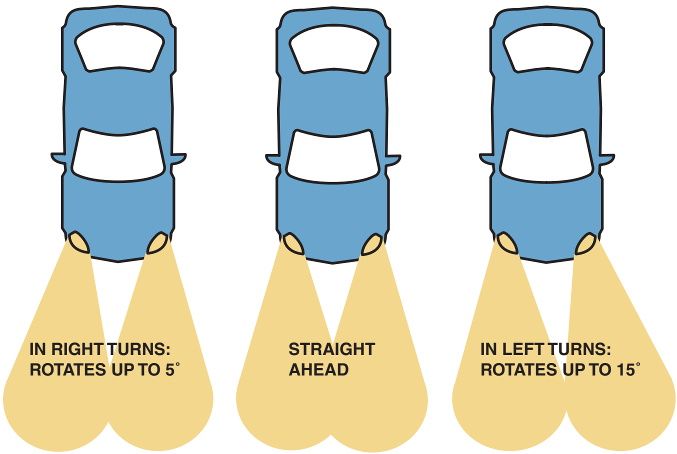

FIGURE 53–20 Adaptive front lighting systems rotate the low-beam headlight in the direction of travel.

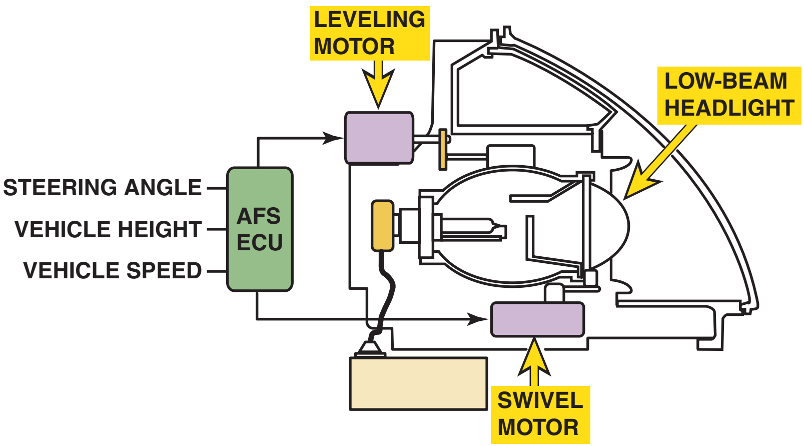

FIGURE 53–21 A typical adaptive front lighting system uses two motors: one for the up-and-down movement and the other for rotating the low-beam headlight to the left and right.

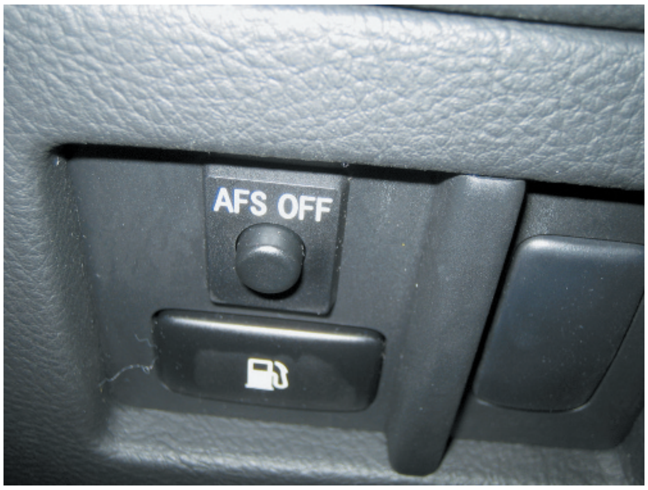

FIGURE 53–22 Typical dash-mounted switch that allows the driver to turn off the front lighting system.

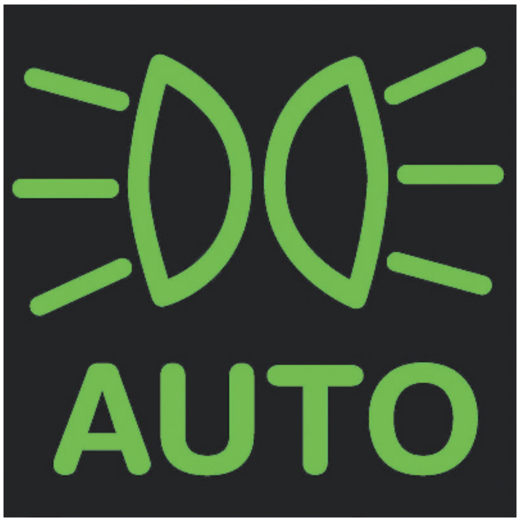

FIGURE 53–23 A dash symbol used to inform the driver that the automatic headlights are on.

DIAGNOSIS AND SERVICE The first step when diagnosing an AFS fault is to perform the following visual inspection:

- Start by checking that the AFS is switched on. Most AFS headlights are equipped with a switch that allows the driver to turn the system on and off. ● **SEE FIGURE 53–22**.
- Check that the system performs a self-test during start-up.
- Verify that both low-beam and high-beam lights function correctly. The system may be disabled if a fault with one of the headlights is detected.
- Use a scan tool to test for any AFS-related diagnostic trouble codes. Some systems allow the AFS to be checked and operated using a scan tool.

Always follow the recommended testing and service procedures as specified by the vehicle manufacturer in service information.

AUTOMATIC HEADLIGHTS

PURPOSE AND FUNCTION **Automatic headlights** automatically turn on the headlights when the light sensor detects low ambient light level. These sensors are usually located on the dash of the vehicle. If the light level is low, the headlights turn on automatically when the engine starts. The ambient light sensor is used to monitor outside lighting conditions. The ambient light sensor provides a voltage signal that varies between 0.2 and 4.9 volts, depending on outside lighting conditions. The BCM provides a 5 volt reference signal to the ambient light sensor. The BCM monitors the ambient light sensor signal circuit to determine if outside lighting conditions are correct for either daytime running lights, or automatic lamp control (ALC) when the headlamp switch is in the AUTO position.

CONTROLS Most vehicles allow the driver to select the headlights in the "AUTO" position or turn them on and off manually. If the headlights are on, a dash symbol is often displayed on the dash to inform the driver. ● **SEE FIGURE 53–23**.

HEADLIGHT HIGH-/LOW-BEAM SWITCH

DIMMER SWITCH Headlights use a high-intensity bulb or lamp and a low-intensity bulb or lamp. The switch used to switch between the two circuits is often called the *dimmer switch* or the high/low switch. An indicator light illuminates on the dash when the high beams are selected. The dimmer switch is usually hand-operated by a lever on the steering column.

AUTO DIMMING HEADLIGHTS

PURPOSE AND FUNCTION An **automatic headlight dimmer** (also called *automatic beam control* or *automatic high beams*) is a system that causes the headlights to switch from high-intensity beams to low-intensity beams when the system detects the headlights from an approaching vehicle.

TYPES OF SYSTEMS Types of automatic headlight dimming include the following:

- **Photo resistor-based system**—A system that uses a photo resistor is usually mounted at the top of the windshield inside the vehicle. This system automatically adjusts the headlight beams from “high-beam” to “low-beam” when approaching oncoming vehicles during nighttime driving. The system also switches back to high-beam after the vehicles have passed. Drivers can also use standard headlight dimmers to override the automatic headlight dimmer on vehicles so equipped.
- **Camera-based systems**—Some vehicles use the camera and lasers already fitted for collision avoidance. These systems can detect an oncoming vehicle from 400 yards (366 m) away, and detect the tail lights of a car in front from more than 120 yards (110 m).

CONDITIONS NEEDED TO FUNCTION For the automatic operation to turn on the high beams, the following conditions are usually required:

- Vehicle speed above 20 MPH
- Dark conditions with few streetlights
- There are no approaching vehicles with the headlights on
- There are no taillights from the vehicle in front

NOTE: High beams may not automatically turn off when an approaching vehicle is hidden from view due to a hill or a curve. This inability is not a fault with the system, but instead is due to the limiting factors of the system.

HEADLIGHT AIMING

According to U.S. federal law, all headlights, regardless of shape, must be able to be aimed using headlight-aiming equipment. The headlights are equipped with adjusting screws that can be used to aim the headlights. Some are also equipped with a bubble level to help make sure that the lights are level. Older vehicles equipped with sealed beam headlights used a headlight-aiming system that is attached to the headlight itself. Check service information for the exact procedure and specifications to follow when aiming headlights. ● **SEE FIGURE 53–24**.

FOG AND DRIVING LIGHTS

FOG LIGHTS The light from regular headlights can reflect off the fog, snow, or dust particles in the air, causing glare. When driving in fog, the use of fog lights reduces the glare. Fog lights have a unique beam that is flat and wide, and is positioned low on the vehicle, usually near the front bumper. Fog lights are also useful where there is dust and snow on the road, either

VERTICAL (UP/DOWN) ADJUSTMENT
(b)

FIGURE 53–24 (a) A typical headlight-aiming diagram as found in service information. (b) Adjustments to move the headlight-aiming point left or right or up and down are usually made using a screwdriver to move the headlight housing.

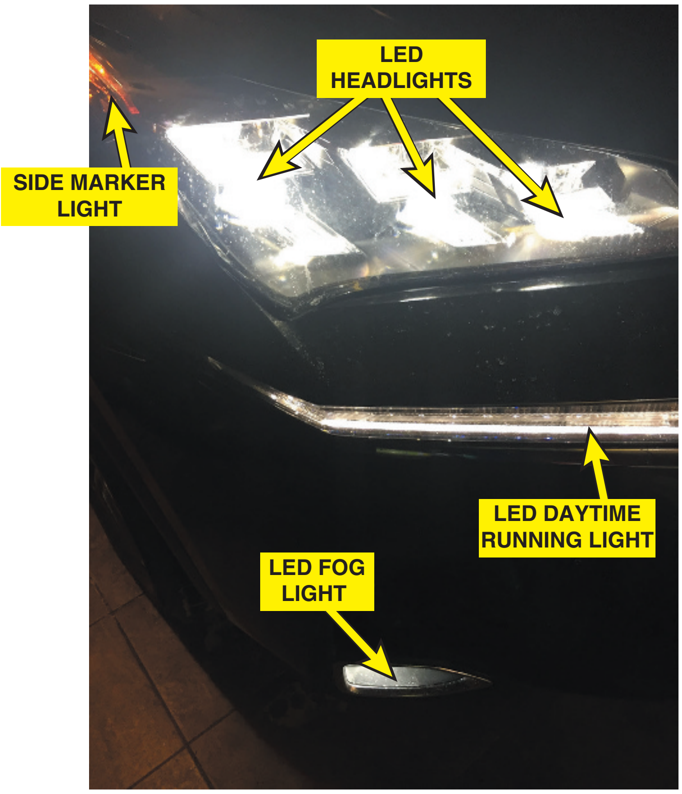

FIGURE 53–25 Fog lights are often included on many vehicles, such as these on a Lexus SUV.

drifting in through the air or being churned up from the surface of the road. Fog lights are usually white, though they can also be yellow or blue. Fog lights in the rear are always red. ● **SEE FIGURE 53–25**.

NOTE: Fog lights should only be used when poor visibility is present and then turned off.

DRIVING LIGHTS Driving lights have a narrow, straight beam, and are used while off-roading or traversing dark, deserted country roads. Driving lights are designed to send powerful beams far ahead, illuminating the next stretch of road. Driving lights are usually installed by the vehicle owner and are usually not available from the factory unless a special off-road equipment package is ordered. If installed, they should be wired to work only when the high beams are in use. Check local and state regulations in regards to the mounting and use of driving lights.

FREQUENTLY ASKED QUESTION

What Are Rear Fog Lights?

Some vehicles, usually European vehicles, are equipped with rear (red) fog lights. These are used so that drivers behind can see the vehicle in front. These could be on whenever the fog lights are turned on, or they could be on a separate switch. These rear fog lights are sometimes confused with brake lights being on because they are often as bright as brake lights. Check the owner's manual or service information if a fault is reported about the rear fog lights.

FREQUENTLY ASKED QUESTION

What Is the Troxler Effect?

The **Troxler effect**, also called *Troxler fading*, is a visual effect where an image remains on the retina of the eye for a short time after the image has been removed. The effect was discovered in 1804 by Ignaz Paul Vital Troxler (1780–1866), a Swiss physician. Because of the Troxler effect, headlight glare can remain on the retina of the eye and create a blind spot. At night, this fading away of the bright light from the vehicle in the rear reflected by the rearview mirror can cause a hazard.

AUTOMATIC DIMMING MIRRORS

PARTS AND OPERATION Automatic dimming mirrors use electrochromic technology to dim the mirror in proportion to the amount of headlight glare from other vehicles at the rear. The electrochromic technology developed by Gentex Corporation uses a gel that changes with light between two pieces of glass. One piece of glass acts as a reflector and the other has a transparent (clear) electrically conductive coating. The inside rearview mirror also has a forward-facing light sensor that is used to detect darkness. It signals the rearward-facing sensor to begin to check for excessive glare from headlights behind the vehicle. The rearward-facing sensor sends a voltage to the electrochromic gel in the mirror that is in proportion to the amount of glare detected. The mirror dims in proportion to the glare, and becomes like a standard rearview mirror when the glare is no longer detected. If automatic dimming mirrors are used on the exterior, the sensors in the interior mirror and electronics are used to control both the interior and exterior mirrors. ● **SEE FIGURE 53–26**.

DIAGNOSIS AND SERVICE If a customer concern states that the mirrors do not dim when exposed to bright headlights from the vehicle behind, the cause could be sensors or the mirror itself. Be sure that the mirror is getting electrical power. Most automotive dimming mirrors have a green light to indicate the presence of electrical power. If no voltage is found at the mirror, follow standard troubleshooting procedures to find the cause. If the mirror is getting voltage, start the diagnosis by placing a strip of tape over the forward-facing light sensor. Turn the ignition key on, engine off (KOEO), and observe the operation of the mirror when a flashlight or trouble light is directed onto the mirror. If the mirror reacts and dims, the forward-facing sensor is defective. Most often, the entire mirror assembly must be replaced, if any sensor or mirror faults are found.

One typical fault with automatic dimming mirrors is that a crack can occur in the mirror assembly, allowing the gel to escape from between the two layers of glass. This gel can drip onto the dash or center console and harm these surfaces. The mirror should be replaced at the first sign of any gel leakage.

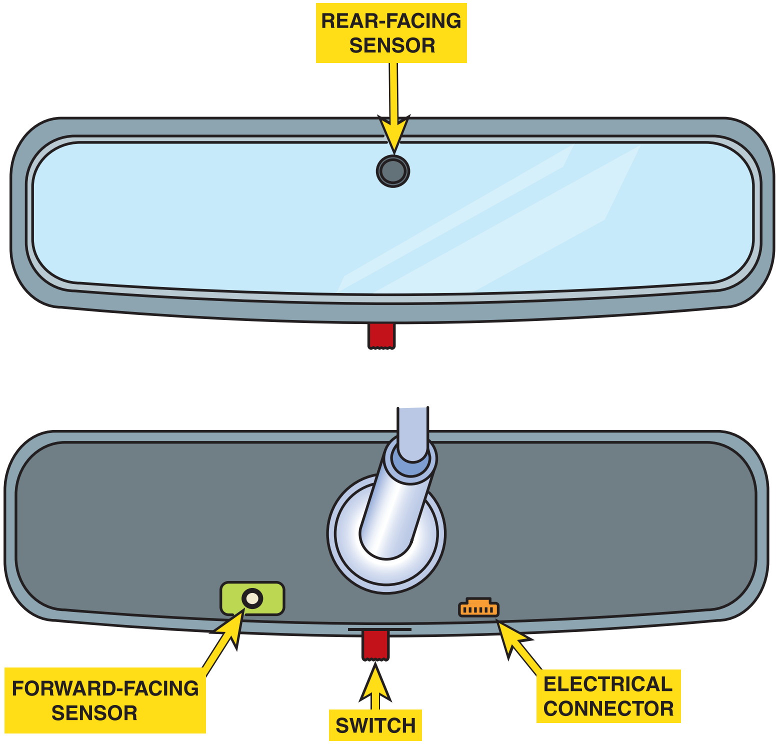

FIGURE 53–26 An automatic dimming mirror compares the amount of light toward the front of the vehicle to the rear of the vehicle and allows a voltage to cause the gel to darken the mirror.

COURTESY LIGHTS

Courtesy lights are a generic term primarily used for interior lights, including overhead (dome) and under-the-dash (courtesy) lights. These interior lights are controlled by switches located in the door handle of the vehicle or by a switch on the dash. Many newer vehicles operate the interior lights through the BCM or through an electronic module. Because the exact wiring and operation of these units differ, check the service information for the exact model of the vehicle being serviced.

ILLUMINATED ENTRY

Some vehicles are equipped with illuminated entry, meaning the interior lights are turned on for a given amount of time when the outside door handle or remote keyless entry (RKE) fob is operated while the doors are locked.

Most vehicles equipped with illuminated entry also light the exterior door lights, called “puddle lights,” that shine downward so people entering a vehicle in the dark can see the ground near the vehicle. The input from the door handle or key fob remote is used to “wake up” the power supply for the BCM and usually turns on the interior lights.

HEADLIGHT SYSTEM DIAGNOSIS

VISUAL INSPECTION All of the lights, including the operation of the headlights, should be a part of any vehicle inspection process. During a visual inspection, check the headlights for the following:

- Are they functioning as designed? (Check service information or a similar vehicle to make sure that the system is not working as designed.)
- Check the brightness to see if they are dim.
- Check if the headlights are too bright.

DIAGNOSTIC PROCEDURE If the headlights are not working at all, perform the following steps:

STEP 1 Use a factory or factory-level scan tool to turn the headlights on using the bidirectional command from the scan tool. If the headlights work, the headlights and the headlight circuit are working normally. The problem is likely the control input to the controller that operates the headlights.

STEP 2 Check the schematic for the headlight circuit and check for voltage at various parts to help pinpoint the location of the open circuit. Always follow the vehicle manufacturer’s specified procedures. ● **SEE FIGURE 53–27**.

- If the headlights are brighter than normal, the battery voltage may be higher than normal. Check the charging system voltage to make sure that it is less than 15.5 volts (on most vehicles). Check service information for the exact specifications.
- If the headlight(s) is/are dimmer than normal, check the electrical circuits to the headlights for excessive circuit resistance, such as any of the following:

  1. Loose electrical connector
  2. Corroded socket
  3. Poor electrical ground connection

LIGHTING SYSTEM DIAGNOSIS

Diagnosing any faults in the lighting and signaling systems usually includes the following steps:

STEP 1 Verify the customer concern.

STEP 2 Perform a visual inspection, checking for collision damage or other possible causes that would affect the operation of the lighting circuit.

TECH TIP

The Weirder the Problem, the More Likely It Is a Poor Ground Connection

Bad grounds are often the cause for feedback or lamps operating at full or partial brilliance. At first, the problem looks weird, because often the switch for the lights that are on dimly is not even turned on. When an electrical device is operating, and it lacks a proper ground connection, the current tries to find ground and often causes other circuits to work. Check all grounds before replacing parts.

STEP 3 Connect a factory or enhanced scan tool with bidirectional control of the control modules to check for proper operation of the affected lighting circuit.

STEP 4 Follow the diagnostic procedure, as found in service information, to determine the root cause of the problem.

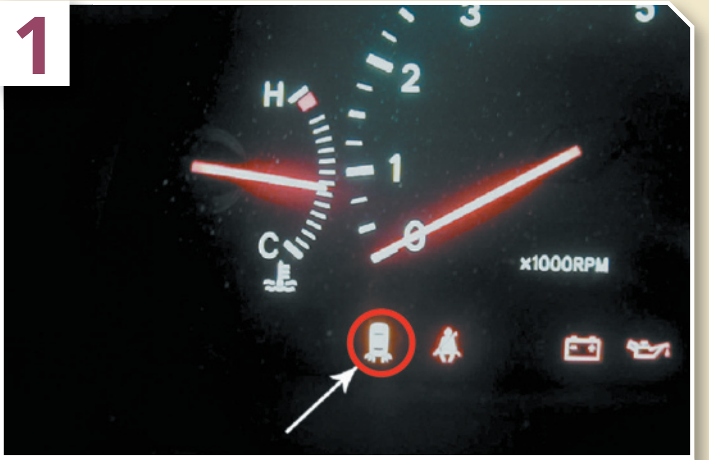
LIGHTING SYSTEM SYMPTOM GUIDE The following list assists technicians in determining lighting systems faults by symptom.

PROBLEM/CONCERN	POSSIBLE CAUSE
One headlight dim	1. Poor ground connection on body 2. Corroded connector
One headlight out (low or high beam)	1. Burned out headlight filament (Check the headlight with an ohmmeter. There should be a low ohm reading between the power-side connection and the ground terminal of the bulb.) 2. Open circuit (no 12 volts to the bulb)
Both high- and low-beam headlights out	1. Burned out bulbs 2. Open circuit (Check for voltage at the wiring connector to the headlights for a possible open circuit to the headlights or open [defective] dimmer switch.)

PROBLEM/CONCERN	POSSIBLE CAUSE
All headlights inoperative	1. Burned out filaments in all headlights (Check for excessive charging-system voltage.) 2. Defective dimmer switch 3. Defective headlight switch
Slow turn-signal operation	1. Defective flasher unit (if equipped) 2. High resistance in sockets or ground wire connections 3. Incorrect bulb numbers
Turn signals operating on one side only	1. Burned out bulb on the affected side 2. Poor ground connection or defective socket on the affected side 3. Incorrect bulb number on the affected side 4. Defective turn-signal switch
Interior light(s) inoperative	1. Burned out bulb(s) 2. Open in the power-side circuit (blown fuse) 3. Open in door switch(es)
Brake lights inoperative	1. Defective brake switch 2. Defective turn-signal switch (mechanical system) 3. Burned out brake light bulbs 4. Open circuit or poor ground connection 5. Blown fuse
Hazard warning lights inoperative	1. Defective hazard flasher unit (if equipped) 2. Open in hazard circuit 3. Blown fuse 4. Defective hazard switch

TAILLIGHT BULB REPLACEMENT

1

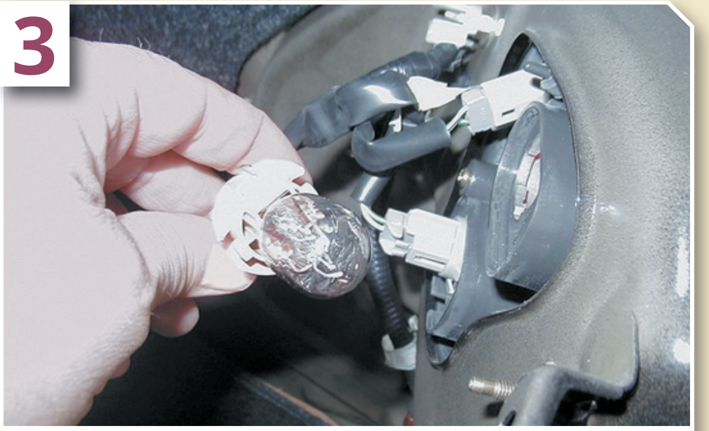


The driver noticed that the taillight fault indicator (icon) on the dash was on any time the lights were on.

2

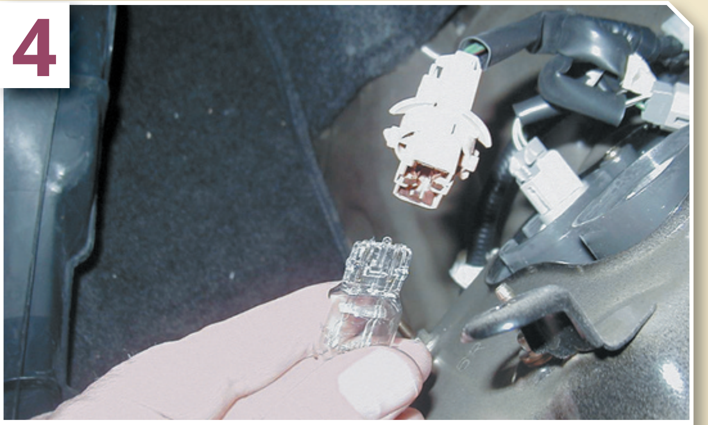
A visual inspection at the rear of the vehicle indicated that the right rear taillight bulb did not light. Removing a few screws from the plastic cover revealed the taillight assembly.

3



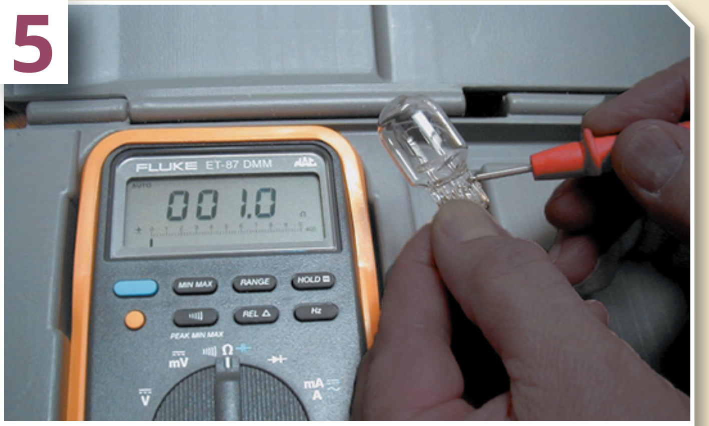
The bulb socket is removed from the taillight assembly by gently twisting the base of the bulb counterclockwise.

4



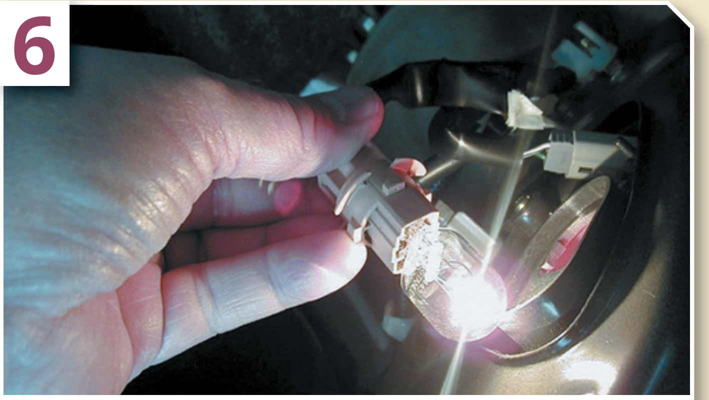
The bulb is removed from the socket by gently grasping the bulb and pulling the bulb straight out of the socket. Many bulbs required that you rotate the bulb 90 degrees (1/4 turn) to release the retaining bulbs.

5



The new 7443 replacement bulb is being checked with an ohmmeter to be sure that it is okay before it is installed in the vehicle.

6



The replacement bulb is inserted into the taillight socket and the lights are turned on to verify proper operation before putting the components back together.

REVIEW QUESTIONS

1. Why should the exact same trade number of bulb be used as a replacement?
2. Why is it important to avoid touching a halogen bulb with your fingers?
3. What are the advantages of LED lights?
4. Why are lights controlled by the BCM in many vehicles?
5. What are the conditions needed for an auto dimming headlight system to work?

CHAPTER QUIZ

1. Technician A says that the bulb trade number is the same for all bulbs of the same size. Technician B says that a dual-filament bulb has different wattage ratings for each filament. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
2. Light-emitting diodes (LEDs) are used for lighting because they __________.
   - **a.** light quicker (faster illumination)
   - **b.** have longer service life
   - **c.** have lower current draw
   - **d.** Any of the above
3. Which statement is true?
   - **a.** Daytime running lights can be separate lights or use the headlights.
   - **b.** Automatic headlights, auto-dimming headlights, and adaptive headlights are different terms for the same system.
   - **c.** The high- and low-beam switch is used to control the current through the low or high filament.
   - **d.** Both a and c are correct
4. Which of the following is used when the brakes lights or turn signal is used?
   - **a.** A brake light switch
   - **b.** The high filament in a dual filament bulb
   - **c.** A turn signal lamp
   - **d.** All of the above
5. Vehicles equipped with the illuminated entry feature typically use the __________ to command the interior lights ON.
   - **a.** BCM
   - **b.** RKE fob
   - **c.** outside door handle
   - **d.** Any of the above
6. Which of the lighting systems could result in an electrical shock hazard if proper precautions are not followed?
   - **a.** LED lights
   - **b.** HID lights
   - **c.** Rear fog lights
   - **d.** Driving lights
7. What type of light bulb should not be touched using bare hands?
   - **a.** 1157 or 2057 bulbs
   - **b.** Halogen bulbs
   - **c.** LED bulbs
   - **d.** HID bulbs
8. The "color" of light produced by a light bulb is measured in what unit?
   - **a.** Kelvin degrees
   - **b.** Amperes
   - **c.** Watts
   - **d.** Volts
9. An automatically dimming mirror is used to __________.
   - **a.** automatically dim the headlights
   - **b.** help prevent the Troxler effect
   - **c.** operate the fog lights when needed
   - **d.** operate the daytime running lights (DRLs)
10. Technician A says that a scan tool is usually needed to aim headlights. Technician B says that the keyless entry key fob is used to wake up the BCM, which usually is responsible to turn on the interior (courtesy) lights. Which technician is correct?
    - **a.** Technician A only
    - **b.** Technician B only
    - **c.** Both Technicians A and B
    - **d.** Neither Technician A nor B

DRIVER INFORMATION AND NAVIGATION SYSTEMS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Identify the meaning of dash warning symbols.
- Describe steering wheel controls.
- Describe voice activation.
- Describe maintenance indicators.
- Describe analog and digital displays.
- Discuss the operation of a head-up display.
- Discuss the operation of night vision systems.
- Discuss the operation of electronic displays.
- Discuss the operation of virtual displays.
- Discuss the operation of touch screens.
- Describe how speedometers and odometers work.
- Discuss the diagnosis of oil pressure lamp, temperature lamp, brake warning lamp, and other analog dash instruments.
- Describe how a navigation system works.
- Explain the operation and diagnosis of Telematics systems.
- Explain the operation of a backup camera.

KEY TERMS:

Analog display 631 • Backup camera 641 • Bulb test 628 • Digital display 631 • EEPROM 635 • Global positioning system (GPS) 637 • Head-up display (HUD) 632 • Instrument panel (IP) 628 • Instrument panel cluster (IPC) 631 • Liquid crystal display (LCD) 633 • Night vision 632 • Nonvolatile random access memory (NVRAM) 635 • OnStar 639 • Steering wheel controls 630 • Stepper motor 631 • Telematics 639 • Thin-film-transistor (TFT) 633 • Touch screen 634 • Virtual display 634 • Voice activation 630 • WOW display 634

DASH WARNING SYMBOLS

PURPOSE AND FUNCTION All vehicles are equipped with warning lights on the **instrument panel (IP)** and they are often confusing to drivers. Symbols are used instead of words because they are universal in a global vehicle market. The dash warning lights are often called *telltale* lights as they are used to notify the driver of a situation or fault.

NOTE: Not all vehicles use all the symbols. Check the owner's manual or service information for the symbols used on the vehicle being checked.

BULB TEST A **bulb test** is performed when the ignition is first turned on. All of the warning lights come on as part of a self-test, and to help the driver or technician spot any warning light that may be burned out or not operating. Technicians or drivers who are familiar with what lights should light may be able to determine if one or more warning lights are not on when the ignition is first turned on. Most factory scan tools can be used to command all of the warning lights on to help determine if one is not working.

GREEN OR WHITE SYMBOLS Green or white symbols are used to notify the driver that certain functions are working, such as the headlights are on or the turn signals have been activated. None of the green or white symbols need any further action by the driver. The blue symbol is used to indicate the high-beam headlights are on. ● **SEE FIGURE 54–1**.

AMBER SYMBOLS Amber-colored symbols mean that a fault or an issue has occurred that may require attention soon. These can include a warning of low air pressure in a tire, or that the powertrain control module (PCM) has detected a fault in the engine that could affect the exhaust emissions.

While these issues should be addressed, there is no urgency and it is not necessary to stop the vehicle. ● **SEE FIGURE 54–2**.

FREQUENTLY ASKED QUESTION

How to Rest Maintenance Indicators?

In most cases, the maintenance required indicators symbols are used only as a reminder that routine maintenance is needed, such as an oil change. For most vehicles, the resetting procedure is often easily done such as: “Depress the accelerator pedal three times to the floor, in less than 10 seconds.” Then when the ignition is turned off, and the light will go out, resetting the indicator. Check service information the owner's manual or perform an Internet search to find the exact procedure to follow for the vehicle being serviced.

RED WARNING SYMBOLS Red symbols mean that a serious fault has been detected and that immediate attention is required. An example of a serious fault that requires the driver’s attention is the red brake warning light or the oil pressure warning light. Both of these indicate that a fault has been detected and the vehicle should not be driven further until the cause has been found and corrected. ● **SEE FIGURE 54–3**.

STEERING WHEEL CONTROLS

PURPOSE **Steering wheel controls** are steering wheels that include buttons to allow the driver to control certain audio, vehicle information, and HVAC functions. The purpose of having steering wheel controls is to allow the driver to keep their hands on the wheel and their eyes on the road at all times. Steering wheels that have controls are often called *multi-function steering wheels*. ● **SEE FIGURE 54–4**.

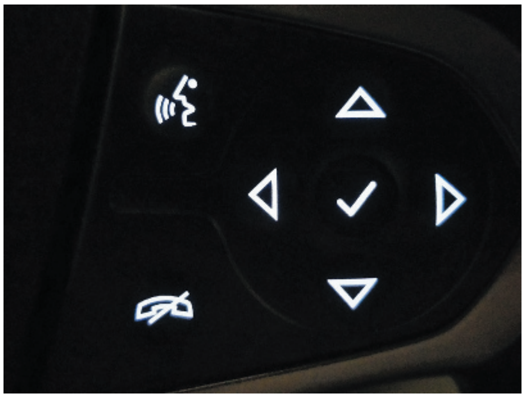

FIGURE 54–4 Steering wheel controls allow the driver to select a function while keeping their hands on the wheel and their eyes on the road.

FUNCTIONS Some of the functions on the steering wheel include the following:

- Radio controls, such as volume up and down and mode selection
- Cruise control
- Telephone answering and calling
- Voice commands

Check service information for the specified tests and procedures to follow if the steering wheel controls do not operate as designed.

VOICE ACTIVATION

PURPOSE Most recent vehicles include *voice commands*, commonly called **voice activation**, that can be used to perform various functions or settings in the vehicle. Most systems include a list of phrases to use to achieve the best results.

FUNCTIONS The typical functions that can be performed using voice commands include the following:

- Phone calls with outgoing or incoming calls usually tied by Bluetooth to a cell phone in the vehicle
- Text messages can be read, and a response sent, using Bluetooth
- Climate-control settings, including desired temperature, in many vehicles
- Select source of audio, such as radio, USB, or satellite
- Navigation system, including destination and points of interest

Check service information for the specified tests and procedures to follow if the voice commands or the controls do not operate as designed.

MAINTENANCE INDICATORS

PURPOSE AND FUNCTION The purpose of the maintenance reminders is to inform the driver that routine maintenance is needed. The message can include what type of maintenance is needed, such as a minor or a major service, but most messages simply state that service is required soon or service is required now. ● **SEE FIGURE 54–5**.

RESET MAINTENANCE INDICATORS To reset the maintenance reminder light or message, check the owner's manual or service information.

ANALOG AND DIGITAL DISPLAYS

TERMINOLOGY Vehicle information is displayed on the **instrument panel cluster (IPC)**:

- An **analog display** uses a needle to show the values, such as engine RPM
- A **digital display** uses numbers to indicate values, such as vehicle speed

Analog electromagnetic dash instruments use small electromagnetic coils that are connected to a sending unit for such things as fuel level, water temperature, and oil pressure. The sensors are the same, regardless of the type of display used. The resistance of the sensor varies with what is being measured.

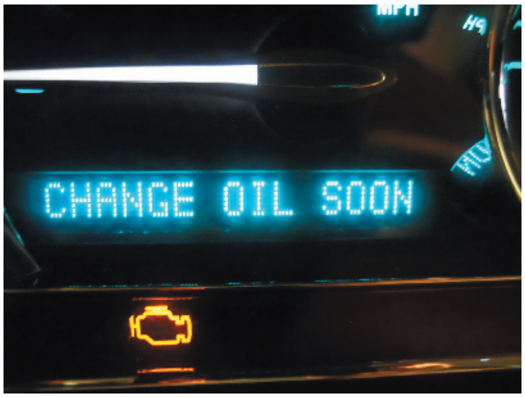

FIGURE 54–5 Maintenance reminders are often messages displayed on the instrument panel informing the driver of needed service, such as the need to change the engine oil.

STEPPER MOTOR ANALOG GAUGES Most analog dash displays use a stepper motor to move the needle. A **stepper motor** is a type of electric motor that is designed to rotate in small steps based on the signal from a computer. This type of gauge is very accurate. A digital output is used to control stepper motors. Stepper motors are direct current motors that move in fixed steps or increments from de-energized (no voltage) to fully energized (full voltage). A stepper motor often has as many as 120 steps of motion.

A typical stepper motor uses a permanent magnet and two electromagnets. Each of the two electromagnetic windings is controlled by the computer. The computer pulses the windings and changes the polarity of the windings to cause the armature of the stepper motor to rotate a degree at a time. Each degree pulse is recorded by the computer as a "count" or "step," which explains the name given to this type of motor. ● **SEE FIGURE 54–6**.

NOTE: Many electronic-gauge clusters are checked when the ignition is first turned on; the dash display needles are commanded to 1/4, 1/2, 3/4, and full positions before returning to their normal readings. This self-test allows the service technician to check the operation of each individual gauge, even though replacing the entire instrument panel cluster is usually necessary to repair an inoperative gauge.

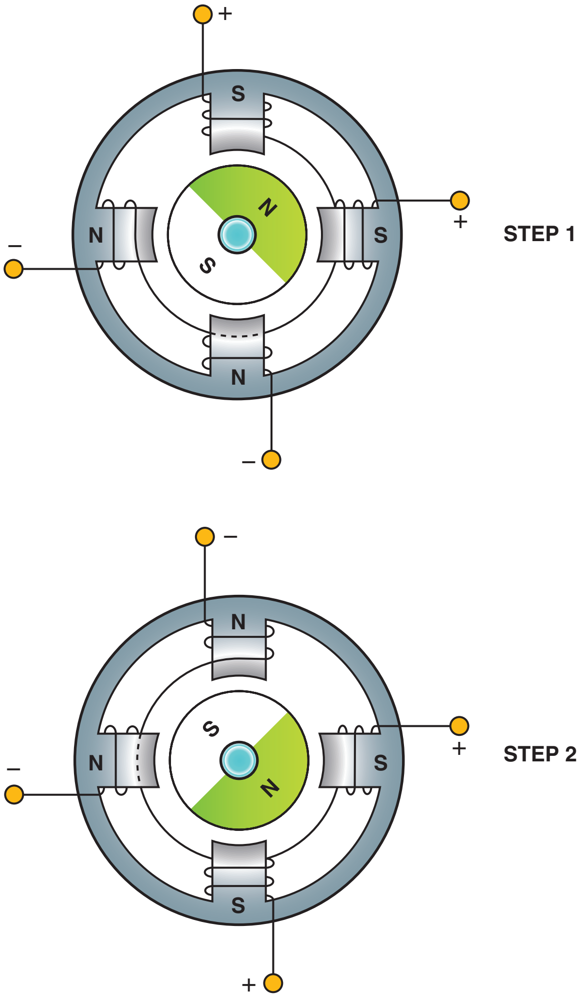

FIGURE 54–6 Most stepper motors use four wires that are pulsed by the computer to rotate the armature in steps.

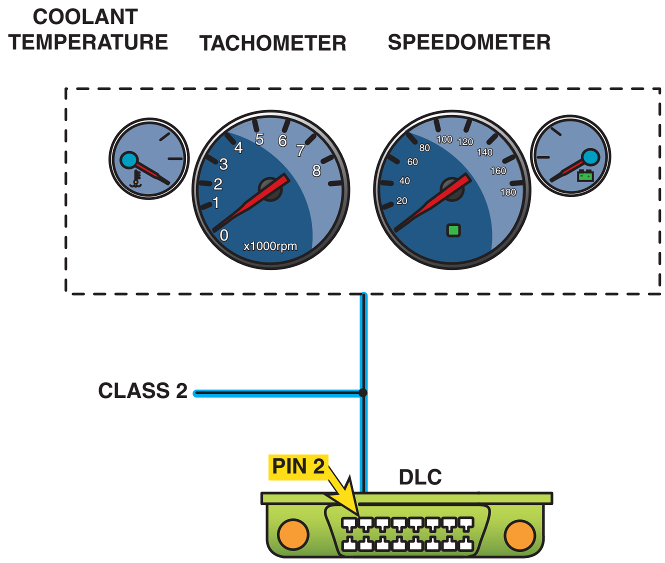

FIGURE 54–7 A typical instrument display uses data from the sensors over serial data lines to the individual gauges.

NETWORK COMMUNICATION Many instrument panels are operated by electronic control units that communicate with the powertrain control module (PCM) for engine data, such as revolutions per minute (RPM) and engine coolant temperature (ECT). The PCM uses the voltage changes from variable-resistance sensors, such as that of the fuel gauge, to determine fuel level. The data is transmitted to the instrument cluster, as well as to the PCM through serial data lines. Because all sensor inputs are interconnected, the technician should always follow the factory recommended diagnostic procedures. ● **SEE FIGURE 54–7**.

HEAD-UP DISPLAY

PURPOSE The **head-up display (HUD)**, also called a *heads-up display*, is a supplemental display that projects the vehicle speed and sometimes other data, such as turn-signal information, onto the windshield. The projected image looks as if it is some distance ahead, making it easy for the driver to see without having to refocus on a closer dash display. ● **SEE FIGURES 54–8 AND 54–9**.

OPERATION On many vehicles, the brightness of the head-up display can be controlled to make it easier for the driver to see the information. The HUD unit is installed in the instrument panel (IP) and uses a mirror to project vehicle information onto the inside surface of the windshield. ● **SEE FIGURE 54–10**.

Follow the vehicle manufacturer's recommended diagnostic and testing procedures if any faults are found with the head-up display.

NIGHT VISION

PURPOSE AND FUNCTION **Night vision** systems use a camera that is capable of observing objects in the dark to assist the driver while driving at night. The primary night-viewing illumination devices are the headlights. The night vision option uses a HUD to improve the vision of the driver beyond the scope of the headlights. Using a HUD allows the driver to keep eyes on

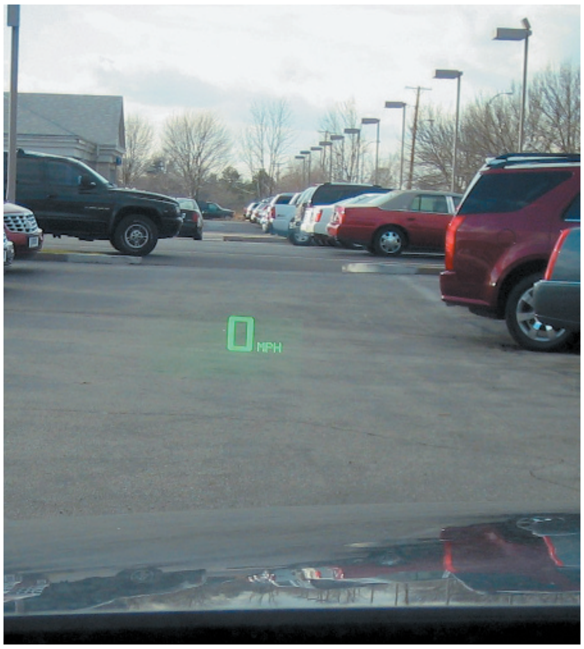

FIGURE 54–8 A typical head-up display showing zero miles per hour, which is actually projected on the windshield from the head-up display in the dash.

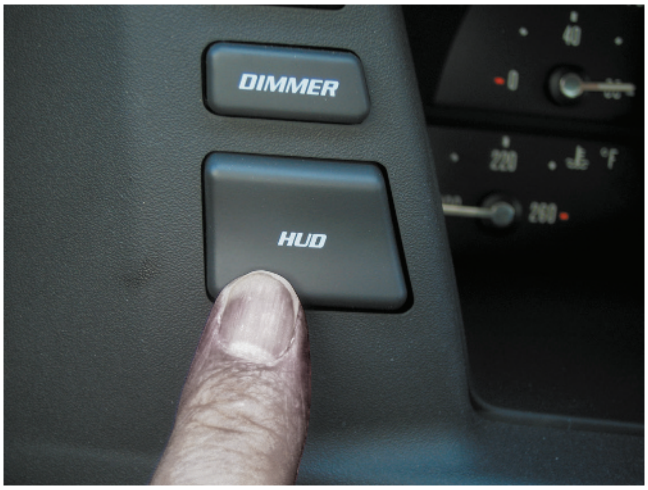

FIGURE 54–9 The dash-mounted control for the head-up display on this Cadillac allows the driver to move the image up and down on the windshield for best viewing.

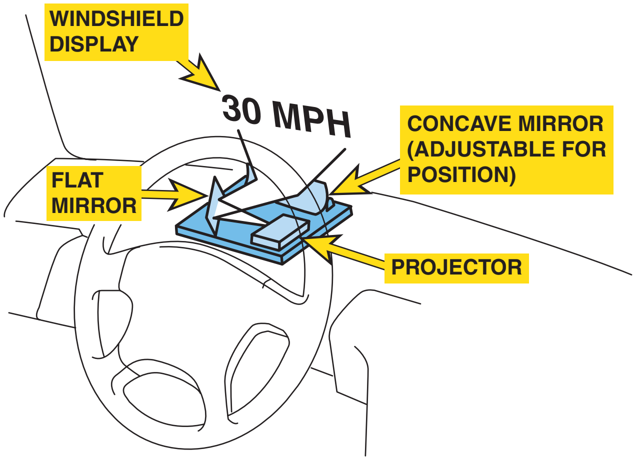

FIGURE 54–10 A typical head-up display (HUD) unit.

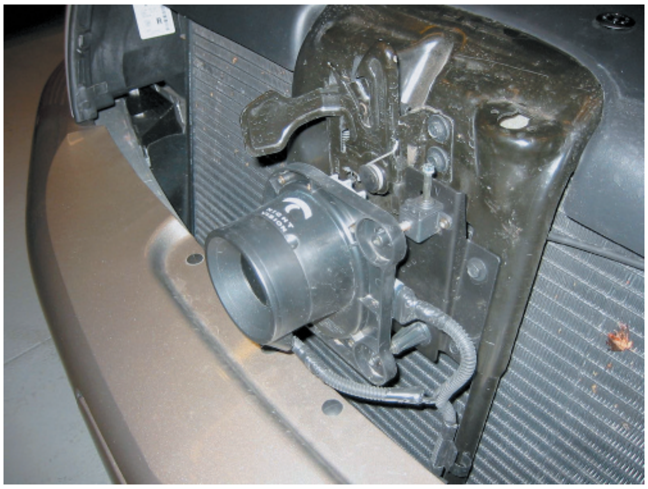

FIGURE 54–11 A night vision camera behind the grille of a Cadillac.

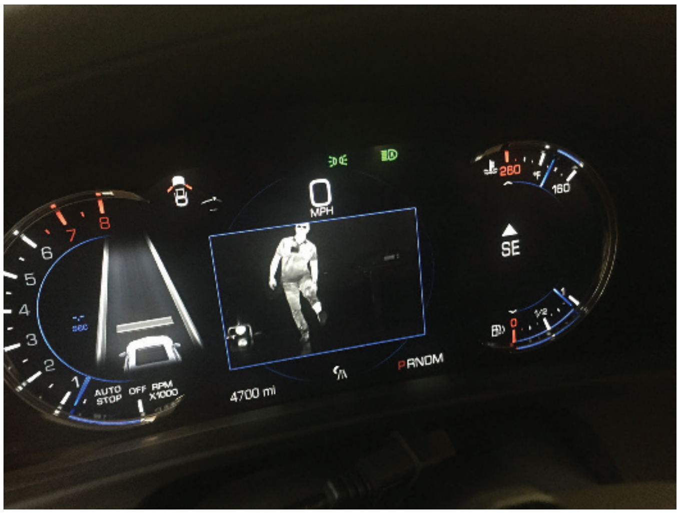

FIGURE 54–12 A view of a person walking in front of a Cadillac equipped with night vision.

the road and hands on the wheel for maximum safety. Besides the HUD, the night vision camera uses a special thermal imaging or infrared technology. The camera is mounted behind the grille in the front of the vehicle. ● **SEE FIGURES 54–11 AND 54–12**.

OPERATION The camera creates pictures based on the heat energy emitted by objects, rather than from light reflected on an object, as in a normal optical camera. The image looks like a black and white photo negative when hot objects (higher thermal energy) appear light or white, and cool objects appear dark or black. Other parts of the night vision system include the following:

- On/off and dimming switch. This allows the driver to adjust the brightness of the display and to turn it on or off, as needed.
- Up/down switch. The night vision HUD system has an electric tilt-adjust motor that allows the driver to adjust the image up or down on the windshield within a certain image.

CAUTION: Becoming accustomed to night vision can be difficult and may take several nights to get used to looking at the HUD.

DIAGNOSIS AND SERVICE The first step when diagnosing a fault with the night vision system is to verify the concern. Check the owner's manual or service information for proper operation. For example, the Cadillac night vision system requires the following actions to function:

1. The ignition has to be in the on (run) position.
2. The Twilight Sentinel photo cell must indicate that it is dark.
3. The headlights must be on.
4. The switch for the night vision system must be on and the brightness adjusted so the image is properly displayed.

Even though the night vision system camera is protected from road debris by a grille, small stones or other debris can get past the grille and damage the lens of the camera. The operation of the night vision can also be affected by an accumulation of heavy ice or snow. If the camera is damaged, it must be replaced as an assembly because no separate parts are available. Always follow the vehicle manufacturer's recommended testing and servicing procedures.

ELECTRONIC DISPLAYS

LIQUID CRYSTAL DISPLAYS A **liquid crystal display (LCD)** can be arranged into a variety of forms, letters, numbers, and bar graph displays.

- LCD construction consists of a special fluid sandwiched between two sheets of polarized glass. The special fluid between the glass plates permit light to pass if a small voltage is applied to the fluid through a conductive film laminated to the glass plates.
- The light from a very bright halogen bulb behind the LCD shines through those segments of the LCD that have been polarized to let the light through, which then show numbers or letters.
- **Thin-film-transistor (TFT)** LCD is a type of a LCD that uses TFT technology. This type of display has enhanced image qualities and contrast compared to simple light-driven LCDs.
- LCD displays can be used to present data in the form of numbers, text messages, or graphical gauges. The high-resolution screen can be programmed to show several functions, such as navigation, radio and media, as well as Google Earth 3-D graphics, and traffic data. This is in addition to the usual functions of showing speed, engine revolutions, outside temperature, and fuel level.

CAUTION: When cleaning an LCD, be careful not to push on the glass plate covering the special fluid. If excessive pressure is exerted on the glass, the display may be permanently distorted. If the glass breaks, the fluid escapes and could damage other components in the vehicle, due to its strong alkaline nature. Use only a soft, damp cloth to clean these displays.

- The major disadvantage of an LCD digital dash is that the numbers or letters are slow to react or change at low temperatures. ● **SEE FIGURE 54–13**.

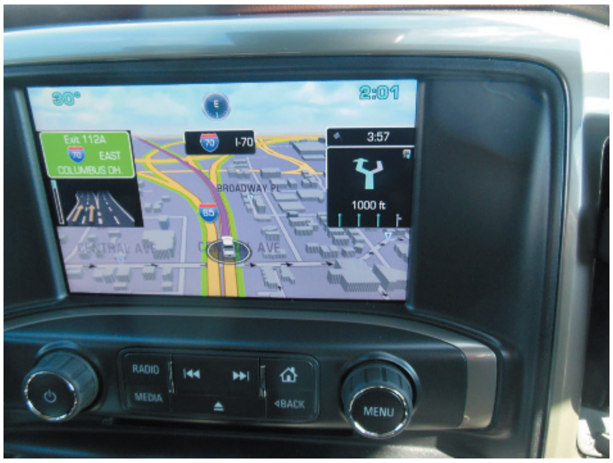

FIGURE 54–13 A typical LCD navigation system display.

FREQUENTLY ASKED QUESTION

What Is the WOW Display?

When a vehicle equipped with a digital dash is started, all segments of the electronic display are turned on at full brilliance for 1 or 2 seconds. This is commonly called the **WOW display** and is used to show off the brilliance of the display. If numbers are part of the display, the number 8 is shown, because this number uses all segments of a number display. Technicians can also use the WOW display to determine if all segments of the electronic display are functioning correctly.

VIRTUAL DISPLAY

PURPOSE AND FUNCTION A **virtual display** is a dash that allows the driver to select what data is being displayed. Many vehicles are equipped with an LCD dash display that can be changed to display various functions based on the driver's preference. This allows the dash display to be totally customized to what the driver wishes to see displayed. For example, a typical display can show any four of the following:

- Coolant temperature
- Voltmeter
- Oil pressure
- Vehicle speed (speedometer)
- Engine speed (tachometer)
- Automatic transmission fluid temperature
- Tire pressures for all four tires

OPERATION The dash display is all that is really different because all the data comes to the IPC on the data bus. The only difference is that the display can be changed to meet the needs of the driver. For example, if a driver is towing a trailer, displaying the automatic transmission fluid temperature is very helpful so that overheating of the transmission is avoided. ● **SEE FIGURE 54–14**.

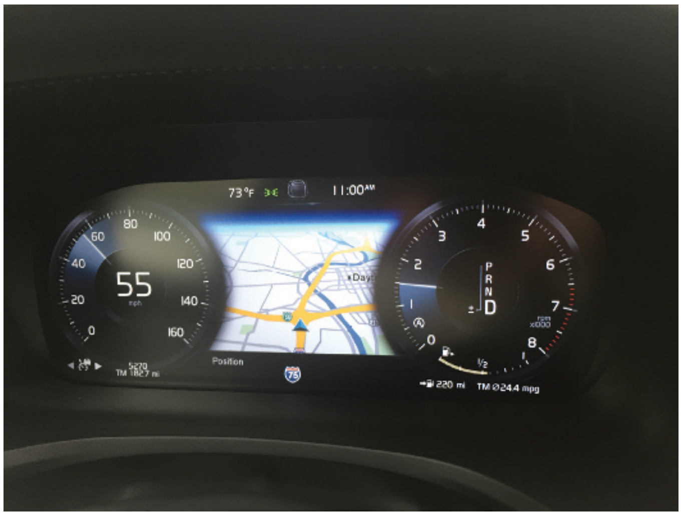

FIGURE 54–14 A virtual dash on this Volvo is able to display a speedometer (left) in both analog (needle-type) and digital (number) as well as a tachometer on the right. In the center of the display, this virtual dash is displaying the navigation screen. What is displayed can be changed by the driver to match what is important to them.

TOUCH SCREENS

PURPOSE A **touch screen** is a dash display, usually LCD, that allows the driver or passenger to use a finger to perform functions that are displayed on the screen.

OPERATION A capacitive touchscreen panel consists of an insulator, such as glass, coated with a transparent conductor, such as indium tin oxide (ITO). Because the human body is also an electrical conductor, touching the surface of the screen results in a distortion of the screen's electrostatic field. The location is then sent to the controller for processing. Placing a finger near the electric fields adds conductive surface area to the capacitive system. This is measurable as a change in capacitance. The capacitance can be changed and measured at every individual point on the grid (intersection). ● **SEE FIGURE 54–15**.

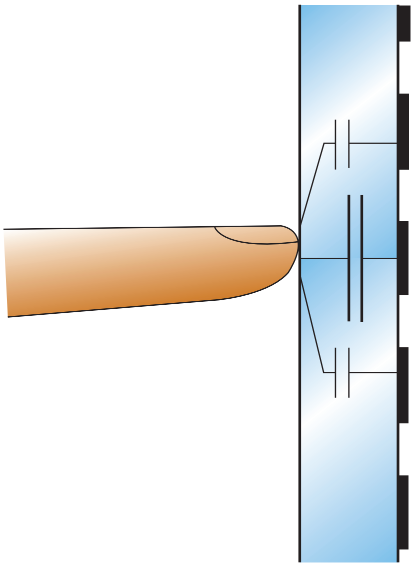

FIGURE 54–15 Schematic of a capacitive touchscreen.

TECH TIP

Touch Screen Tip

Most vehicle navigation systems use a touch screen for use by the driver (or passenger) to input information or other on-screen prompts. Most touch screens use a change in capacitance at the surface of the screen to determine when and where some action is being performed. Do not push harder on the display if the unit does not respond, or the display unit may be damaged. If no response is detected when lightly touching the screen, rotate the finger to cause the capacitance area to increase so it can be easily detected.

TOUCH SCREEN FEEDBACK Many touch screens include feedback to the user by either using a beep or a small vibration when the screen is touched. This is called *haptic* response system and helps improve the user experience by giving immediate feedback.

SPEEDOMETERS/ODOMETERS

OPERATION Dash displays use an electric vehicle speed sensor on the output of the transmission or from the input from the wheel speed sensors (WSS). Some vehicles use the ABS wheel speed sensors to get vehicle speed, rather than a dedicated vehicle speed sensor. Many speed sensors contain a permanent magnet and generate a voltage in proportion to the vehicle speed. These speed sensors are commonly called permanent magnet (PM) generators. ● **SEE FIGURE 54–16**.

The output of a PM generator speed sensor is an AC voltage that varies in frequency and amplitude with increasing vehicle speed. The PM generator speed signal is sent to the instrument cluster electronic circuits. These specialized electronic circuits include a buffer amplifier circuit that converts the variable sine wave voltage from the speed sensor to an on/off signal that can be used by other electronic circuits to indicate a vehicle's speed. The vehicle speed is then displayed by either an electronic needle-type speedometer or by numbers on a digital display.

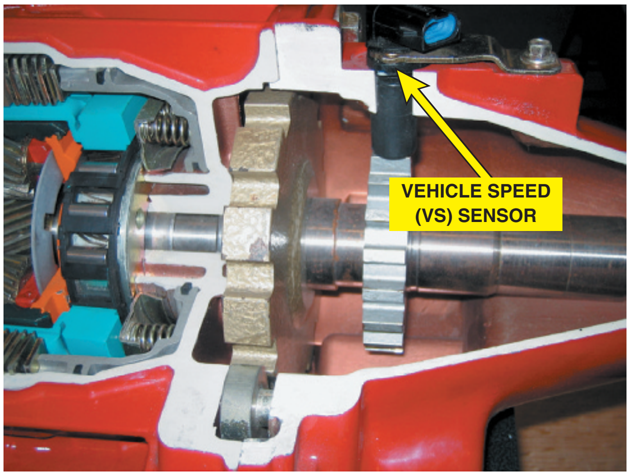

FIGURE 54–16 A vehicle speed sensor located in the extension housing of the transmission. Some vehicles use the wheel speed sensors for vehicle speed information.

ODOMETERS An odometer is a dash display that indicates the total miles traveled by the vehicle. Electronic dash displays can use either an electrically driven mechanical odometer or a digital display odometer to indicate miles traveled. On mechanical-type odometers, a small electric motor, called a stepper motor, is used to turn the number wheels of a mechanical-style odometer. A pulsed voltage is fed to this stepper motor, which moves in relation to the miles traveled. ● **SEE FIGURE 54–17**.

Digital odometers use LED, LCD, or VTF displays to indicate miles traveled in the instrument cluster. Because total miles must be retained when the ignition is turned off or the battery is disconnected, a special electronic chip must be used that retains the miles traveled. These special chips are called **nonvolatile random access memory (NVRAM)**. *Nonvolatile* means that the information stored in the electronic chip is not lost when electrical power is removed. Some vehicles use a chip called electronically erasable programmable read-only memory (**EEPROM**). Most digital odometers can read up to 999,999.9 miles or kilometers (km), and then the display indicates error. If the chip is damaged or exposed to static electricity, it may fail to operate and "error" may appear.

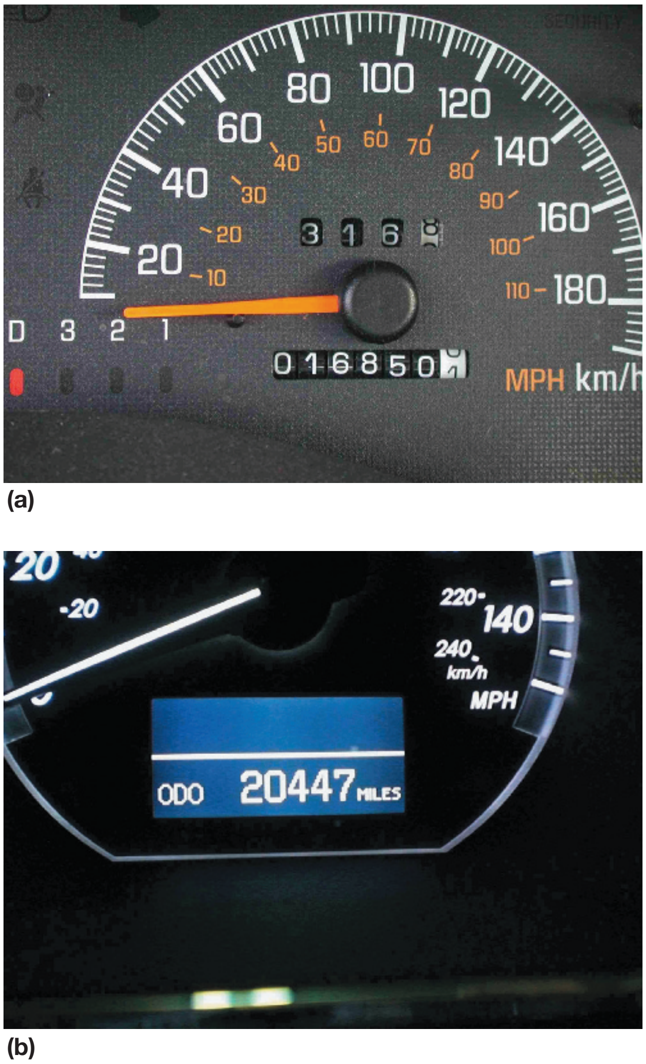

FIGURE 54–17 (a) Some odometers are mechanical and are operated by a stepper motor. (b) Many vehicles are equipped with an electronic odometer.

TECH TIP

Keep the Same Overall Tire Diameter

Whenever larger (or smaller) wheels or tires are installed, the speedometer and odometer calibration are thrown off. This can be summarized as follows:

- **Larger diameter tires.** The speed showing on the speedometer is slower than the actual speed.

  The odometer reading shows fewer miles than actual.
- **Smaller diameter tires.** The speed showing on the speedometer is faster than the actual speed. The odometer reading shows more miles than actual.

  To avoid speedometer and odometer issues, select a wheel/tire combination that has the same outside diameter (OD) of the original wheel/tire combination. Many newer vehicles can use the scan tool to change the tire size (from a select group of sizes) to minimize the effects of tires size change on odometer and speedometer readings.

  To determine the exact effects of a replacement size wheel or tire, perform an Internet search for a tire size comparison chart.

CASE STUDY

The Speedometer Works as if It Is a Tachometer

The owner of a Ford F-150 pickup truck complained that all of a sudden the speedometer needle went up and down with engine speed, rather than vehicle speed. In fact, the speedometer needle went up and down with engine speed, even though the gear selector was in "park" and the vehicle was not moving. After hours of troubleshooting, the service technician went back and started checking the basics and discovered that the alternator had a bad diode. The technician measured over 1 volt AC and over 10 ampere AC ripple current using a clamp-on AC/DC ammeter. Replacing the alternator restored the proper operation of the speedometer.

Summary:

Complaint—Customer stated that the speedometer moves in relation to engine speed and not vehicle speed.
Cause—Tests confirmed that the alternator was producing excessive AC voltage due to a bad diode.
Correction—Replacing the alternator restored proper operation of the speedometer.

SPEEDOMETER/ODOMETER SERVICE If the speedometer and odometer fail to operate, check the following:

- Use a scan tool and monitor the vehicle speed as displayed on the scan tool. If the speed is zero, then check the output from the vehicle speed sensor. With the vehicle safely raised off the ground and supported so the drive wheels rotate, check the vehicle speed using a scan tool.
- If a scan tool is not available, disconnect the wires from the speed sensor near the output shaft of the transmission. Connect a multimeter set on AC volts to the terminals of the speed sensor, and rotate the drive wheels with the transmission in neutral. A good speed sensor should indicate approximately 2 volt AC if the drive wheels are rotated by hand.
- If the speed sensor is working, check the wiring from the speed sensor to the dash cluster. If the wiring is good, the instrument panel (IP) should be sent to a specialized repair facility.
- If the speedometer operates correctly, but the mechanical odometer does not work, the odometer stepper motor, the number wheel assembly, or the circuit controlling the stepper motor is defective. If the digital odometer does not operate, but the speedometer operates correctly, the dash cluster must be removed and sent to a specialized repair facility.

DASH GAUGES

FUEL LEVEL Fuel level gauges use a fuel tank sending unit that consists of a float attached to a variable resistor. When the fuel level changes, the resistance of the fuel level sending unit also changes. As the resistance of the tank unit changes, the dash-mounted gauge also changes to show the level of the fuel in the tank.

OIL PRESSURE The oil pressure lamp operates through use of an oil pressure sending unit, which is a switch screwed into the engine block, and grounds the electrical circuit. It lights the dash warning lamp in the event of low oil pressure, that is, 3 to 7 PSI (20 to 50 kPa). Normal oil pressure is generally between 10 and 60 PSI (70 and 400 kPa). Some vehicles are equipped with variable-voltage oil pressure sensors rather than a simple pressure switch. ● **SEE FIGURE 54–18**.

To test the operation of the oil pressure warning circuit, unplug the wire from the oil pressure sending unit, usually located

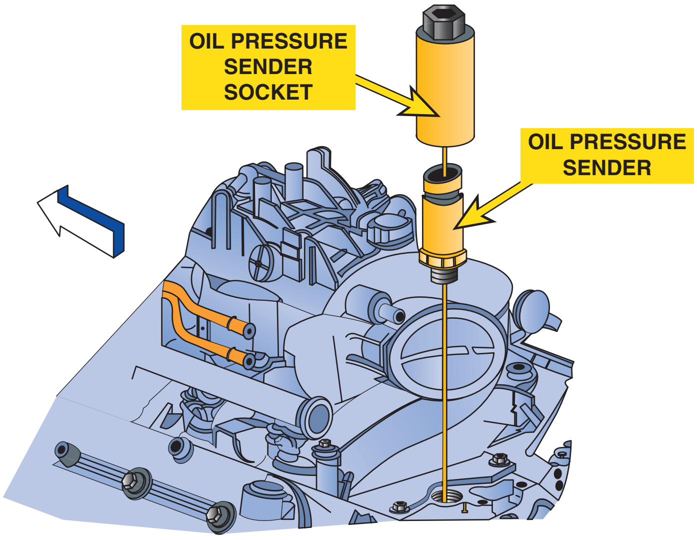

FIGURE 54–18 A sending unit socket being used to remove an oil pressure sender unit.

CASE STUDY

Electronic Devices Cannot Swim

The owner of a Dodge minivan complained that after the vehicle was cleaned inside and outside, the temperature gauge, fuel gauge, and speedometer stopped working. The vehicle speed sensor was checked and found to be supplying a square wave signal that changed with vehicle speed. A scan tool indicated a speed, yet the speedometer displayed zero all the time. Finally, the service technician checked the body control module (BCM) to the right of the accelerator pedal and noticed that it had been wet, from the interior cleaning. Drying the BCM did not fix the problem, but a replacement BCM fixed all the problems. The owner discovered that electronic devices do not like water and that computers cannot swim.

Summary:

Complaint—Customer complained that many gauges stopped working after the vehicle was cleaned.
Cause—The body control module (BCM) was found to be wet from interior cleaning.
Correction—Replacing the BCM fixed all the problems.

FREQUENTLY ASKED QUESTION

What Does the Arrow Mean?

Many fuel gauges have an arrow next the symbol of a fuel pump. The arrow points to the side where the fill cap is located. This is very helpful if using a rental vehicle as it indicates which side to pull up to a filling station pump. ● **SEE FIGURE 54–19**.

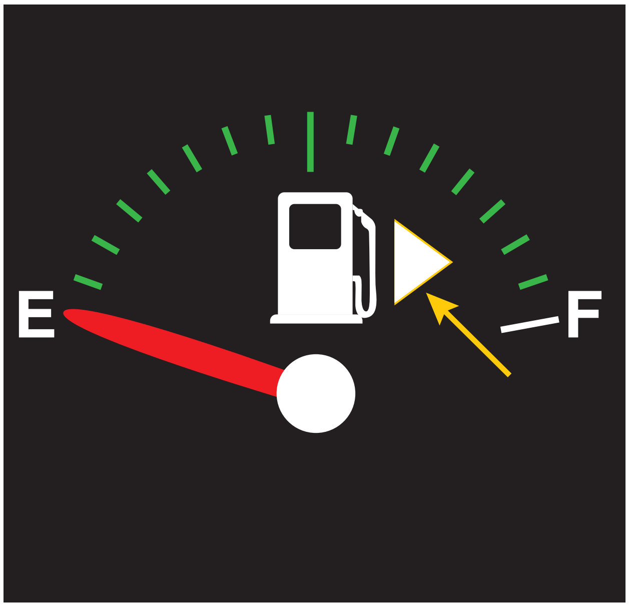

FIGURE 54–19 The arrow next to the fuel pump symbol shows which side of the vehicle the fuel cap is located.

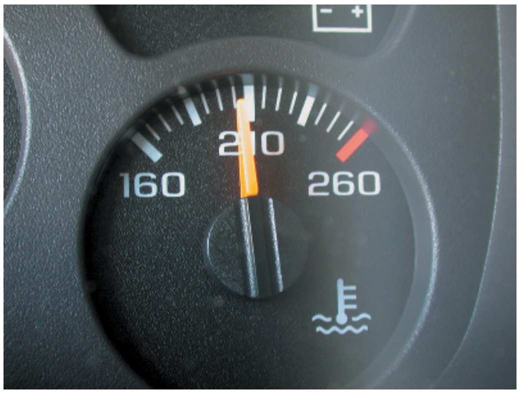

FIGURE 54–20 A temperature gauge showing normal operating temperature between 180°F and 215°F, depending on the specific vehicle and engine.

near the oil filter, with the ignition switch on. With the wire disconnected from the sending unit, the warning lamp should be off. If the wire is touched to a ground, the warning lamp should be on. If there is *any* doubt of the operation of the oil pressure warning lamp, always check the actual engine oil pressure, using a mechanical gauge that can be screwed into the opening that is left after unscrewing the oil pressure sending unit. For removing the sending unit, special sockets are available at most auto parts stores, or a 1 inch or 1 1/16 inch 6-point socket may be used for most sending units.

COOLANT TEMPERATURE The "hot" lamp, or engine coolant overheat warning lamp, warns the driver whenever the engine coolant temperature is between 248°F and 258°F (120°C and 126°C). Most vehicles use the engine coolant temperature (ECT) sensor for engine temperature gauge operation. To test this sensor, use a scan tool to verify proper engine temperature and follow the vehicle manufacturer's recommended testing procedures. ● **SEE FIGURE 54–20**.

DASH INSTRUMENT DIAGNOSIS If one or more electronic dash gauges do not work correctly, first perform a bulb check. The electronic dash instruments can be tested using the following procedure:

1. Use a factory or factory-level scan tool to check for any "B" (body) or "C" (chassis) diagnostic trouble codes (DTCs) that may be set and stored. If a DTC is stored, follow the service information instructions to find the root cause.
2. Use the bidirectional control features on the scan tool to actuate the dash display to see if they function. If not, the replacement of the entire IPC may be required.

Always follow the specified testing and diagnostic procedures found in service information for the vehicle being tested.

NAVIGATION AND GPS

PURPOSE AND FUNCTION The **global positioning system (GPS)** uses 24 satellites in orbit around the earth to provide signals for navigation devices. GPS is funded and controlled by the U.S. Department of Defense (DOD). While the system can be used by anyone with a GPS receiver, it was designed for and is operated by the U.S. military. ● **SEE FIGURE 54–21**.

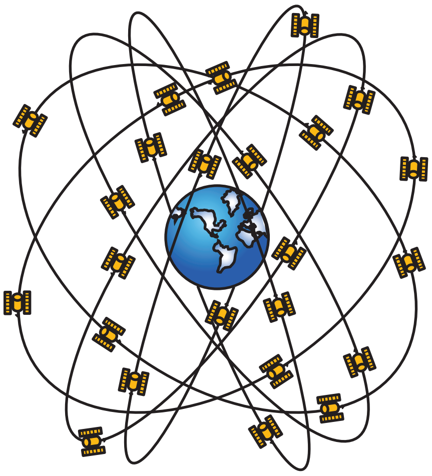

FIGURE 54–21 Global positioning systems use 24 satellites in high earth orbit whose signals are picked up by navigation systems. The navigation system computer then calculates the location based on the position of the satellite overhead.

NAVIGATION SYSTEM PARTS AND OPERATION Navigation systems use the GPS satellites for basic location information. The navigation controller uses other sensors, including a digitized map to display the location of the vehicle.

- **GPS satellite signals.** Signals from at least three satellites are needed to locate the vehicle.
- **Yaw sensor.** This sensor is often used inside the navigation unit to detect movement of the vehicle during cornering. This sensor is also called a *"g" sensor* because it measures force; 1 g is the force of gravity.
- **Vehicle speed sensor.** A yaw sensor is a device, usually a chip that measures the movement of a vehicle around its vertical axis. This sensor input is used by the navigation controller to determine the speed and distance the vehicle travels. This information is compiled and compared to the digital map and GPS satellite inputs to locate the vehicle.
- **Audio output/input.** Voice-activated factory units use a built-in microphone at the center top of the windshield and the audio speakers speech output.

Navigation systems include the following components:

1. Screen display ● **SEE FIGURE 54–22**.
2. GPS antenna
3. Navigation control unit, usually with map information on a DVD or memory card.

The memory card includes street names and the following information:

1. Points of interest (POI), including automated teller machines (ATMs), restaurants, schools, colleges, museums, shopping mall, and airports, as well as vehicle dealer locations.
2. Business addresses and telephone numbers, including hotels and restaurants. (If the telephone number is listed in the business telephone book, it can usually be displayed on the navigation screen. If the telephone number of the business is known, the location can be displayed.)

NOTE: Private residences or cellular telephone numbers are not included in the database of telephone numbers stored on the navigation system memory card.

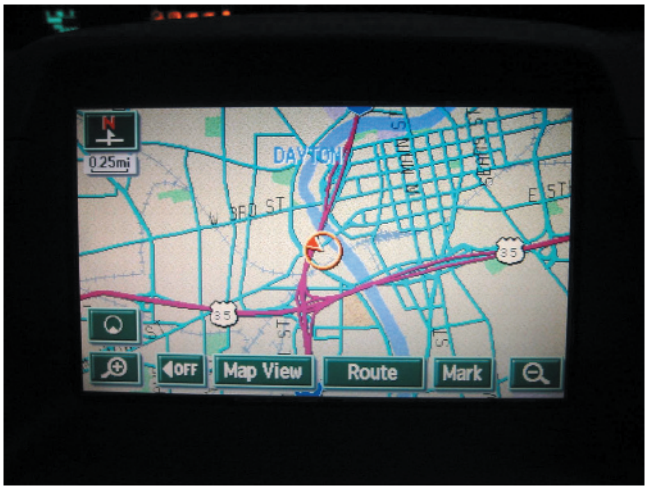

FIGURE 54–22 A typical GPS display screen showing the location of the vehicle.

FREQUENTLY ASKED QUESTION

What Is Navigation-Enhanced Climate Control?

Some vehicles use data from the navigation system to help control the automatic climate control system. Data about the location of the vehicle includes

- Time and date. This information allows the automatic climate control system to determine where the sun is located.
- Direction of travel. The navigation system can also help the climate control system determine the direction of travel.

As a result of the input from the navigation system, the automatic climate control system can control cabin temperature, in addition to various other sensors in the vehicle. For example, if the vehicle is traveling south in the late afternoon in July, the climate control system could assume that the passenger side of the vehicle is warmed more by the sun than the driver's side, and could increase the airflow to the passenger side to help compensate for the additional solar heating.

3. Turn-by-turn directions to addresses that are selected by:
    - Points of interest (POI)
    - Typed in using a keyboard shown on the display

The navigation unit then often allows the user to select the fastest way to the destination, as well as the shortest way, or assists in how to avoid toll roads. ● **SEE FIGURE 54–23**.

DIAGNOSIS AND SERVICE For the correct functioning of the navigation system, three inputs are needed:

- Location
- Direction
- Speed

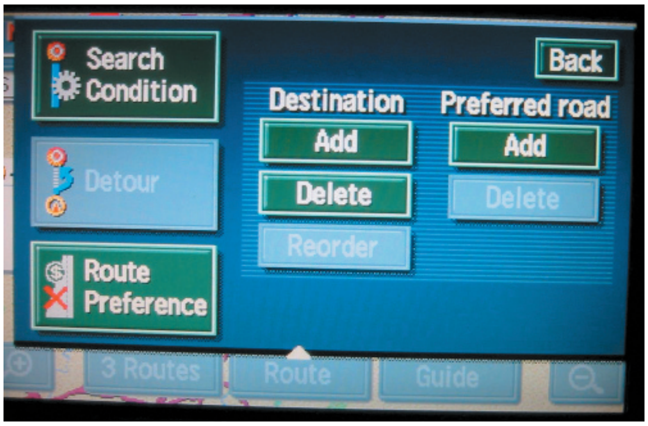

FIGURE 54–23 A typical navigation display showing various options. Some systems do not allow access to these if the vehicle is in gear and/or moving.

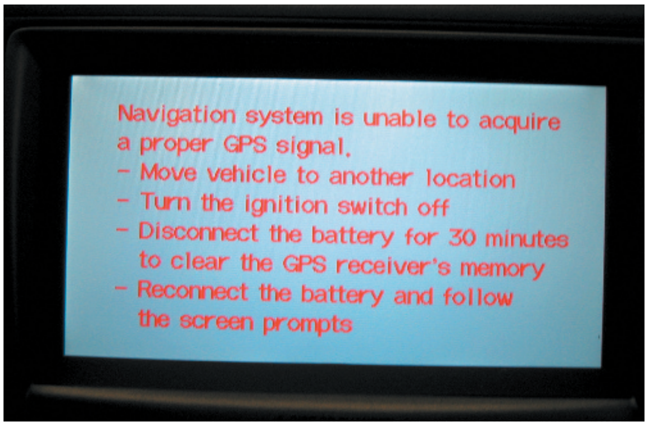
The navigation system uses the GPS satellite and map data to determine a location. Direction and speed are determined by the navigation computer from inputs from the satellite, plus the yaw sensor and vehicle speed sensor. The following symptoms may occur and be a customer complaint. Knowing how the system malfunctions helps to determine the most likely cause:

- If the vehicle symbol jumps down the road, a fault with the vehicle speed (VS) sensor input is usually indicated.
- If the symbol rotates on the screen, but the vehicle is not being driven in circles, a fault with the yaw sensor or yaw sensor input to the navigation controller is likely.
- If the symbol goes off course and shows the vehicle on a road that it is not on, a fault with the GPS antenna is the most common reason.
- Most factory-installed navigation systems use a GPS antenna inside the rear back glass or under the rear package shelf. If a metalized window tint is applied to the rear glass, the signal strength from the GPS satellites can be reduced. If the customer concern includes inaccurate or nonfunctioning navigation, check for window tint.

Sometimes the navigation system itself displays a warning that views from the satellite are not being received. Always follow the displayed instructions. ● **SEE FIGURE 54–24**.



Navigation system is unable to acquire a proper GPS signal.
- Move vehicle to another location
- Turn the ignition switch off
- Disconnect the battery for 30 minutes to clear the GPS receiver's memory
- Reconnect the battery and follow the screen prompts

FIGURE 54–24 A screen display of a navigation system that is unable to acquire usable signals from GPS satellites.

TELEMATICS

WHAT IS TELEMATICS?

Telematics is an interconnected system that combines telecommunications (cellular systems) and GPS navigation satellite system technology. Telematics is a method of monitoring a vehicle by combining a GPS system with on-board diagnostic systems. It is possible to record and map exactly where a vehicle is located and how fast it's traveling.

A typical telematics system includes

- Telecommunications, such as cell phone communication
- Vehicle technologies, such as self-diagnostics
- Electrical sensors, instrumentation, wireless communications
- Multimedia and Internet

Telematics, such as **OnStar**, can be a manufacturer-installed system or an aftermarket-installed system. The systems offer a variety of features, including the following:

1. **Vehicle tracking**—Used by the GPS, an onboard telematics system can track the vehicle location.
2. **User-based Insurance (UBI)**—Insurance companies want to control their cost, so many offer a discount if the vehicle owner allows a tracking device to be installed on their vehicle. This unit usually plugs into the data link connector (DLC) under the dash for its power and ground, as well as some of the data that is available on the data stream, such as throttle position and vehicle speed.

NOTE: This type of add-on tracking devices are sometimes responsible for some false diagnostic trouble codes. The devices should be removed when diagnosing any suspected vehicle network faults.

3. **Security Services**—Services, such as vehicle-collision notification and emergency services, are the core telematics features found on all systems. When an airbag deploys or other sensors are triggered, the vehicle-collision notification sends an alert to a telematics command center. An operator then contacts the vehicle's occupants through the telematics system's built-in cellular modem to assess the situation. Once the occupants confirm there's been an accident—or if the operator doesn't get a response—the command center dispatches emergency-response personnel. A telematics system also pinpoints the vehicle's location using GPS.
4. **Convenience Services**—Telematics systems offer various convenience features to help vehicle owners out of a nonemergency jam, or just make their lives easier. The system can remotely unlock a car's door after you've accidentally left the keys inside, for example. A telematics system can also flash a car's lights and sound the horn in a crowded parking lot to help you find it.

TELEMATICS SYSTEMS

There are many brand names for what is considered to be a telematics system, including

- Acura Link
- Audi Connect
- Blue Link (Hyundai)
- BMW Assist
- Care Track (Volvo)
- Car-Net (VW)

- CUE (Cadillac)
- Honda Link
- InControl (Jaguar)
- IntelliLink (Buick and GMC)
- Lexus Enform
- Mbrace (Mercedes)
- OnStar (Chevrolet and others)
- Porsche Car Connect
- Starlink (Subaru)
- Sync (Ford)
- T Connect (Toyota)
- UVO (Kia)

PARTS AND OPERATION One example of a telematics system is OnStar. OnStar was first introduced in 1996 as an option on some Cadillac models. This is a system that includes the following functions:

1. Cellular telephone
2. Global positioning antenna and computer

The cellular telephone is used to communicate with the driver from advisors at service centers. The advisor at the service center is able to see the location of the vehicle as transmitted from the GPS antenna and computer system in the vehicle on a display.

OnStar does not display the location of the vehicle to the driver unless the vehicle is also equipped with a navigation system. Unlike most navigation systems, the OnStar system requires a monthly fee. The driver interface unit is a group of three buttons mounted on the inside rearview mirror and a hands-free cellular telephone. ● **SEE FIGURE 54–25**.

The OnStar system includes the following features, which can vary, depending on the level of service desired and cost per month:

- **Automatic notification of airbag deployment.** If the airbag is deployed, the advisor is notified immediately and attempts to call the vehicle. If there is no reply or if the occupants report an emergency, the advisor contacts emergency services and gives them the location of the vehicle.
- **Emergency services.** If the red button is pushed, OnStar immediately locates the vehicle and contacts the nearest emergency service agency.
- **Stolen vehicle location assistance.** If a vehicle is reported stolen, a call-center advisor can track the vehicle.
- **Remote door unlock.** An OnStar advisor can send a cellular telephone message to the vehicle to unlock the vehicle, if needed.
- **Roadside assistance.** When called, an OnStar advisor can locate a towing company or locate a provider who can bring gasoline or change a flat tire.
- **Accident assistance.** An OnStar advisor is able to help with the best way to handle an accident. The advisor can supply a step-by-step checklist of the things that should be done, plus call the insurance company, if desired.
- **Remote horn and lights.** The OnStar system is tied into the lights and horn circuits, so an advisor can activate them, if requested, to help the owner locate the vehicle in a parking lot or garage.
- **Vehicle diagnosis.** Because the OnStar system is tied to the PCM, an OnStar advisor can help with diagnosis if there is a fault detected. The system works as follows:
    - The malfunction indicator light (MIL) (check engine) comes on to warn the driver that a fault has been detected. The driver can depress the OnStar button to talk to an advisor and ask for a diagnosis.
    - The OnStar advisor sends a signal to the vehicle requesting the status from the powertrain control module, as well as the controller for the antilock brakes and the airbag module.
    - The vehicle then sends any diagnostic trouble codes (DTCs) to the advisor. The advisor can then inform the driver about the importance of the problem and give advice as to how to resolve the problem.

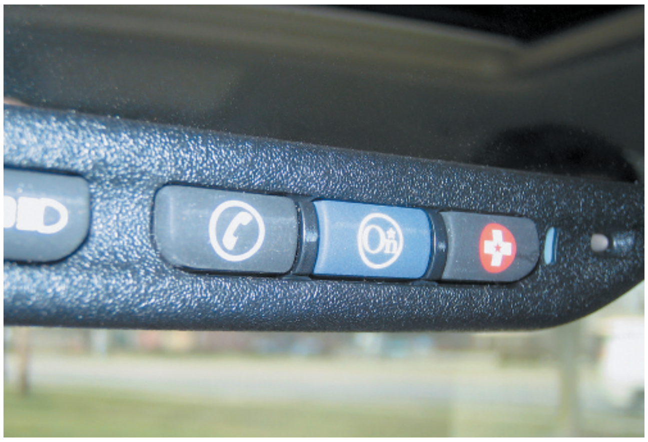


FIGURE 54–25 The three-button OnStar control is located on the inside rearview mirror. The left button (telephone handset icon) is pushed if a hands-free cellular call is to be made. The center button is depressed to contact an OnStar advisor and the right emergency button is used to request that help be sent to the vehicle's location.

DIAGNOSIS AND SERVICE The OnStar system can fail to meet the needs of the customer if any of the following conditions occur:

1. Lack of cellular telephone service in the area
2. Poor global positioning system (GPS) signals, which can prevent an OnStar advisor from determining the position of the vehicle
3. Transport of the vehicle by truck or ferry so that it is out of contact with the GPS satellite for an advisor to properly track the vehicle

If all of the above are normal and the problem still exists, follow service information diagnostic and repair procedures. If a new vehicle communication interface module (VCIM) is installed in the vehicle, the electronic serial number (ESN) must be tied to the vehicle. Check service information instructions for the exact procedures to follow.

BACKUP CAMERA

PARTS AND OPERATION

A **backup camera** is used to display the area at the rear of the vehicle in a screen display on the dash, or in the inside rear-view mirror when the gear selector is placed in reverse. Backup cameras are also called:

- *Reversing cameras*
- *Rearview cameras*

Backup cameras are different from normal cameras because the image displayed on the dash is flipped, so it is a mirror image of the scene at the rear of the vehicle. This reversing of the image is needed because the driver and the camera are facing in opposite directions. Backup cameras were first used in large vehicles with limited rearward visibility, such as motor homes. Many vehicles equipped with navigation systems today include a backup camera for added safety while reversing. ● **SEE FIGURE 54–26**.

The backup camera contains a wide-angle or fisheye lens to give the largest viewing area. Most backup cameras are pointed downward so that objects on the ground, as well as walls, are displayed. ● **SEE FIGURE 54–27**.

REAR CAMERA IMAGE ISSUES

The quality of the image projected on the display may be not be clear if any of the following conditions occur:

- Dark conditions
- Damage to the rear camera or the rear of the vehicle, affecting the aiming of the camera
- Dirt, mud, ice, or snow blocking the camera view
- Excessive high or low temperature that could affect the camera or lens
- Glare caused by the sun or a nearby bright light source, such as headlights of another vehicle

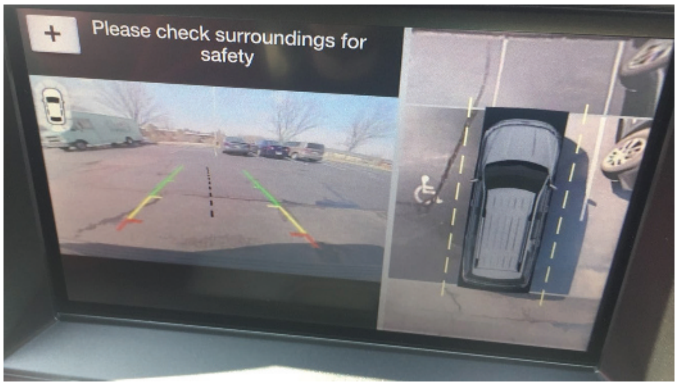

FIGURE 54–26 A dash display on a Ford F-150 pickup truck showing the backup camera image on the left side of the screen and a bird's eye view on the right side showing the vehicle next to the truck on the right and the handicap parking stop on the left. The bird's eye view is created by combining the images from the front, side mirror, and rear cameras together to create the virtual image.

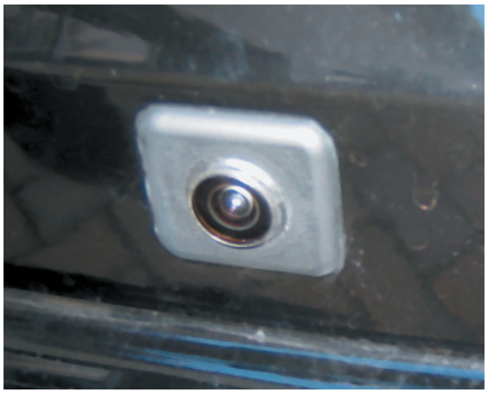

FIGURE 54–27 A typical fisheye-type backup camera usually located near the center on the rear of the vehicle near the license plate.

DIAGNOSIS AND SERVICE

Faults in the backup camera system can be related to the camera itself, the display, or the connecting wiring. The main input to the display unit comes from the transmission range switch, which signals the backup camera when the transmission is shifted into reverse.

To check the transmission range switch, perform the following:

1. Check if the backup (reverse) lights function when the gear selector is placed in reverse with the key on, engine off (KOEO).
2. Check that the transmission/transaxle is fully engaged in reverse when the selector is placed in reverse.

Most of the other diagnosis involves visual inspection:

1. Check the backup camera for damage.
2. Check the screen display for proper operation.
3. Check that the wiring from the rear camera to the body is not cut or damaged.
4. Always follow the vehicle manufacturer's recommended diagnosis and repair procedures.

REVIEW QUESTIONS

1. How does a stepper motor analog dash gauge work?
2. What do the colors of the dash symbols mean?
3. Night vision is used to detect what type of objects?
4. What is meant by the term telematics?
5. How does a navigation system determine the location of the vehicle?

CHAPTER QUIZ

1. Which color symbol requires immediate attention by the driver?
   - **a.** Red
   - **b.** Amber
   - **c.** Green
   - **d.** White
2. Technician A says that LCDs may be slow to work at low temperatures. Technician B says that an LCD dash display can be damaged if pressure is exerted on the front of the display during cleaning. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
3. Technician A says that metal-type tinting can affect the navigation system. Technician B says most telematic systems require a monthly payment for full use of their system. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
4. Technician A says that the data displayed on the dash can or in the windshield (head up display) can come from the powertrain control module (PCM). Technician B says that a virtual display can be set to show what the driver wishes to see displayed.
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
5. Which of the following is NOT included on a vehicle using a steering wheel control system?
   - **a.** Power window control
   - **b.** Cruise control
   - **c.** Radio controls
   - **d.** HVAC functions
6. What is the minimum oil pressure required to keep the oil pressure warning light turned OFF?
   - **a.** 10 PSI (70 kPa)
   - **b.** 3 to 7 PSI (20 to 50 kPa)
   - **c.** 60 PSI (400 kPa)
   - **d.** None of these
7. Where are the total miles traveled stored in a vehicle equipped with an electronic odometer?
   - **a.** LCD
   - **b.** NVRAM
   - **c.** LED
   - **d.** VTF
8. A backup camera can show a poor quality image on the interior display if what occurs?
   - **a.** Ice or snow on the camera
   - **b.** Bright lights aimed at the camera
   - **c.** Extreme temperatures
   - **d.** Any of the above
9. The vehicle voice activation system can be used to control ____________.
   - **a.** text messages
   - **b.** phone calls
   - **c.** the sound system
   - **d.** All of the above
10. What system uses a special camera?
   - **a.** Touch screens
   - **b.** Night vision system
   - **c.** Electronic displays
   - **d.** Any of the above

Chapter

SECURITY AND IMMOBILIZER SYSTEMS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe the purpose and function of a security system.
- Explain how an immobilizer system works and identify its major components.
- Describe immobilizer systems in Chrysler vehicles.
- Describe the Ford passive antitheft system.
- Describe the General Motors antitheft system.
- Explain how to diagnose a fault with an immobilizer system.

KEY TERMS:

Key fob 644 • Radio frequency identification (RFID) 644 • Remote keyless entry (RKE) 644 • Transceiver 644 • Transponder 644

VEHICLE SECURITY SYSTEMS

PURPOSE AND FUNCTION The purpose and function of a security system on a vehicle is to prevent the unauthorized use (theft) of the vehicle. This function is accomplished by installing the following locks:

1. A lock on the doors to help prevent unauthorized entry to the interior of the vehicle.
2. A lock for the ignition so a key is needed to crank and start the engine and unlock the steering wheel, starting in 1970.

While these locks have worked, vehicles can still be easily stolen if access to the interior and the ignition switch is accessible. It is the purpose and function of an immobilizer system to prevent the vehicle from being started if the correct ignition key is not used, even if an intruder gets access to the interior of the vehicle and tries to use a key that fits the lock cylinder.

POSSIBLE IMMOBILIZER CAUSED FAULTS Faults with the immobilizer system can be the cause of one of the following

FREQUENTLY ASKED QUESTION

What Is Content Thief Protection?

Content Thief protection is a security system that includes sensors that detect glass breakage or entry into the vehicle and sounds an alarm when these occur. The purpose of the content theft system is to prevent the theft of objects inside the vehicle and sound an alarm when someone enters the vehicle without using the proper remote or key. Most systems use a motion detector for content theft protection, as well as switches in the doorjambs, trunk, and hood that provide an input signal to the control module. Some antitheft systems are more complex and also have electronic sensors that trigger the alarm if glass is broken or a change in battery current draw occurs. These sensors also provide an input signal to the control module, which may be a separate antitheft unit, or may be incorporated into the PCM or BCM. ● **SEE FIGURE 55–1**.

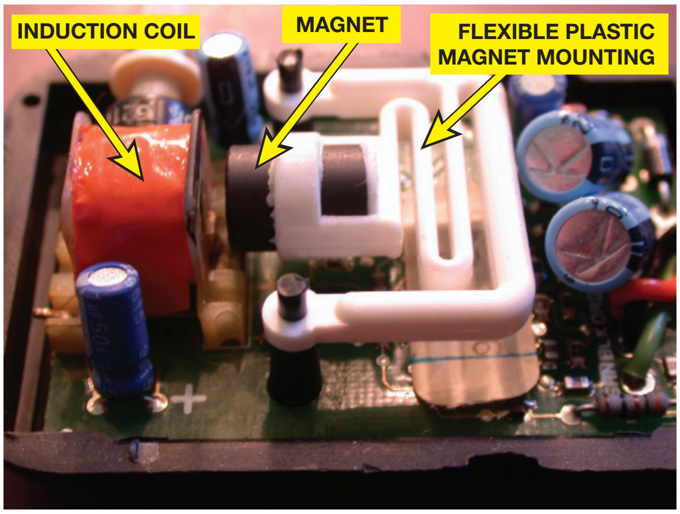

FIGURE 55–1 A shock sensor used in alarm and antitheft systems. If the vehicle is moved, the magnet moves relative to the coil, inducing a small voltage that triggers the alarm.

conditions depending on the exact make and model of a vehicle:

- No crank condition (the starter motor does not operate)
- The engine cranks but does not start (fuel disabled in most vehicles)
- The engine starts but then almost immediately stalls

Therefore, if a customer concern involves any of these situations, a fault in the immobilizer system is a possible cause, rather than a fault with the ignition or fuel system.

IMMOBILIZER SYSTEMS

NORMAL OPERATION A vehicle equipped with an immobilizer system operates normally as follows:

- When a valid key is used and is rotated to the start position, the engine cranks and starts and the immobilizer symbol on the dash flashes on and off for about two seconds, and then goes off. ● **SEE FIGURE 55–2**.

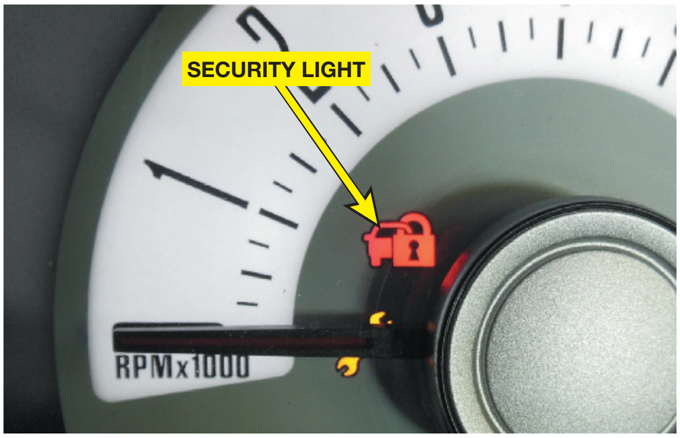

FIGURE 55–2 The security system symbol used on a Ford. The symbol varies by make, model, and year, so check service information to determine what symbol is used on the vehicle being diagnosed.

- If there is a fault with an invalid key, the dash symbol flashes continuously and the engine does not start or, if it does crank and start, the engine does not continue to run.

IMMOBILIZER SYSTEM PARTS Most security systems today use a **Radio Frequency Identification (RFID)** security system, which has two main components:

1. A **key fob** is the object that is a decoration on a key ring and usually contains a transmitter used to unlock a vehicle. While the **remote keyless entry (RKE)** part of the key fob has a battery to power the transmitter, the RFID chip part of the key fob does not require a battery to function. The **transponder** is mounted in the key or the body of the key fob. A transponder has an antenna, which consists of a coil of wire, as well as a circuit board containing the processing electronics and data memory. ● **SEE FIGURE 55–3**.
2. The transponder key has the transponder electronics integrated in its plastic body. It consists of the following components:
    - A microchip contains the unique internal identification (ID) number. To prevent an unauthorized scanning of the ID number, the code changes with each transfer and uses several million different coding possibilities. ● **SEE FIGURE 55–4**.
    - The coil antenna in the key consists of a copper coil wound up in a ring case and an integrated circuit to create a high-frequency alternating voltage for the inductive coupling. Through inductive (electromagnetic) coupling, the data from the key is transferred to the immobilizer module.
    - Another coil is installed around the lock cylinder and connected to the control module of the immobilizer system. This coil transfers and receives all data signals to and from the immobilizer control module using the coil antenna/transceiver. It does not need to be reprogrammed to the immobilizer system in case of replacement.
    - A **transceiver** is inside the vehicle and receives the signal transmitted by the transponder in the key. A "transceiver"

functions as both a reviewer and a transmitter. The transceiver is usually mounted on the steering column assembly. The antenna for the transceiver is a coil of wire mounted within the plastic ring that mounts around the lock cylinder. ● **SEE FIGURE 55–5**.

IMMOBILIZER SYSTEM OPERATION When the ignition key in inserted, the transceiver sends out an electromagnetic energy pulse. This energy pulse is received by the coil inside the key transponder, which creates a voltage. The information or data in the magnetic pulses is in the form of a frequency modulated signal.

A typical immobilizer system consists of transponder key, coil antenna, key reminder switch, separate immobilizer module, PCM, and security light. Most immobilizer systems work as follows:

- The key identification (ID) numbers are stored in a nonvolatile memory of the immobilizer module. At each start, the module compares the ID number of the transponder key used with those stored in the memory.
- If the verification has been successful, the immobilizer module sends a request signal to the PCM to compare the key ID number with the numbers registered in the PCM.
- Each immobilizer module has its unique code word that is stored in the PCM. After the verification of the ID number, the immobilizer module requests the code word from the PCM.
- The immobilizer module controls the starter circuit and the security light and signals the PCM to activate fuel injection and ignition when the ID number and code word verification have been successful.
- The signals between immobilizer module and PCM are transmitted via a serial data line.

SECURITY LIGHT OPERATION Normal operation of the security light includes a self-test and flashes a few times, then goes out. However, if a fault is detected, the security light continues to flash and the engine may not start. If a fault occurs with the immobilizer system when the engine is running, then the security

TECH TIP

Do Not Have Other Keys Near

Whenever diagnosing an immobilizer system, keep other key fobs away from the area. If another key fob were close, it could be transmitting a signal that is not recognized by the vehicle and the security system could prevent proper vehicle operation. Even having other metal objects near the key can affect the strength of the electromagnetic pulses and could interfere with the immobilizer system and prevent it from working as designed. ● **SEE FIGURE 55–6**.

light comes on, but the engine is not shut off, as this condition is not a theft attempt.

PRECAUTIONS To avoid damage to the key, do not allow the key to:

- Be dropped onto a hard surface
- Get wet
- Be exposed to any kind of magnetic field
- Be exposed to high temperatures on places, such as the top of the dash under direct sunlight.

A system malfunction may occur if any of the following items are touching the key or are near the key head:

- A metal object
- Spare keys or keys for other vehicles equipped with an immobilizer system
- An electronic device, such as cards with magnetic strips

TYPICAL IMMOBILIZER CIRCUITS The diagnostic process involved with positively identifying the defective security system component can be quick and accurate. At the transceiver, check for power, ground, and proper communication on data transmission lines. ● **SEE FIGURE 55–7**.

CAUTION: Do not leave the key in the ignition, as this often keeps the immobilizer system alive and drains the vehicle battery. If leaving the vehicle, take the key out of the ignition and place it 15 feet (5 meters) away to help avoid possible issues.

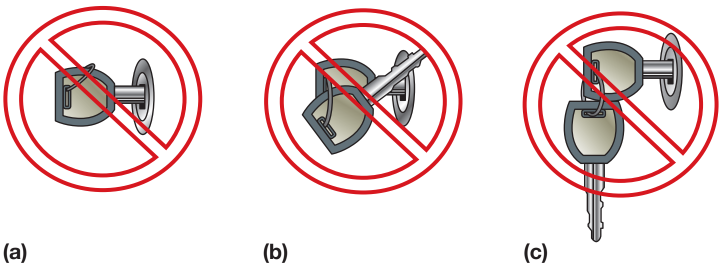

FIGURE 55–6 (a) Avoid using a key where the key ring is over the top of the key, which can interfere with the operation of the immobilizer system. (b) Do not angle another key upward from the key being used to help prevent interference with the magnetic field used to energize the key. (c) Do not have the keys from another vehicle near the key being used.

CHRYSLER IMMOBILIZER SYSTEM

BACKGROUND Beginning in 1998, Chrysler started a security system known as the **Sentry Key Immobilizer System (SKIS)**. When an attempt to start a vehicle arises, the onboard computer sends out a radio-frequency (RF) signal that is read by the electronic transponder chip embedded in the key. The transponder then returns a unique signal back to the SKIM, giving it the okay signal for the vehicle to start and continue to run. This all happens in under a second and is completely transparent to the vehicle driver. For additional security, two preprogrammed keys are needed in order to register additional keys into the system. In the event of the loss of all keys, special programming equipment is needed to register new keys into the system.

CHRYSLER SELF-PROGRAMMING ADDITIONAL SENTRY KEYS (REQUIRES TWO ORIGINAL KEYS)

Quick steps:

STEP 1 Purchase a blank key and have it cut to fit the lock cylinder.

STEP 2 Insert the original key #1 into the ignition and turn to ON.

STEP 3 Wait five seconds and turn the key to OFF.

STEP 4 Immediately insert the original key #2 into the ignition and turn to ON.

STEP 5 Wait 10 seconds for the SKIS indicator in the dash to start to flash.

STEP 6 Turn the ignition off, insert the new blank key, and turn the ignition back on.

STEP 7 Once the SKIS light stops flashing and turns off, the new key is programmed.

FORD PATS SYSTEM

BACKGROUND Ford uses a responder key for their antitheft system, which is called the **Passive Antitheft System** (**PATS**).

FORD PROGRAMMING FOR ADDITIONAL (PATS) KEYS This procedure works only if two or more programmed ignition keys are available. The steps include

STEP 1 Insert the first programmed ignition key into the ignition lock cylinder. Turn the ignition switch from the LOCK to RUN position (ignition switch must stay in the run position for one second). Turn the ignition switch to the LOCK position and remove the ignition key from the ignition lock cylinder.

STEP 2 Within five seconds of turning the ignition switch to the LOCK position, insert the second programmed ignition key into the ignition lock cylinder. Turn the ignition switch from the LOCK to RUN position (ignition switch must stay in the RUN position for one second). Turn the ignition switch to the LOCK position and remove the second ignition key from the ignition lock cylinder.

STEP 3 Within five seconds of turning the ignition switch to the LOCK position, insert a new unprogrammed ignition key into the ignition lock cylinder. Turn the ignition switch

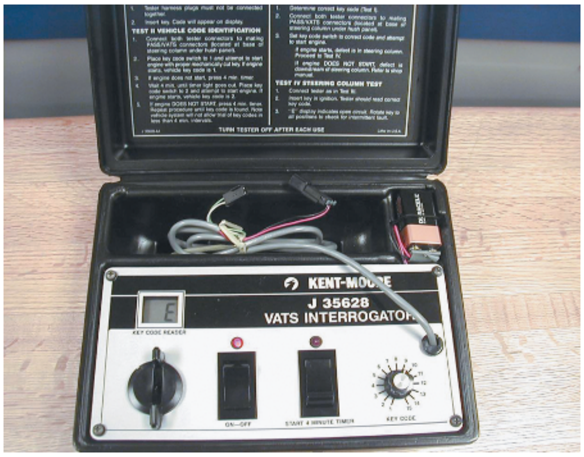
from the LOCK to RUN position (the ignition switch must stay in the RUN position for one second). Turn the ignition switch to the LOCK position and remove the ignition key from the ignition lock cylinder. The new ignition key should now be programmed. To program additional key(s), repeat the key programming procedure from Step 1.

GENERAL MOTORS ANTITHEFT SYSTEM

BACKGROUND The type of antitheft system used on General Motors vehicles has included many different systems, starting with an antitheft system that used a resistor pellet in the ignition key. If the key fit the lock cylinder and the resistance was the correct value, the engine would crank and start. This system was called the **Vehicle Antitheft System** or **(VATS)**. A special tester was required to test this system. ● **SEE FIGURE 55–8**.

Newer systems include the **Passkey I** and **Passkey II**, which also use a resistor pellet in the ignition key. **Passlock I**, **Passlock II,** and **Passlock truck** systems use a Hall-effect sensor and magnets in the lock cylinder with a conventional key. ● **SEE FIGURE 55–9**.



KENT-MOORE
J 35628
VATS INTERROGATOR

FIGURE 55–8 A special tool is needed to diagnose a General Motors VATS security system and special keys that contain a resistor pellet.

Passkey III systems use a transponder embedded into the head of the key, which is stamped "SK3." Most of the systems disable the starter and the fuel injectors, but Passlock I disables fuel after the engine starts, and the security light then flashes. Due to the various systems, service information must be used and followed to diagnose and repair a fault in these systems.

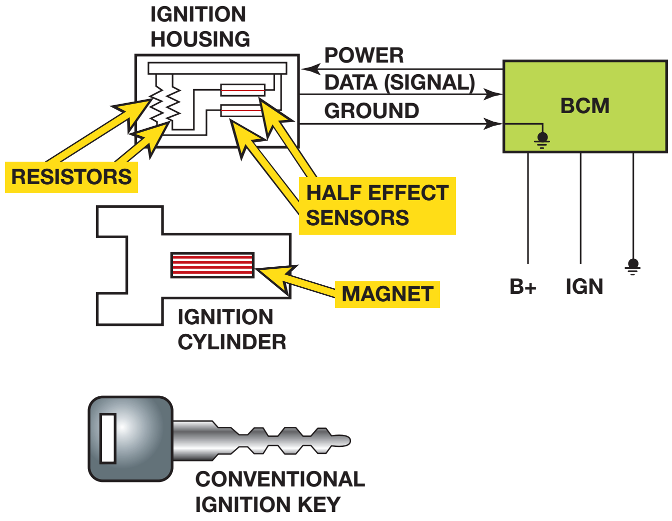


FIGURE 55–9 The Passlock series of General Motors security systems uses a conventional key. The magnet is located in the ignition lock cylinder and triggers the Hall-effect sensors.

FIGURE 55–10 Scan tools, such as this factory tool being used on a BMW, are capable of many diagnostic functions that can help the technician zero in on the root cause of a problem.

TESTING IMMOBILIZER SYSTEMS

DIAGNOSTIC STEPS Most vehicle manufacturers recommend a series of steps that a technician should follow when diagnosing a fault with the immobilizer system:

STEP 1 **Verify the Customer Concern**—A fault with the immobilizer system often causes the engine to not start or start, then stall. Faults can also be intermittent because many systems "time out" after 20 minutes if an error occurs, and then works normally after the wait period. A "no-start" condition can also occur that is not associated with the immobilizer system and should be handled using normal diagnostic procedures as specified by the vehicle manufacturer for a no-start condition.

STEP 2 **Visual Inspection—**Most vehicle manufacturers specify that the first step after the customer concern has been verified is that a visual inspection be performed. A visual inspection includes checking the security light status. A typical security light status includes the following:

- **Normal**—The security dash lamp comes on for two to five seconds for a bulb check when the ignition is turned on, then goes out.
- **Tamper mode**—The security lamp flashes about once per second if the system detects a bad key, lock cylinder, or security-related wiring problem. The engine does not start or, if it does start, does not continue to run.
- **Fail enable mode**—If a fault with the security system occurs when the vehicle is running, the security light remains on, but the immobilizer system is disabled because it is apparently not a theft attempt. Therefore, the engine starts and runs as normal, except that the security warning light on the dash is on all the time.

Check for the presence of aftermarket accessories, such as an add-on remote starter system. These systems require the use of a spare key that is held near the lock cylinder, thereby allowing the engine to start using a remote control. A fault with the aftermarket system could have an effect on the proper operation of the immobilizer system.

TECH TIP

Look for DTCs in "Body" and "Chassis"

Whenever diagnosing a customer concern with the immobilizer system, check for diagnostic trouble codes (DTCs) under chassis and body systems. A global or generic scan tool that can read only "P" codes is not suitable for diagnosing many faults with the immobilizer system. These codes are most often found under chassis or body systems. Chassis-related codes are labeled "C" and body system-related codes are labeled "B" codes and these can cause an immobilizer issue if they affect a sensor that is used by the system. ● **SEE FIGURE 55–10**.

STEP 3 **Check for Diagnostic Trouble Codes**—Use a factory or enhanced factory-level aftermarket scan tool and retrieve diagnostic trouble codes. Check service information for the exact codes for the vehicle being checked. ● **SEE CHART 55–1** for some sample DTCs and their meaning.

STEP 4 **Check for Technical Service Bulletins**—Technical service bulletins (TSBs) are issued by vehicle and aftermarket manufacturers to inform technicians of a situation or technical problem and give the corrective steps and a list of parts needed to solve the problem. Any diagnostic trouble codes should be retrieved before looking at the technical service bulletins because many bulletins include what DTCs may or may not be present. ● **SEE FIGURE 55–11**.

DTC	DESCRIPTION OF FAULT
P0513	Incorrect immobilizer key
P1570	Fault in antenna detected
P1517	Reference code not compatible with ECM
P1572	Communications failure with ECM
B2957	Security system data circuit low
B2960	Security system data wrong but valid

CHART 55–1

Sample diagnostic trouble codes for an immobilizer system. These codes vary by make, model, and year of manufacture, so check service information for the exact vehicle being diagnosed.

FIGURE 55–11 After checking for stored diagnostic trouble codes (DTCs), the wise technician checks service information for any technical service bulletins (TSBs) that may relate to the vehicle being serviced.

While some of these TSBs concern minor problems covering few vehicles, many contain very helpful solutions to hard-to-find problems that cover many vehicles. TSBs can also be purchased through aftermarket companies that are licensed and available on a website. Visit the National Automotive Service Task Force (NASTF) website (www.NASTF.org) for a list of the Web addresses for all vehicle manufacturers' sites where the full text of TSBs can be purchased directly. Factory TSBs can often save the technician many hours of troubleshooting.

STEP 5 **Perform Pinpoint Tests**—Following the specified diagnostic steps found in service information, check for the system for proper voltage at each of the components.

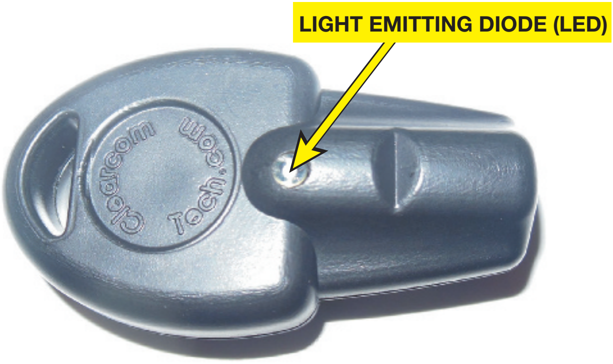

FIGURE 55–12 Immobilizer coil detectors can be found online by searching for immobilizer transponder coil detector.

TECH TIP

Use an Antenna Coil Tester to Save Time

The procedure for testing the antenna coil using an antenna tester includes the following:

- Insert the ignition key into the ignition lock cylinder. On some vehicles, inserting the key causes the transceiver to activate. On some vehicles, the key must be rotated to the ON position.
- Use a handheld tester to check that the transceiver is able to transmit a signal. A coil detector is used to check the immobilizer coil that surrounds the lock cylinder. The coil is working normally if the LED lights up as the key is inserted into the lock cylinder. If the coil is defective, this can save the technician a lot of time troubleshooting the system. The coil can be replaced without the need to reprogram the keys. ● **SEE FIGURE 55–12**.

STEP 6 **Determine the Root Cause**—By following the specified diagnostic routine, the root cause can often be determined. If a module is replaced, it usually must be programmed to accept the ignition key and this can be a huge problem if a used module is chosen instead of a new one. Always check service information for the exact procedure to follow.

STEP 7 **Verify the Repair**—After the repairs or service procedures have been performed, verify that the system is working as designed. If needed, operate the vehicle under the same conditions that it was when the customer concern was corrected to verify the repair. Document the work order and return the vehicle to the customer in clean condition.

REVIEW QUESTIONS

1. What faults will an immobilizer system cause?
2. How is the security information transferred from the key to the vehicle?
3. A typical immobilizer system consists of what parts?
4. To avoid damage to the key, what precautions are needed to be performed?
5. An antenna coil tester is used to test what part of the immobilizer system?

CHAPTER QUIZ

1. What is the purpose and function of an immobilizer system?
   - **a.** Prevents entry inside the vehicle
   - **b.** Only allows the use of the ignition key that is properly matched to the lock cylinder
   - **c.** Prevents the vehicle from starting or running if the correct key is not used
   - **d.** Requires that the driver enter a password to start the vehicle
2. What does the battery in the key fob power?
   - **a.** The shock sensor
   - **b.** The remote keyless entry (RKE)
   - **c.** The immobilizer circuit
   - **d.** Both the remote keyless entry and the immobilizer circuit
3. What can occur if the immobilizer system is not working as designed?
   - **a.** No crank condition (the starter motor does not operate)
   - **b.** The engine cranks but does not start
   - **c.** The engine starts but then almost immediately stalls
   - **d.** Any of the above
4. An immobilizer fault may occur if the ____________.
   - **a.** key is dropped onto a hard surface
   - **b.** key gets wet
   - **c.** key is exposed to any kind of magnetic field
   - **d.** Any of the above
5. How is data transmitted between the key and the steering column (lock cylinder)?
   - **a.** By inductive coupling
   - **b.** By electrical contacts inside the lock cylinder
   - **c.** Transmitted from the key to the vehicle using the battery inside the key
   - **d.** Transferred from the key to the BCM using a small transmitter in the key
6. A typical Ford immobilizer system is called ____________.
   - **a.** VATS
   - **b.** PATS
   - **c.** Passlock
   - **d.** SKIS
7. A typical Chrysler immobilizer system is called ____________.
   - **a.** VATS
   - **b.** PATS
   - **c.** Passlock
   - **d.** SKIS
8. The security dash lamp comes on for two to five seconds and then goes out. This indicates what condition?
   - **a.** A fault has been detected in the key transponder
   - **b.** A fault has been detected in the wiring near the ignition lock cylinder
   - **c.** Normal security light operation
   - **d.** The system has entered tamper mode
9. Immobilizer diagnostic trouble codes are often found under what area?
   - **a.** Engine-related “P” codes
   - **b.** Body-related “B” codes
   - **c.** Chassis-related “C” codes
   - **d.** Any of the above
10. If an immobilizer-related fault occurs, what symbol is likely to be displayed on the dash?
    - **a.** “IM”
    - **b.** A padlock symbol
    - **c.** The “check engine” light
    - **d.** The “service engine soon” light

56

AIRBAG AND PRETENSIONER CIRCUITS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain how safety belts and retractors function.
- Explain the operation of front airbags.
- Describe the procedures to diagnose common faults in airbag systems.
- Describe the procedures to repair common faults in airbag systems.
- Discuss driver side airbag module replacement.
- Discuss safety issues when manually deploying airbags.
- Explain how the passenger presence system works.
- Describe how seat and side curtain airbags function.
- Describe the data recorded by an event data recorder when an airbag is deployed.

KEY TERMS:

Airbag 653 • Arming sensor 653 • Clockspring 656 • Deceleration sensors 654 • Dual-stage airbags 655 • EDR 662 • Integral sensors 654 • Occupant detection system (ODS) 660 • Passenger presence system (PPS) 660 • Pretensioners 652 • SAR 653 • SIR 653 • Squib 653 • SRS 653

SAFETY BELTS AND RETRACTORS

SAFETY BELTS Safety belts are used to keep the driver and passengers secured to the vehicle in the event of a collision. Most safety belts include three-point support and are constructed of nylon webbing about 2 inches (5 cm) wide. The three support points include two points on either side of the seat for the belt over the lap and one crossing over the upper torso, which is attached to the "B" pillar or seat back. Every crash consists of three types of collisions:

Collision 1: The vehicle strikes another vehicle or object.

Collision 2: The driver and/or passengers hit objects inside the vehicle if unbelted.

Collision 3: The internal organs of the body hit other organs or bones, which causes internal injuries.

If a safety belt is being worn, the belt stretches, absorbing a lot of the impact, thereby preventing collision with other objects in the vehicle and reducing internal injuries. ● **SEE FIGURE 56–1**.

BELT RETRACTORS Safety belts are also equipped with one of the following types of retractors:

- Emergency locking retractors, which lock the position of the safety belt in the event of a collision or rollover
- Emergency and web speed-sensitive retractors, which allow freedom of movement for the driver and passenger, but lock if the vehicle is accelerating too fast or if the vehicle is decelerating too fast

● **SEE FIGURE 56–2** for an example of an inertia-type seat belt locking mechanism.

SAFETY BELT LIGHTS AND CHIMES All late-model vehicles are equipped with a safety belt warning light on the dash and a chime that sounds if the belt is not fastened. ● **SEE FIGURE 56–3**.

Some vehicles intermittently flash the reminder light and sound a chime until the driver, and sometimes the front passenger, fasten their safety belts.

REST
WEIGHT
ACTIVE

FIGURE 56–2 Most safety belts have an inertia-type mechanism that locks the belt in the event of rapid movement.

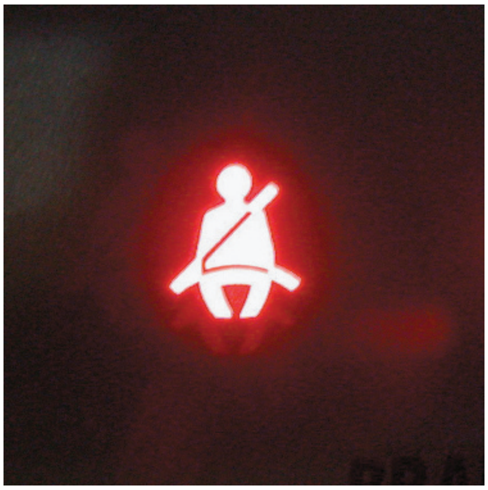

FIGURE 56–3 A typical safety belt warning light.

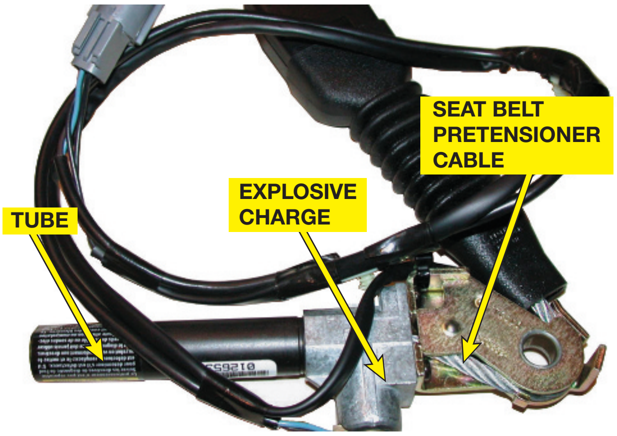
PRETENSIONERS A **pretensioner** is an explosive (pyrotechnic) device that is part of the seat belt retractor assembly and tightens the seat belt as the airbag is being deployed. The purpose of the pretensioning device is to force the occupant back into position against the seat back and to remove any slack in the seat belt. ● **SEE FIGURE 56–4**.



SEAT BELT PRETENSIONER CABLE
EXPLOSIVE CHARGE
TUBE

FIGURE 56–4 A small explosive charge in the pretensioner forces the end of the seat belt down the tube, which removes any slack in the seat belt.

CAUTION: The seat belt pretensioner assemblies must be replaced in the event of an airbag deployment. Always follow the vehicle manufacturer's recommended service procedure. Pretensioners are explosive devices that could be ignited if voltage is applied to the terminals. Do not use a jumper wire or powered test light around the seat belt latch wiring. Always follow the vehicle manufacturer's recommended test procedures.

FRONT AIRBAGS

PURPOSE AND FUNCTION

Airbag passive restraints are designed to cushion the driver (or passenger, if the passenger side is so equipped) during a frontal collision. The system consists of one or more nylon bags folded up in compartments located in the steering wheel, dashboard, interior panels, and/or side pillars of the vehicle. During a crash of sufficient force, pressurized gas instantly fills the airbag and then deploys out of the storage compartment to protect the occupant from serious injury. These airbag systems may be known by many different names, including the following:

1. **Supplemental restraint system (SRS)**
2. **Supplemental inflatable restraints (SIR)**
3. **Supplemental air restraints (SAR)**

Most airbags are designed to supplement the safety belts in the event of a collision, and front airbags are meant to be deployed only in the event of a frontal impact within 30 degrees of center. Front (driver and passenger side) airbag systems are *not* designed to inflate during side or rear impact. The force required to deploy a typical airbag is approximately equal to the force of a vehicle hitting a wall at over 10 MPH (16 km/h).

The force required to trigger the sensors within the system prevents accidental deployment if curbs are hit or the brakes are rapidly applied. The system requires a substantial force to deploy the airbag to help prevent accidental inflation.

PARTS INVOLVED

● **SEE FIGURE 56–5** for an overall view of the parts included in a typical airbag system.

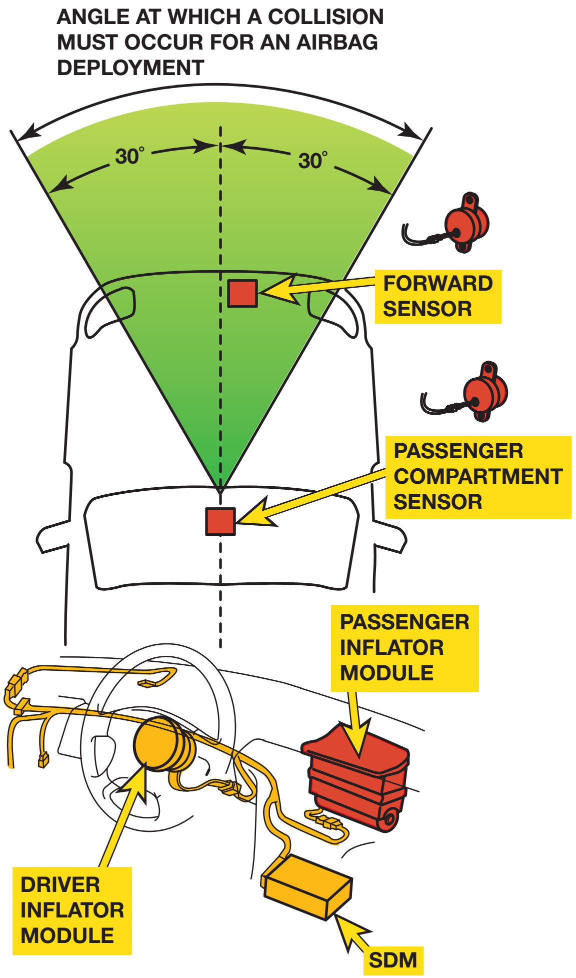
The parts include:

1. Sensors
2. Airbag (inflator) module
3. Clockspring wire coil in the steering column
4. Control module
5. Wiring and connectors

OPERATION

To cause inflation, the following events must occur:

- To cause a deployment of the airbag, two sensors must be triggered at the same time. The **arming sensor** is used to provide electrical power, and a *forward* or *discriminating sensor* is used to provide the ground connection.
- The arming sensor provides the electrical power to the airbag heating unit, called a **squib**, inside the inflator module.
- The squib uses electrical power and converts it into heat for ignition of the propellant used to inflate the airbag.



ANGLE AT WHICH A COLLISION MUST OCCUR FOR AN AIRBAG DEPLOYMENT
30°
30°
FORWARD SENSOR
PASSENGER COMPARTMENT SENSOR
PASSENGER INFLATOR MODULE
DRIVER INFLATOR MODULE
SDM

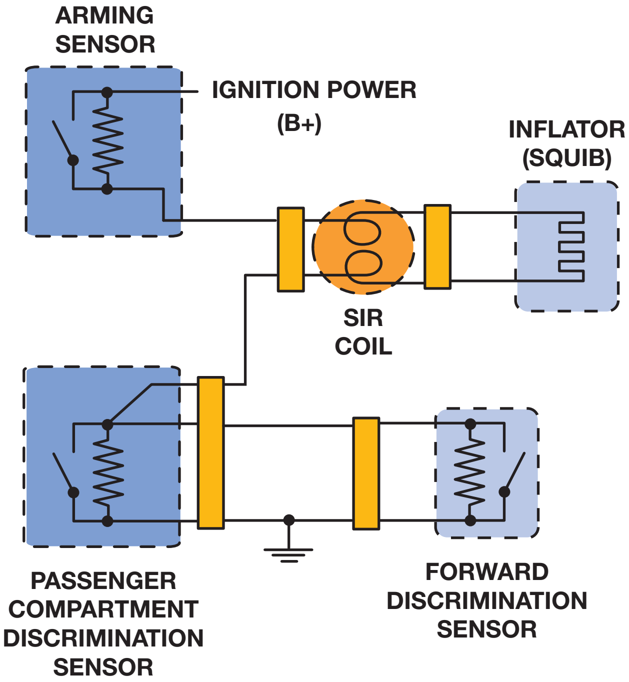
FIGURE 56–5 A typical airbag system showing many of the components. The SDM is the "sensing and diagnostic module" and includes the arming sensor, as well as the electronics that keep checking the circuits for continuity and the capacitors that are discharged to deploy the airbags.

- Before the airbag can inflate, however, the squib circuit also must have a ground provided by the forward or the discriminating sensor. In other words, two sensors (arming and forward sensors) *must* be triggered *at the same time* before the airbag is deployed. ● **SEE FIGURE 56–6**.

TYPES OF AIRBAG INFLATORS

There are two different types of inflators used in airbags:

1. **Solid fuel.** This type uses sodium azide pellets, and when ignited, generates a large quantity of nitrogen gas that quickly inflates the airbag. This was the first type used and is still commonly used in driver and passenger side airbag inflator modules. ● **SEE FIGURE 56–7**. The squib is the electrical heating element used to ignite the gas-generating material, usually sodium azide. It requires about 2 amperes of current to heat the heating element and ignite the inflator.
2. **Compressed gas.** Commonly used in passenger side airbags and roof-mounted systems, the compressed gas system uses a canister filled with argon gas, plus a small percentage of helium at 3,000 PSI (435 kPa). A small igniter ruptures a burst disc to release the gas when energized. The compressed gas inflators are long cylinders that can be installed inside the instrument panel, seat back, door panel, or along any side rail or pillar of the vehicle. ● **SEE FIGURE 56–8**.



ARMING SENSOR
IGNITION POWER (B+)
INFLATOR (SQUIB)
SIR COIL
PASSENGER COMPARTMENT DISCRIMINATION SENSOR
FORWARD DISCRIMINATION SENSOR

FIGURE 56–6 A simplified airbag deployment circuit. Note that both the arming sensor and at least one of the discriminating sensors must be activated at the same time. The arming sensor provides the power, and either one of the discriminating sensors can provide the ground for the circuit.

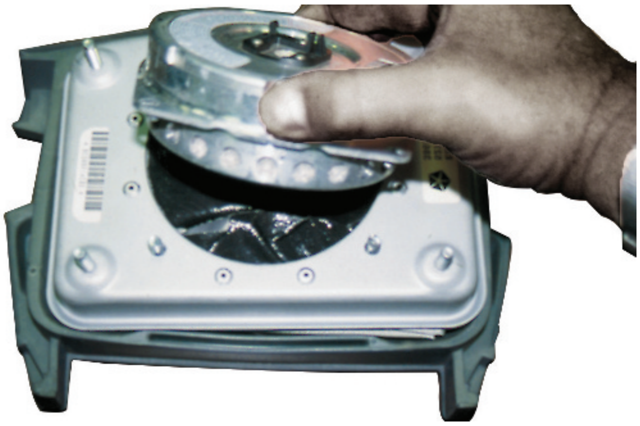


FIGURE 56–7 The inflator module is being removed from the airbag housing. The squib, inside the inflator module, is the heating element that ignites the pyrotechnic gas generator that rapidly produces nitrogen gas to fill the airbag.

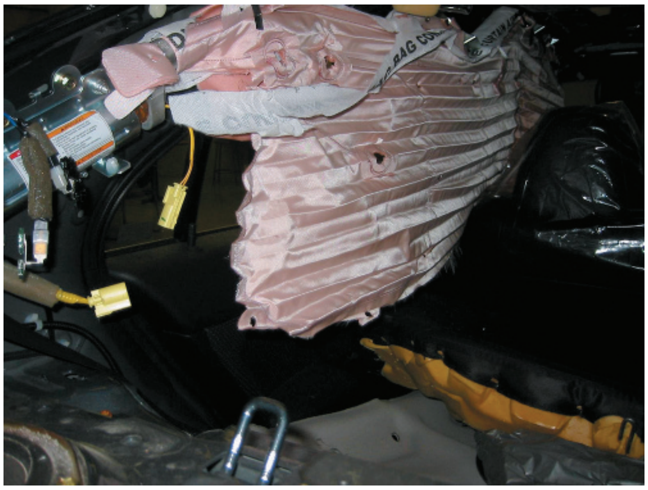

FIGURE 56–8 This figure shows a deployed side curtain airbag on a training vehicle.

Once the inflator is ignited, the nylon bag quickly inflates (in about 30 milliseconds or 0.030 second) with nitrogen gas generated by the inflator. During an actual frontal collision accident, the driver is being thrown forward by the driver's own momentum toward the steering wheel. The strong nylon bag inflates at the same time. Personal injury is reduced by the spreading of the stopping force over the entire upper-body region. The normal collapsible steering column remains in operation and collapses in a collision when equipped with an airbag system. The bag is equipped with two large side vents that allow the bag to deflate immediately after inflation, once the bag has cushioned the occupant in a collision.

TIMELINE FOR AIRBAG DEPLOYMENT Following are the times necessary for an airbag deployment in milliseconds (each millisecond is equal to 0.001 second or 1/1,000 of a second):

1. Collision occurs: 0.0 millisecond
2. Sensors detect collision: 16 milliseconds (0.016 second)
3. Airbag is deployed and seam cover rips: 40 milliseconds (0.040 second)
4. Airbag is fully inflated: 100 milliseconds (0.100 second)
5. Airbag deflated: 250 milliseconds (0.250 second)

In other words, an airbag deployment occurs and is over in about a quarter of a second. ● **SEE FIGURE 56–9**.

SENSOR OPERATION All three sensors are basically switches that complete an electrical circuit when activated. The sensors are similar in construction and operation, and the *location* of the sensor determines its name. All airbag sensors are rigidly mounted to the vehicle and *must* be mounted with the arrow pointing toward the front of the vehicle to ensure that the sensor can detect rapid forward deceleration.

There are three basic styles (designs) of airbag sensors:

1. **Magnetically retained gold-plated ball sensor.** This sensor uses a permanent magnet to hold a gold-plated steel ball away from two gold-plated electrical contacts. ● **SEE FIGURE 56–10**.

   If the vehicle (and the sensor) stops rapidly enough, the steel ball is released from the magnet because the inertia force of the crash was sufficient to overcome the magnetic pull on the ball and then makes contact with the two gold-plated electrodes. The steel ball only remains in contact with the electrodes for a relatively short time because the steel ball is drawn back into contact with the magnet.
2. **Rolled up stainless-steel ribbon-type sensor.** This sensor is housed in an airtight package with nitrogen gas inside to prevent harmful corrosion of the sensor parts. If the vehicle (and the sensor) stops rapidly, the stainless-steel roll "unrolls" and contacts the two gold-plated contacts. Once the force is stopped, the stainless-steel roll rolls back into its original shape. ● **SEE FIGURE 56–11**.
3. **Integral sensor.** Some vehicles use electronic **deceleration sensors** built into the inflator module, called **integral sensors**. For example, General Motors uses the term *sensing and diagnostic module* (SDM) to describe their integrated sensor/module assembly. These units contain an accelerometer-type sensor that measures the rate of deceleration and, through computer logic, determines if the airbags should be deployed. ● **SEE FIGURE 56–12**.

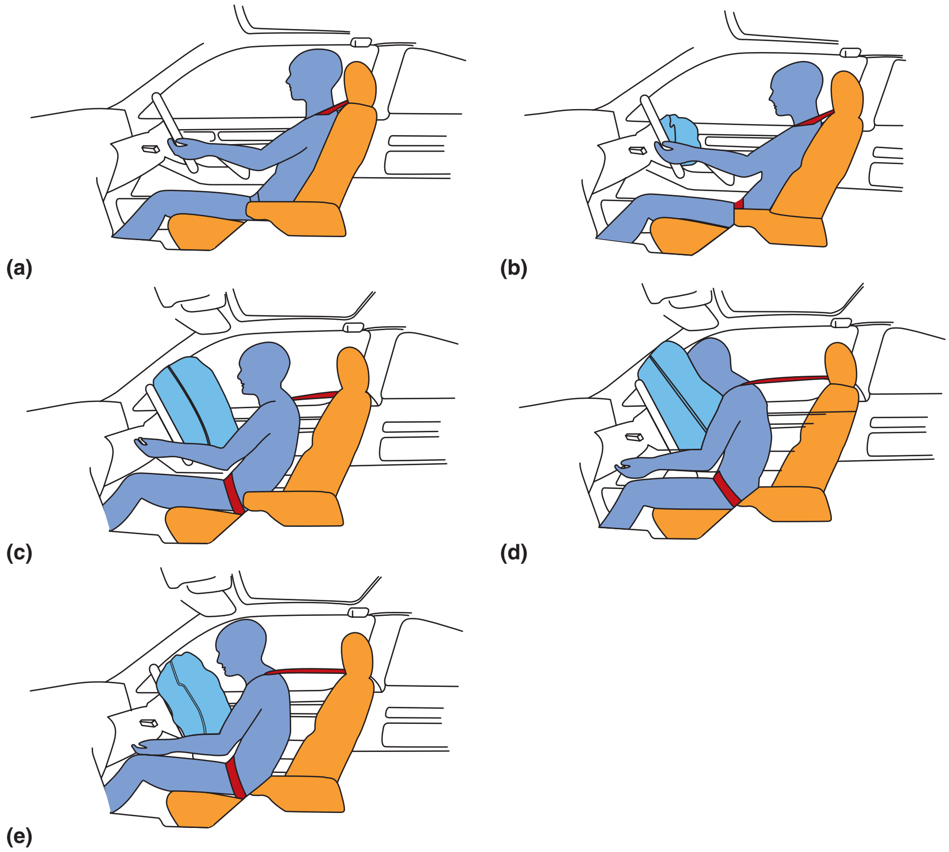

FIGURE 56–9 The sequence of deployment of a typical airbag includes the following:
(a) The driver is sitting in a normal driving position.
(b) About 16 milliseconds (0.016 second) after an impact with a solid object that results in a rapid deceleration causing the triggering of the airbag.
(c) About 40 milliseconds after impact, the airbag deploys and the driver's body is moving forward.
(d) At 100 milliseconds after impact, the airbag has fully inflated and the driver's body is being slowed by the airbag and by the seat belt.
(e) Starting at about 120 milliseconds, the driver's body will start to move back toward the seat and the airbag will be deflated by 250 milliseconds after the impact.

FIGURE 56–10 An airbag magnetic sensor.

TWO-STAGE AIRBAGS Two-stage airbags, often called advanced airbags or smart airbags, use an accelerometer-type of sensor to detect force of the impact. This type of sensor measures the actual amount of deceleration rate of the vehicle and is used to determine whether one or both elements of a two-stage airbag should be deployed.

- **Low-stage deployment.** This lower-force deployment is used if the accelerometer detects a low-speed crash.

SAFETY TIP

Dual-Stage Airbag Caution

Many vehicles are equipped with **dual-stage airbags** (two-stage airbags) that actually contain two separate inflators, one for less severe crashes and one for higher-speed collisions. These systems are sometimes called *smart airbag systems* because the accelerometer-type sensor used can detect how severe the impact is and deploy one or both stages. If one stage is deployed, the other stage is still active and could be accidentally deployed. A service technician cannot tell by looking at the airbag whether both stages have deployed. Always handle a deployed airbag as if it has not been deployed, and take all precautions necessary to keep any voltage source from getting close to the inflator module terminals.

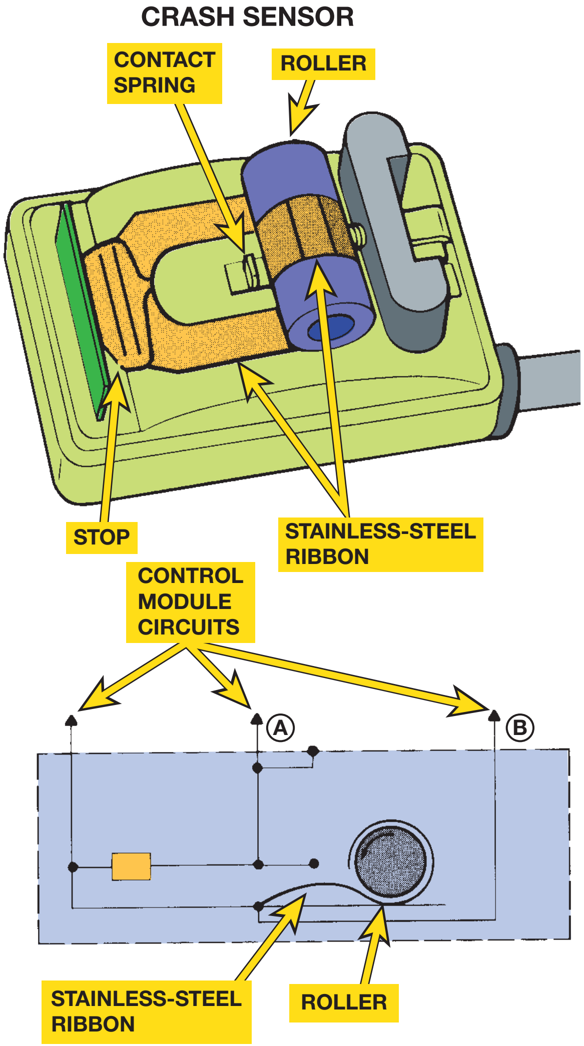

FIGURE 56–11 Some vehicles use a ribbon-type crash sensor.

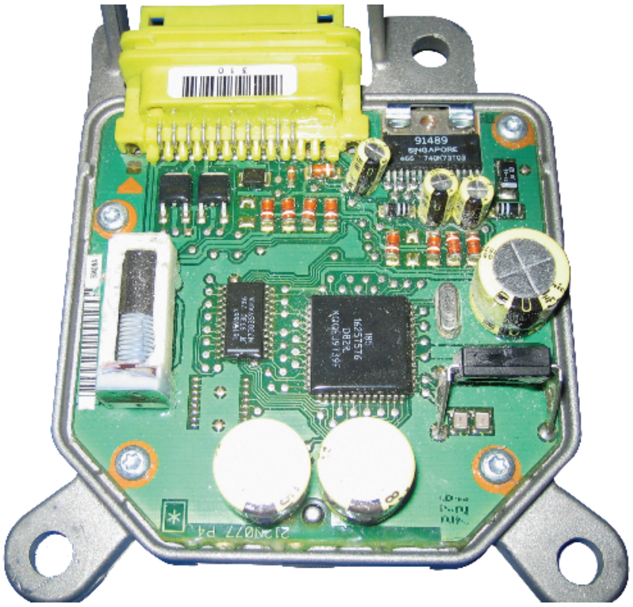

FIGURE 56–12 A sensing and diagnostic module that includes an accelerometer.

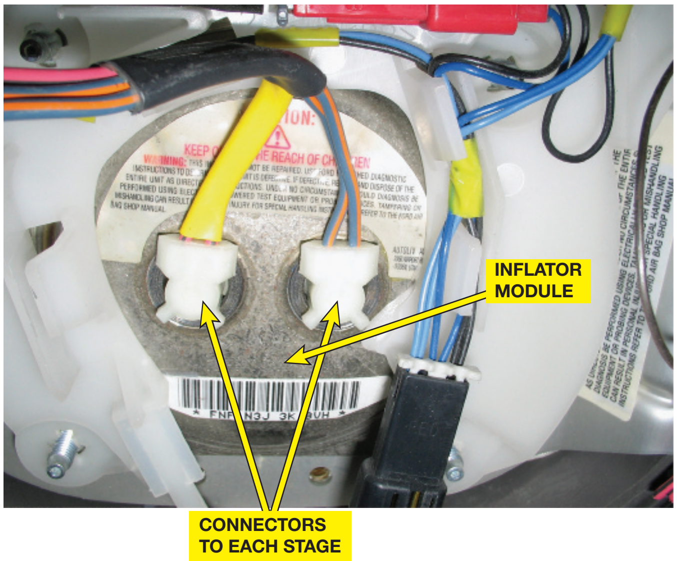

FIGURE 56–13 A driver's side airbag showing two inflator connectors. One is for the lower-force inflator and the other is for the higher-force inflator. Either can be ignited, or both at the same time if the deceleration sensor detects a severe impact.

- **High-stage deployment.** This stage is used if the accelerometer detects a higher-speed crash or a more-rapid deceleration rate.
- **Both low- and high-stage deployment.** Under severe high-speed crashes, both stages can be deployed.

● **SEE FIGURE 56–13**.

WIRING Wiring and connectors are very important for proper identification and long life. Airbag-related circuits have the following features:

- All electrical wiring connectors and conduit for airbags are colored yellow.
- To ensure proper electrical connection to the inflator module in the steering wheel, a coil assembly is used in the steering column. This coil is a ribbon of copper wires that operates much like a window shade when the steering wheel is rotated. As the steering wheel is rotated, this coil, usually called a **clockspring**, prevents the lack of continuity between the sensors and the inflator assembly that might result from a horn-ring type of sliding conductor.
- Inside the yellow plastic airbag connectors are gold-plated terminals that are used to prevent corrosion.

● **SEE FIGURE 56–14**.

Most airbag systems also contain a diagnostic unit that often includes an auxiliary power supply, which is used to provide the current to inflate the airbag if the battery is disconnected from the vehicle during a collision. This auxiliary power supply normally uses capacitors that are discharged through the squib of the inflation module. When the ignition is turned off, these capacitors are discharged. Therefore, after a few minutes, an airbag system does not deploy if the vehicle is hit while parked.

FIGURE 56–14 The airbag control module is linked to the powertrain control module (PCM) and the body control module (BCM) on this Chrysler system. Notice the airbag wire connecting the module to the airbag through the clockspring. Both power, labeled "driver airbag high," and ground, labeled "driver airbag low," are conducted through the clockspring.

AIRBAG DIAGNOSIS TOOLS AND EQUIPMENT

SELF-TEST PROCEDURE The electrical portion of airbag systems is constantly checked by the circuits within the airbag-energizing power unit or through the airbag controller. The electrical airbag components are monitored by applying a small-signal voltage from the airbag controller through the various sensors and components. Each component and sensor uses a resistor in parallel with the load or open sensor switch for use by the diagnostic signals. If continuity exists, the testing circuits measure a small voltage drop. If an open or short circuit occurs, a dash warning light is lighted and a possible diagnostic trouble code (DTC) is stored. Follow exact manufacturer's recommended procedures for accessing and erasing airbag DTCs.

Diagnosis and service of airbag systems usually require some or all of the following items:

- Digital multimeter (DMM)
- Airbag simulator, often called a load tool
- Scan tool
- Shorting bar or shorting connector(s)
- Airbag system tester

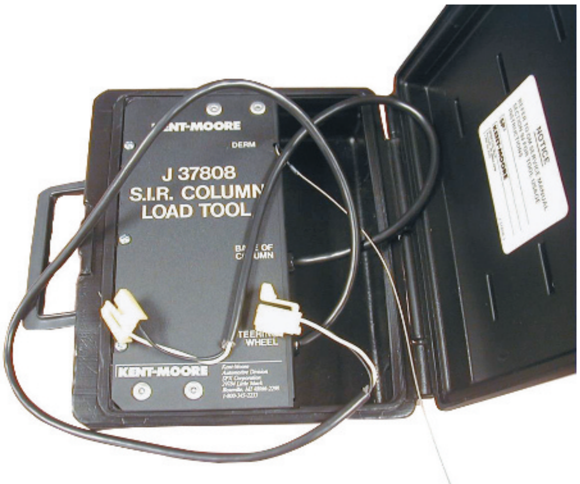

FIGURE 56–15 An airbag diagnostic tester. Included in the plastic box are electrical connectors and a load tool that substitutes for the inflator module during troubleshooting.

- Vehicle-specific test harness
- Special wire repair tools or connectors, such as crimp-and-seal weatherproof connectors

● **SEE FIGURE 56–15.**

CAUTION: Most vehicle manufacturers specify that the negative battery terminal be removed when testing or working around airbags. Be aware that a memory saver device used to keep the computer and radio memory alive can supply enough electrical power to deploy an airbag.

PRECAUTIONS Take the following precautions when working with or around airbags:

1. Always follow all precautions and warning stickers on vehicles equipped with airbags.
2. Maintain a safe working distance from all airbags to help prevent the possibility of personal injury in the unlikely event of an unintentional airbag deployment:
   - Side impact airbag: 5 inches (13 cm) distance
   - Driver front airbag: 10 inches (25 cm) distance
   - Passenger front airbag: 20 inches (50 cm) distance
3. In the event of a collision in which the bag(s) is deployed, the inflator module *and* all sensors usually must be replaced to ensure proper future operation of the system.
4. Avoid using a self-powered test light around the yellow airbag wiring. Even though it is highly unlikely, a self-powered test light could provide the necessary current to accidentally set off the inflator module and cause an airbag deployment.
5. Use care when handling the inflator module section when it is being removed from the steering wheel. Always hold the inflator away from your body.
6. If handling a deployed inflator module, always wear gloves and safety glasses to avoid the possibility of skin irritation from the sodium hydroxide dust, which is used as a lubricant on the bag(s), that remains after deployment.
7. Never jar or strike a sensor. The contacts inside the sensor may be damaged, preventing the proper operation of the airbag system in the event of a collision.
8. When mounting a sensor in a vehicle, make certain that the arrow on the sensor is pointing toward the front of the vehicle. Also be certain that the sensor is securely mounted.

TECH TIP

Pocket the Ignition Key to Be Safe

When replacing any steering gear, such as a rack-and-pinion steering unit, be sure that no one accidentally turns the steering wheel. If the steering wheel is turned without being connected to the steering gear, the airbag wire coil (clockspring) can become off center. This can cause the wiring to break when the steering wheel is rotated after the steering gear has been replaced. To help prevent this from occurring, simply remove the ignition key from the ignition and keep it in your pocket while servicing the steering gear.

FREQUENTLY ASKED QUESTION

What Are Smart Airbags?

Smart airbags use the information from sensors to determine the level of deployment. Sensors used include the following:

- **Vehicle speed (VS) sensors.** This type of sensor has a major effect on the intensity of a collision. The higher the speed is, the greater is the amount of impact force.
- **Seat belt fastened switch.** If the seat belt is fastened, as determined by the seat belt buckle switch, the airbag system deploys accordingly. If the driver or passenger is not wearing a seat belt, the airbag system deploys with greater force compared to when the seat belt is being worn.
- **Passenger seat sensor.** The sensor in the seat on the passenger's side determines the force of deployment. If there is not a passenger detected, the passenger side airbag does not deploy on the vehicle equipped with a passenger seat sensor system.

AIRBAG SYSTEM SERVICE

DIS-ARMING The airbags should be disarmed (temporarily disconnected) whenever performing service work on any of the following locations:

- Steering wheel
- Dash or instrument panel
- Glove box (instrument panel storage compartment)

Check service information for the exact procedure, which usually includes the following steps:

STEP 1 Disconnect the negative battery cable.

STEP 2 Remove the airbag fuse (has a yellow cover).

STEP 3 Disconnect the yellow electrical connector located at the base of the steering column to disable the driver's-side airbag.

STEP 4 Disconnect the yellow electrical connector for the passenger-side airbag.

This procedure is called "disabling airbags" in most service information. Always follow the vehicle manufacturer's specified procedures.

DIAGNOSTIC AND SERVICE PROCEDURE Airbag system components and their location in the vehicle vary according to system design, but the basic principles of testing are the same as for other electrical circuits. Use service information to determine how the circuit is designed and the correct sequence of tests to be followed.

- Some airbag systems require the use of special testers. The built-in safety circuits of such testers prevent accidental deployment of the airbag.
- If such a tester is not available, follow the recommended alternative test procedures specified by the manufacturer.
- Access the self-diagnostic system and check for DTC records.
- The scan tool is needed to access the data stream on most systems.

SELF-DIAGNOSIS All airbag systems can detect system electrical faults and, if found, disables the system and notifies the driver through an airbag warning lamp in the instrument cluster. Depending on circuit design, a system fault may cause the warning lamp to fail to illuminate, remain lit continuously, or flash. Some systems use a tone generator that produces an audible warning when a system fault occurs, or if the warning lamp is inoperative.

The warning lamp should illuminate with the ignition key on and engine off as a bulb check. If not, the diagnostic module is likely disabling the system. If the airbag warning light remains on, the airbags may or may not be disabled, depending on the specific vehicle and the fault detected. Some warning lamp circuits have a timer that extinguishes the lamp after a few seconds. The airbag system generally does not require service unless there is a failed component. However, a steering wheel–mounted airbag module is routinely removed and replaced in order to service switches and other column-mounted devices.

FREQUENTLY ASKED QUESTION

Why Change Knee Bolsters If Switching to Larger Wheels?

Larger wheels and tires can be installed on vehicles, but the powertrain control module (PCM) needs to be reprogrammed so the speedometer and other systems that are affected by a change in wheel/tire size can work effectively. When 20 inch wheels are installed on General Motors trucks or sport utility vehicles (SUVs), GM specifies that replacement knee bolsters be installed. Knee bolsters are the padded area located on the lower part of the dash where a driver or passenger's knees would hit in the event of a front collision. The reason for the need to replace the knee bolsters is to maintain the crash testing results. The larger 20 inch wheels tend to be forced further into the passenger compartment in the event of a front-end collision. Therefore, to maintain the frontal crash rating standard, the larger knee bolsters are required.

WARNING

Failure to perform the specified changes when changing wheels and tires could result in the vehicle not being able to provide occupant protection as designed by the crash test star rating that the vehicle originally achieved.

KNEE AIRBAGS Some vehicles are equipped with knee airbags usually on the driver's side. Use caution if working under the dash and always follow the vehicle manufacturer's specified service procedures.

DRIVER SIDE AIRBAG MODULE REPLACEMENT

For the specific model being serviced, carefully follow the procedures provided by the vehicle manufacturer to disable and remove the airbag module. Failure to do so may result in serious injury and extensive damage to the vehicle. Replacing a discharged airbag is costly. The following procedure reviews the basic steps for removing an airbag module. Do not substitute these general instructions for the specific procedure recommended by the manufacturer:

1. Turn the steering wheel until the front wheels are positioned straight ahead. Some components on the steering column are removed only when the front wheels are straight.
2. Switch the ignition off and disconnect the negative battery cable, which cuts power to the airbag module.
3. Once the battery is disconnected, wait as long as recommended by the manufacturer before continuing. When in doubt, wait at least 10 minutes to make sure the capacitor is completely discharged.
4. Loosen and remove the nuts or screws that hold the airbag module in place. On some vehicles, these fasteners are located on the back of the steering wheel. On other vehicles, they are located on each side of the steering wheel. The fasteners may be concealed with plastic finishing covers that must be pried off with a small screwdriver to access them.
5. Carefully lift the airbag module from the steering wheel and disconnect the electrical connector. Connector location varies: Some are below the steering wheel behind a plastic trim cover; others are at the top of the column under the module. ● **SEE FIGURES 56–16 AND 56–17**.

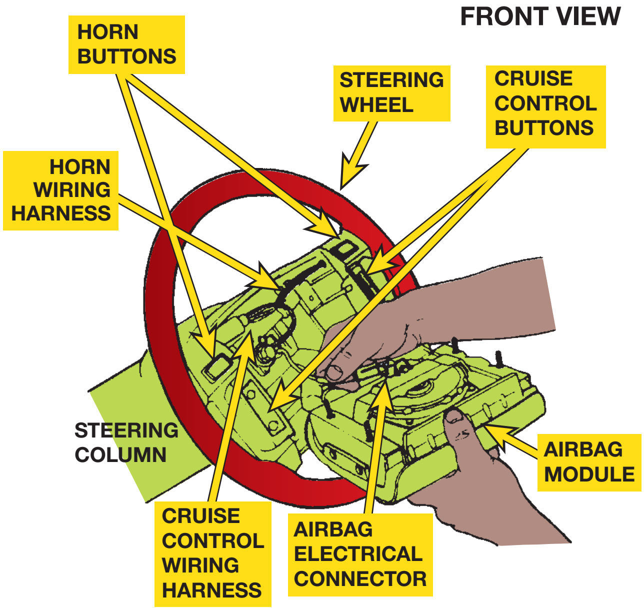

FIGURE 56–16 After disconnecting the battery and the yellow connector at the base of the steering column, the airbag inflator module can be removed from the steering wheel and the yellow airbag electrical connector at the inflator module be disconnected.

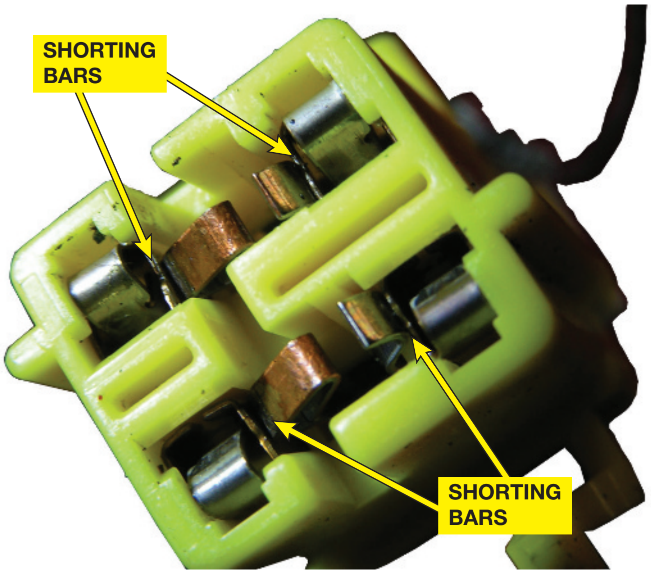

FIGURE 56–17 Shorting bars are used in most airbag connectors. These spring-loaded clips short across both terminals of an airbag connector when it is disconnected to help prevent accidental deployment of the airbag. If electrical power is applied to the terminals, the shorting bars simply provide a low-resistance path to the other terminal and do not allow current to flow past the connector. The mating part of the connector has a tapered piece that spreads apart the shorting bars when the connector is reconnected.

6. Store the module pad side up in a safe place where it cannot be disturbed or damaged while the vehicle is being serviced. Do not attempt to disassemble the airbag module. If the airbag is defective, replace the entire assembly.

When installing the airbag module, make sure the clockspring is correctly positioned to ensure module-to-steering-column continuity. ● **SEE FIGURE 56–18**.

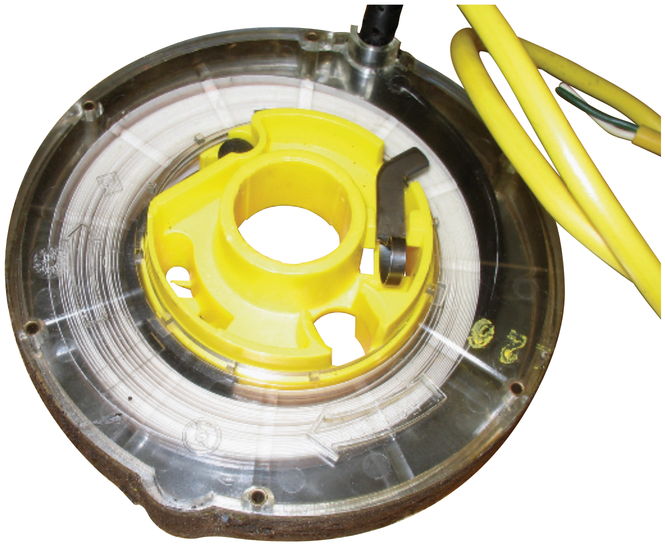

FIGURE 56–18 An airbag clockspring showing the flat conductor wire. It must be properly positioned to ensure proper operation.

Always route the wiring exactly as it was before removal. Also, make sure the module seats completely into the steering wheel. Secure the assembly using new fasteners, if specified.

SAFETY WHEN MANUALLY DEPLOYING AIRBAGS

Airbag modules cannot be disposed of unless they are deployed. Do the following to prevent injury when manually deploying an airbag:

- When possible, deploy the airbag outside of the vehicle. Follow the vehicle manufacturer's recommendations.
- Follow the vehicle manufacturer's procedures and equipment recommendations.
- Wear the proper hearing and eye protection.
- Deploy the airbag with the trim cover facing up.
- Stay at least 20 feet (6 m) from the airbag. (Use long jumper wires attached to the wiring and routed outside the vehicle to a battery.)
- Allow the airbag module to cool.

● **SEE FIGURE 56–19**.

OCCUPANT DETECTION SYSTEMS

PURPOSE AND FUNCTION The U.S. Federal Motor Vehicle Safety Standard 208 (FMVSS) specifies that the passenger side airbag be disabled or deployed with reduced force under the following conditions. This system is referred to as an **occupant detection system (ODS)** or the **passenger presence system (PPS)**.

- When there is no weight on the seat and no seat belt is fastened, the passenger-side airbag does not deploy and the passenger airbag light should be off. ● **SEE FIGURE 56–20**.

FIGURE 56–19 An airbag being deployed as part of a demonstration in an automotive laboratory.

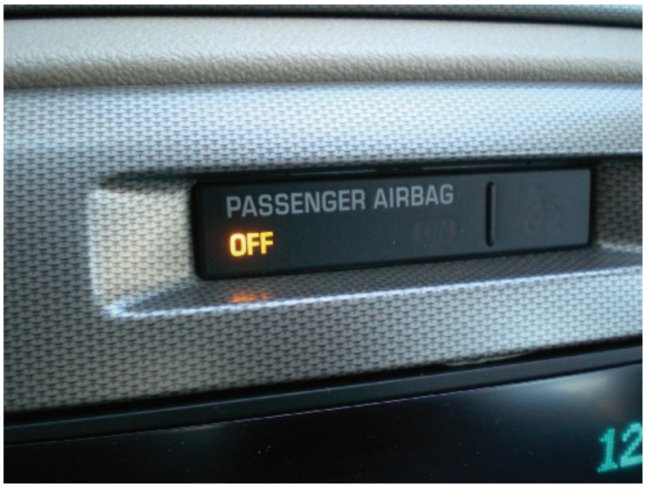

FIGURE 56–20 A dash warning lamp lights if the passenger side airbag is off because no passenger was detected by the seat sensor.

- The passenger-side airbag is disabled and the disabled airbag light is "on" only if at least 10 to 37 pounds (4.5 to 17 kg) is on the passenger seat, which generally represents a seated child.
- If 38 to 99 pounds (17 to 45 kg) is detected on the passenger seat, which represents a child or small adult, the airbag deploys at a decreased force.
- If 99 pounds (45 kg) or more is detected on the passenger seat, the airbag deploys at full force, depending on the severity of the crash, speed of the vehicle, and other factors, which may result in the airbag deploying at a reduced force.
  ● **SEE FIGURE 56–21**.

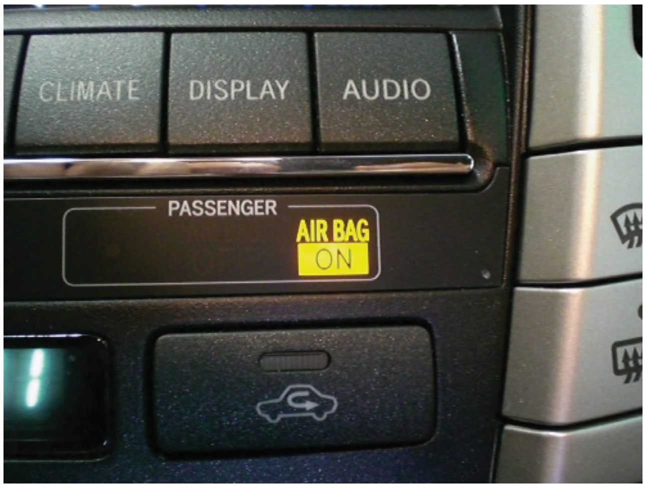

FIGURE 56–21 The passenger side airbag "on" lamp lights if a passenger is detected on the passenger seat.

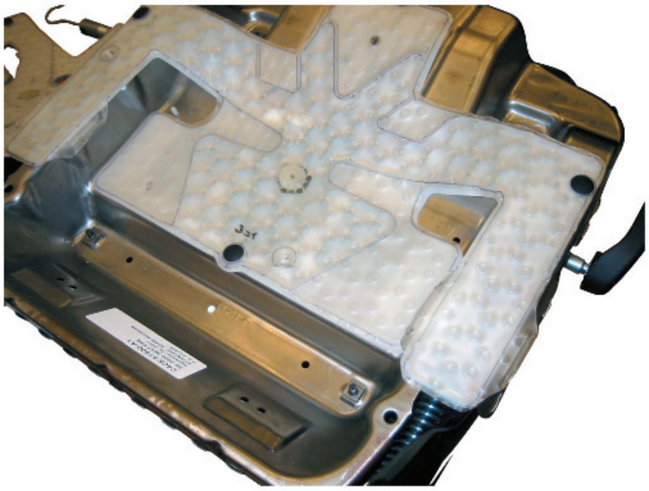

FIGURE 56–22 A gel-filled (bladder-type) occupant detection sensor showing the pressure sensor and wiring.

TYPE OF SEAT SENSOR The passenger presence system uses one of three types of sensors:

- **Gel-filled bladder sensor.** This type of occupant sensor uses a silicone-filled bag that has a pressure sensor attached. The weight of the passenger is measured by the pressure sensor, which sends a voltage signal to the module controlling the airbag deployment. A safety belt tension sensor is also used with a gel-filled bladder system to monitor the tension on the belt. The module then uses the information from both the bladder and the seat belt sensor to determine if a tightened belt may be used to restrain a child seat. ● **SEE FIGURE 56–22**.
- **Capacitive strip sensors.** This type of occupant sensor uses several flexible conductive metal strips under the seat cushion. These sensor strips transmit and receive a low-level electric field, which changes due to the weight of the front passenger seat occupant. The module determines the weight of the occupant based on the sensor values.
- **Force-sensing resistor sensors.** This type of occupant sensor uses resistors, which change their resistance based on the stress that is applied. These resistors are part of the

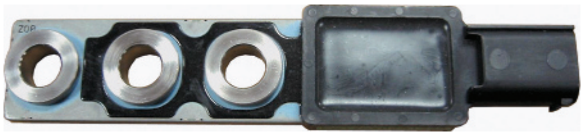

FIGURE 56–23 A resistor-type occupant detection sensor. The weight of the passenger strains these resistors, which are attached to the seat, thereby signaling to the module the weight of the occupant.

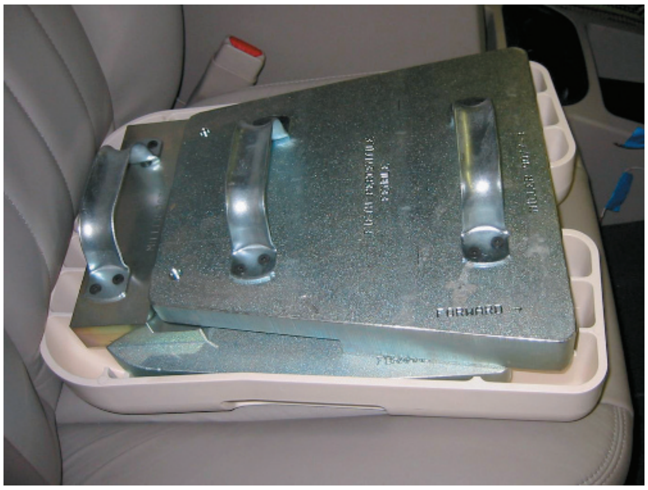

FIGURE 56–24 A test weight is used to calibrate the occupant detection system on a Chrysler vehicle.

seat structure, and the module can determine the weight of the occupant based on the change in the resistance of the sensors. ● **SEE FIGURE 56–23**.

CAUTION: Because the resistors are part of the seat structure, it is very important that all seat fasteners be torqued to factory specifications to ensure proper operation of the occupant detection system. A *seat track position* (STP) *sensor* is used by the airbag controller to determine the position of the seat. If the seat is too close to the airbag, the controller may disable the airbag.

DIAGNOSING OCCUPANT DETECTION SYSTEMS A fault in the system may cause the passenger side airbag light to turn on when there is no weight on the seat. A scan tool is often used to check or calibrate the seat, which must be empty, by commanding the module to rezero the seat sensor. Some systems, such as those on Chrysler vehicles, use a unit that has various weights along with a scan tool to calibrate and diagnose the occupant detection system. ● **SEE FIGURE 56–24**.

SEAT AND SIDE CURTAIN AIRBAGS

SEAT AIRBAGS Side and/or *curtain airbags* use a variety of sensors to determine if they need to be deployed. Side airbags are mounted in one of two general locations:

- In the side bolster of the seat (● **SEE FIGURE 56–25**.)
- In the door panel

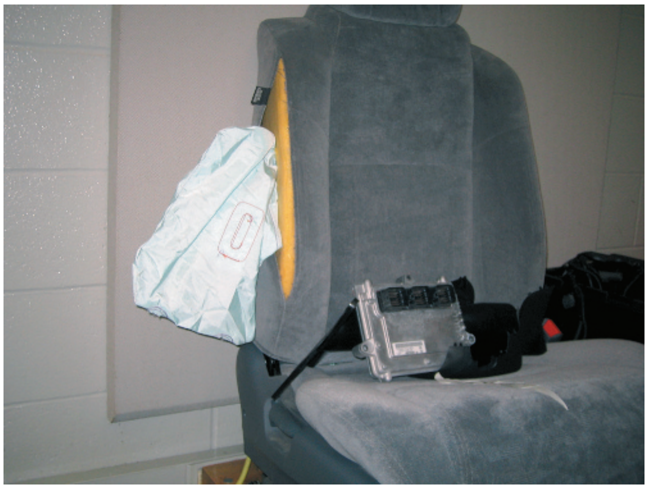

FIGURE 56–25 A typical seat (side) airbag that deploys from the side of the seat.

TECH TIP

Aggressive Driving and OnStar

If a vehicle equipped with the OnStar system is being driven aggressively and the electronic stability control system has to intercede to keep the vehicle under control, OnStar may call the vehicle to see if there has been an accident. The need for a call from OnStar is usually determined if the accelerometer registers slightly over 1 g-force, which could be achieved while driving on a race track.

Most side airbag sensors use an electronic accelerometer to detect when to deploy the airbags, which are usually mounted to the bottom of the left and right "B" pillars (where the front doors latch) behind a trim panel on the inside of the vehicle.

CAUTION: Avoid using a lockout tool (e.g., a "slim jim") in vehicles equipped with side airbags to help prevent damage to the components and wiring in the system.

SIDE CURTAIN AIRBAGS Side curtain airbags are usually deployed by a module based on input from many different sensors, including a lateral acceleration sensor and wheel speed sensors. For example, in one system used by Ford, the ABS controller commands that the brakes on one side of the vehicle be applied, using down pressure while monitoring the wheel speed sensors. If the wheels slow down with little brake pressure, the controller assumes that the vehicle could roll over, thereby deploying the side curtain airbags.

EVENT DATA RECORDERS

PARTS AND OPERATION As part of the airbag controller on many vehicles, the **event data recorder (EDR)** is used to record parameters just before and slightly after an airbag deployment. The following parameters are recorded:

- Vehicle speed
- Brake on/off

- Seat belt fastened
- G-forces as measured by the accelerometer

Unlike an airplane event data recorder, a vehicle unit is not a separate unit and does not record voice conversations nor include all crash parameters. This means that additional crash data, such as skid marks and physical evidence at the crash site, is needed to fully reconstruct the incident.

The EDR is embedded into the airbag controller and receives data from many sources and at varying sample rates. The data are constantly being stored in a memory buffer and are not recorded into the EPROM unless an airbag deployment has been commanded. The combined data are known as an *event file.* The airbag is commanded on, based on input mainly from the accelerometer sensor. This sensor, usually built into the airbag controller, is located inside the vehicle. The accelerometer calculates the rate of change of the speed of the vehicle. This determines the acceleration rate and is used to predict if that rate is high enough to deploy the frontal airbags. The airbags are deployed if the threshold g-value is exceeded. The passenger side airbag is also deployed unless it is suppressed by either of the following:

- No passenger is detected.
- The passenger side airbag switch is off.

DATA EXTRACTION Data extraction from the event data recorder in the airbag controller can only be achieved using a piece of equipment known as the Crash Data Retrieval System, manufactured by Vetronics Corporation. This is the only authorized method for retrieving event files and only certain organizations are allowed access to the data. These groups or organizations include:

- Original equipment manufacturer's representatives
- National Highway Traffic Safety Administration
- Law enforcement agencies
- Accident reconstruction companies

Crash data retrieval must only be done by a trained crash data retrieval (CDR) technician or analyst. A technician undergoes specialized training and must pass an examination. An analyst must attend additional training beyond that of a technician to achieve CDR analyst certification.

REVIEW QUESTIONS

1. What are the safety precautions to follow when working around an airbag?
2. What sensor(s) must be triggered for an airbag deployment?
3. How should deployed inflation modules be handled?
4. What is the purpose of pretensioners?
5. What is the purpose of the event data recorder?

CHAPTER QUIZ

1. A vehicle is being repaired after an airbag deployment. Technician A says that the inflator module should be handled as if it is still live. Technician B says gloves should be worn to prevent skin irritation. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. A seat belt pretensioner is ___________.
   a. a device that contains an explosive charge
   b. used to remove slack from the seat belt in the event of a collision
   c. used to force the occupant back into position against the seat back in the event of a collision
   d. All of the above
3. The occupant detection system measures the ___________ of the person in the passenger seat.
   a. height
   b. weight
   c. age
   d. distance from the seat belt
4. Two technicians are discussing dual-stage airbags. Technician A says that a deployed airbag is safe to handle, regardless of which stage caused the deployment of the airbag. Technician B says that both stages ignite, but at different speeds, depending on the speed of the vehicle. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
5. Where are shorting bars used?
   a. In pretensioners
   b. At the connectors for airbags
   c. In the crash sensors
   d. In the airbag controller
6. Technician A says that a deployed airbag can be repacked, reused, and reinstalled in the vehicle. Technician B says that a deployed airbag should be discarded and replaced with an entire new assembly. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

7. What color are the airbag electrical connectors and conduit?
  - **a.** Blue
  - **b.** Red
  - **c.** Yellow
  - **d.** Orange

8. On some vehicles, the side curtain airbags use which of the following devices to determine when to deploy?
  - **a.** Wheel speed sensors
  - **b.** Lateral acceleration sensor
  - **c.** Passenger presence system (PPS) seat sensor
  - **d.** Seat belt sensor

9. How many sensors must be triggered at the same time to cause an airbag deployment?
  - **a.** One
  - **b.** Two
  - **c.** Three
  - **d.** Four

10. Which parameters might be stored in the airbag controller in the event of a deployment?
  - **a.** Voice recordings
  - **b.** A 10-second video of the driver
  - **c.** Whether the windows were open or closed
  - **d.** Seat belt fastened

Chapter

57

BODY ELECTRICAL ACCESSORIES

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe how the horn operates.
- Diagnose faulty horn operation.
- Explain the testing and diagnosis of windshield wipers.
- Explain the testing and diagnosis of windshield washers.
- Describe how rain-sense wipers operate and are serviced.
- Describe the operation of the blower motor.
- Describe the operation of cruise control.
- Discuss electrically heated rear window defogger systems.
- Explain the operation and testing procedures for power windows.
- Discuss electric power door locks and trunk/lift gate locks.
- Discuss the operation of power sun roofs/moon roofs and sun shades.
- Describe the operation of power seats.
- Describe the operation of electrically heated seats and cooled seats.
- Describe the operation of heated steering wheels.
- Describe the operation of heated mirrors.
- Explain the operation of adjustable pedals and folding outside mirrors.
- Describe the operation and diagnosis of remote keyless entry.
- Describe the operation and diagnosis of garage door openers.
- Discuss remote start systems.
- Explain the diagnosis of body electrical communications systems and describe the process to reprogram electronic modules.

KEY TERMS:

Automatic reversal systems (ARS) 678 • Cruise control 675 • Electric adjustable pedals (EAP) 685 • Heated rear window defogger 676 • Heated seats 684 • Heated steering wheel 685 • Horns 665 • Moon roof 681 • Over the air (OTA) 690 • Passive entry, passive starting (PEPS) 688 • Power windows 678 • Pulse wipers 668 • Rain-sense wipers 672 • Remote start 689 • Sun roof 681 • Sun shades 681 • Variable-delay wipers 668 • Windshield wipers 666

HORNS

PURPOSE AND FUNCTION **Horns** are electric devices that emit a loud sound used to alert other drivers or persons in the area. Horns are manufactured in several different tones, ranging from 1,800 to 3,550 Hz, and must be heard from a minimum distance of 200 feet (60 m). Vehicle manufacturers select from various horn tones for a particular vehicle sound. ● **SEE FIGURE 57–1**.

When two horns are used, each has a different tone, yet the sound combines when both are operated. Most horns since 2000 have used the body control module (BCM) to control the actual operation.

HORN CIRCUITS Automotive horns usually operate on full battery voltage wired from the battery, through a fuse. Older vehicles use a horn relay with a horn button on the steering wheel or column that completes a circuit to ground that closes the control side of the relay. The heavy current flow required to operate the horn travels through the load side of the relay to the horn. ● **SEE FIGURE 57–2**.

FIGURE 57–1 Two horns are used on this vehicle. Many vehicles use only one horn, often hidden underneath the vehicle.

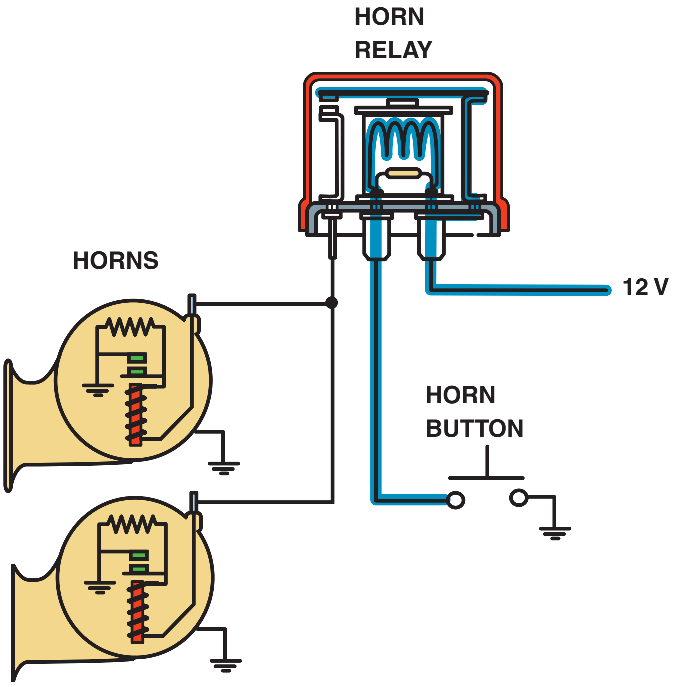

FIGURE 57–2 A simplified horn circuit where the horn button completes the ground circuit of the relay coil.

COMPUTER-CONTROLLED HORNS On most recent model vehicles, the horn button is an input to the body control module (BCM) or electronic control unit (ECU). The BCM controls the operation of the horn relay. The horn relay may also be controlled by the BCM, which "beeps" the horn when the vehicle is locked or unlocked, using the key fob remote, and can be sounded by the alarm system. Check service information for the exact details about the horn circuit for the vehicle being checked. ● **SEE FIGURE 57–3.**

HORN OPERATION A vehicle horn is an actuator that converts an electrical signal to sound. The horn circuit has an armature (a coil of wire) and contacts that are attached to a diaphragm. When energized, the armature causes the diaphragm to move up, which then opens a set of contact points that de-energize the armature circuit. As the diaphragm moves down, the contact points close, re-energizing the armature circuit, and the diaphragm moves up again. This rapid opening and closing of the contact points causes the diaphragm to vibrate at an audible frequency. The sound created by the diaphragm is magnified as it travels through a trumpet attached to the diaphragm chamber. Most horn systems typically use one or two horns, but some have up to four. Those with multiple horns use both high- and low-pitch units to achieve a harmonious tone. Only a high-pitched unit is used in single-horn applications. The horn assembly is marked with an "H" or "L" for pitch identification.

HORN DIAGNOSIS

SCAN TOOL TESTING A scan tool can be used to test a horn that is computer controlled by using the bidirectional feature of a factory or factory-level aftermarket scan tool. Because most horn buttons are an input to the BCM or similar module, a scan tool can often be used to command the horn to sound. Check service information for the vehicle being tested for the exact tests and testing procedures to follow.

HORN CIRCUIT TESTING Once the cause of an inoperative horn has been reduced to the horn wiring circuit, the wiring needs to be checked. Typically, a digital multimeter (DMM) is used to perform voltage drop and continuity checks to isolate the failure. A momentary contact switch, horn button, is used to sound the horn. The horn switch is mounted to the steering wheel in or near the center of the steering column.

CAUTION: If the steering wheel needs to be removed for diagnosis or repair of the horn circuit, follow service information procedures for disarming the airbag circuit prior to removing the steering wheel, and for the specified test equipment to use.

On most recent-model vehicles, the horn relay is in a centralized power distribution center along with other relays, circuit breakers, and fuses. Check the relay to determine if the coil is being energized and if current passes through the power circuit when the horn switch is depressed. Check service information for the exact diagnosis and horn replacement procedures to follow.

HORN REPLACEMENT Horns are generally mounted on the radiator core support by bolts and nuts or sheet metal screws. To replace a horn, remove the fasteners and lift the old horn from its mounting bracket. Clean the attachment area on the mounting bracket and chassis before installing the new horn. Some models use a corrosion-resistant mounting bolt to ensure a ground connection.

WINDSHIELD WIPERS

PURPOSE AND FUNCTION **Windshield wipers** are used to keep the viewing area of the windshield clear of rain. Windshield wiper systems and circuits vary greatly between manufacturers as well as between models. Some vehicles combine the windshield wiper and windshield washer functions into a single system. Many minivans and sport utility vehicles (SUVs) also have a rear window wiper and washer system that works independently of the windshield system. Generally, all windshield and rear window wiper and washer systems operate in a similar fashion. Wiper control switches are installed on the steering column, usually as part of a multifunction switch that controls several other functions.

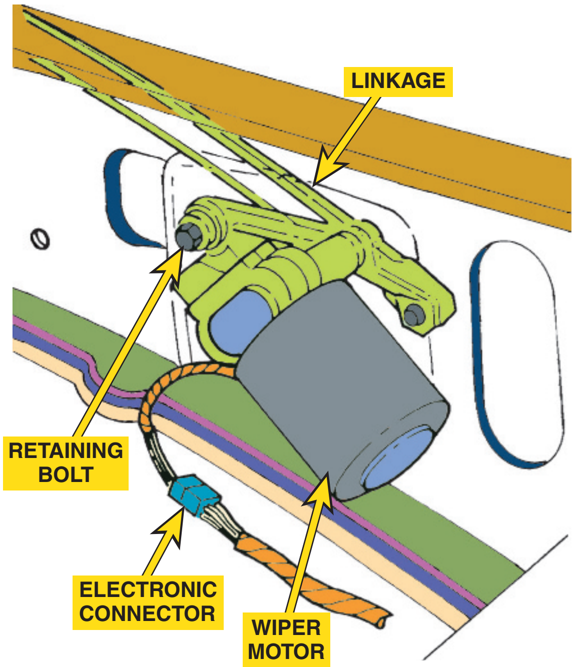
COMPUTER CONTROLLED WIPERS Most wipers, since the 1990s, have used the BCM to control the actual operation of the wiper. The wiper controls are an input to the control module and may also turn on the headlights whenever the wipers are on, which is the law in some states. ● **SEE FIGURE 57–4**.



LINKAGE
RETAINING BOLT
ELECTRONIC CONNECTOR
WIPER MOTOR

FIGURE 57–4 The motor and linkage bolt to the body and connect to the switch with a wiring harness.

WIPER AND WASHER COMPONENTS A typical combination wiper and washer system consists of the following:

- Wiper motor(s)
- Gearbox
- Wiper arms and linkage
- Wiper blades
- Washer pump
- Hoses and jets (nozzles)
- Fluid reservoir
- Combination switch
- Wiring and electrical connectors

● **SEE FIGURE 57–5**.

WINDSHIELD WIPER MOTORS The windshield wipers ordinarily use a special two-speed electric motor. Some are compound-wound motors, a motor type that provides for two different speeds.

- Series-wound field
- Shunt field

One speed is achieved in the series-wound field and the other speed in the shunt-wound field. Other wiper motors are of the permanent magnet type. ● **SEE FIGURE 57–6**.

WIPER MOTOR OPERATION Wiper motors using a permanent magnet motor have a low-speed positive brush, a high-speed positive brush, and a ground (negative) brush. The brushes connect the battery to the internal windings of the motor, and the

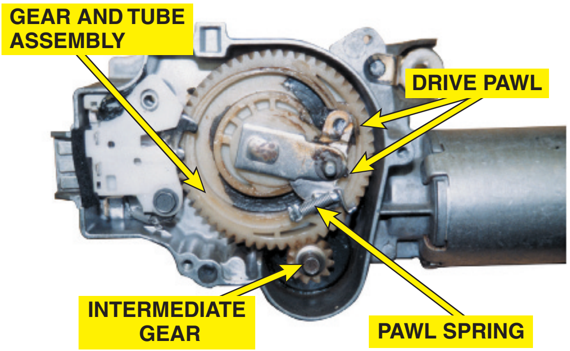


FIGURE 57–5 A typical wiper motor with the housing cover removed. The motor itself has a worm gear on the shaft that turns the small intermediate gear, which then rotates the gear and tube assembly, which rotates the crank arm (not shown) that connects to the wiper linkage.

FREQUENTLY ASKED QUESTION

How Do Wipers Park?

Some vehicles have wiper arms that park lower than the normal operating position, so they are hidden below the hood when not in operation. This is called a *depressed park position.* When the wiper motor is turned off, the park switch allows the motor to continue to turn until the wiper arms reach the bottom edge of the windshield. Then the park switch reverses the current flow through the wiper motor, which makes a partial revolution in the opposite direction.

The wiper linkage pulls the wiper arms down below the level of the hood and the park switch is opened, stopping the wiper motor.

two brushes provide for two different motor speeds. The ground brush is directly opposite the low-speed brush. The high-speed brush is off to the side of the low-speed brush. When current flows through the high-speed brush, there are fewer turns on the armature between the hot and ground brushes and, therefore, the resistance is less. With less resistance, more current flows and the armature revolves faster.

PARK POSITION Windshield wiper motor park operation is controlled by the wiper motor module using an input from the park switch within the wiper motor assembly. When the windshield wiper/washer switch is turned to the OFF position while the wiper blades are somewhere on the windshield, the wiper motor module continues to operate the wiper motor until the wipers reach the park position. Check service information for the exact operation for the vehicle being serviced.

VARIABLE WIPERS The **variable-delay wipers** (also called **pulse wipers**) is a term used to describe the operation of the wipers that operate on an interval that can be delayed when the rain is light. Older vehicles use an electronic circuit with a variable resistor that controls the time of the charge and discharge of a capacitor. The charging and discharging of the capacitor controls the circuit for the operation of the wiper motor. On newer vehicles, the wipers are controlled by the BCM with input from the driver using a knob or dial to adjust the wiper interval.

WINDSHIELD WIPER DIAGNOSIS If the windshield wipers are not working, use a factory or factory-level scan tool and check for operation using the bidirectional controls.

- If the wipers function when commanded by the scan tool, check service information for the exact procedures to follow when checking the switch input and BCM connections.
- If the wipers do not function when being commanded by the scan tool, perform circuit testing, which usually includes determining if the fault is electrical or mechanical. ● **SEE FIGURE 57–7**.

To determine if there is an electrical or mechanical problem, access the motor assembly and disconnect the wiper arm linkage

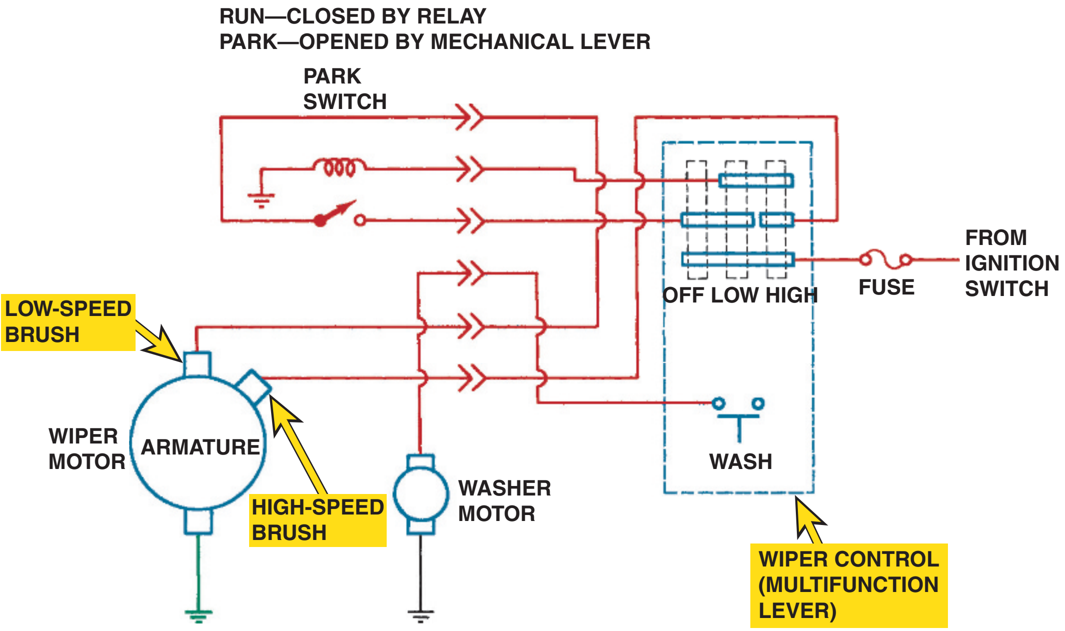

FIGURE 57–6 A wiring diagram of a two-speed windshield wiper circuit using a three-brush, two-speed motor. The dashed line for the multifunction lever indicates that the circuit shown is only part of the total function of the steering column lever.

CASE STUDY

Wipers Would Stop Working

The owner of a Ford Focus stated that the wipers would stop working randomly in the middle of a sweep. The technician saw that the wiper blades were aftermarket multiple blade type. The wiper motors have a fail-safe over load protection built in. If the body control module (BCM) detects too much current, it will shut the motors down to protect them. The motors communicate over a LIN network between the two motors.

The technician replaced the wiper blades with factor original equipment (OE) blades. This corrected the customer concern.

Summary:

Complaint—The wipers would stop working randomly in the middle of a sweep.
Cause—The aftermarket wiper blades created too much of a drag on the wiper motor and caused it to stop working.
Correction—The wiper blades were replaced with the factory original type.

from the motor and gearbox. If the motor operates, but the wipers do not, check for the following:

- Stripped gears in the gearbox or stripped linkage connection
- Loose or separated motor-to-gearbox connection
- Loose linkage to the motor connection

If the motor does not shut off, check for the following:

- Defective park switch inside the motor
- Defective wiper switch
- Poor ground connection at the wiper switch

WIPER MOTOR REPLACEMENT Wiper motors are replaced if defective. The motor usually mounts on the bulkhead (firewall). Bulkhead-mounted units are accessible from under the hood, while the cowl panel needs to be removed to service a motor mounted in the cowl. ● **SEE FIGURE 57–8**.

REAR WIPERS Rear window wiper motors are generally located inside the rear hatch panel on vehicles with a hatchback or lift gate. After removing the trim panel covering the motor, replacement is essentially the same as replacing the front wiper motor.

WINDSHIELD WASHERS

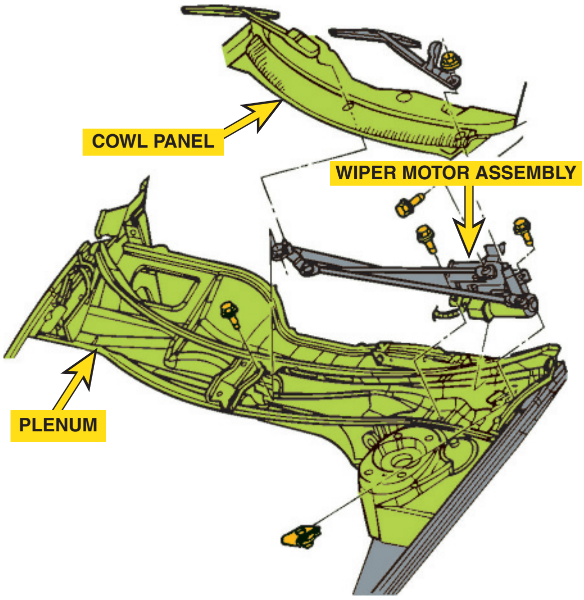

FIGURE 57–8 The wiper motor and linkage mount under the cowl panel on many vehicles.

OPERATION Windshield washers are used to squirt washer fluid onto the surface of the windshield where it can help dissolve debris and clean the viewing area of the windshield when the wipers are used. Most vehicle windshield washers use a positive-displacement or centrifugal-type washer pump located in the washer reservoir. A momentary contact switch, which is often part of a steering column–mounted combination switch assembly, energizes the washer pump. Washer pump switches are installed either on the steering column or on the instrument panel. The nozzles can be located on the bulkhead, in the hood, or mounted as part of the wiper arms, depending on the vehicle.

REAR WASHERS Vehicles equipped with a rear wiper are also equipped with a rear washer. The rear washer may share a fluid reservoir with the front wipers, or it may have its own reservoir.

TECH TIP

Scan Tool Bidirectional Control

Most vehicles built since 2000 can have the lighting and accessory circuits checked using a scan tool. A technician can use the following:

Factory scan tool, such as:

- GDS II (General Motors vehicles)
- DRB III, Star Scan, Star Mobile, WiTech, or MicroPOD II (Chrysler-Jeep vehicles)
- New Generation Star or IDS (Ford)
- Honda Diagnostic System (HDS)
- TIS Tech Stream (Toyota/Lexus)

An enhanced aftermarket scan tool has body bidirectional control capability, including

- Snap-on Modis, Solus, or Verus
- OTC Genisys
- AutoEnginuity

Using a bidirectional scan tool allows the technician to command the operation of electrical accessories, such as horns, windows, lights, door locks, and wipers. ● **SEE FIGURE 57–9**.

If the circuit operates correctly when commanded by the scan tool and does not function using the switch(s), follow service information instructions for the exact tests and testing procedures to follow for the vehicle being tested.

FIGURE 57–9 A typical schematic showing how relays inside the front control module are all tied to other modules on the BUSS.

The rear washer switch is located on either the steering column or on the instrument panel.

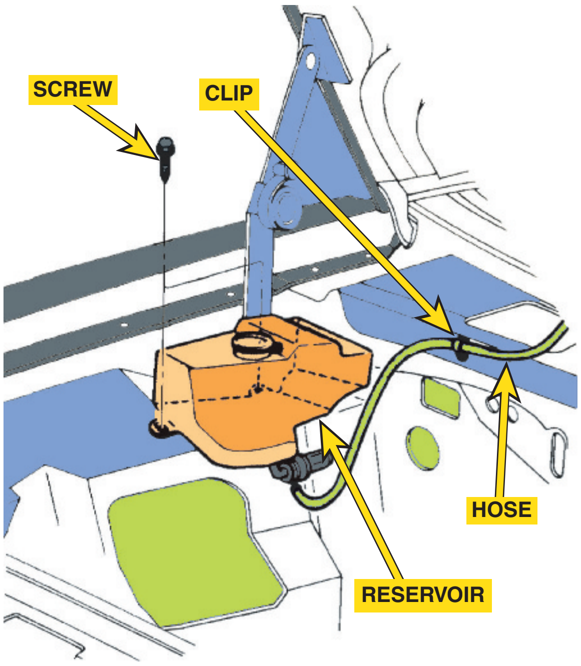
HEADLIGHT WASHERS Many vehicles are equipped with headlight washers that spray washer fluid into the surface of the headlights when actuated. Some systems even include small wiper blades. Headlight washers are usually operated from the main headlight control switch, if equipped. Most headlight washers use the same windshield washer reservoir as is used for the front windshield washers.

WINDSHIELD WASHER DIAGNOSIS To diagnose the washer system, follow service information procedures that usually include the following steps:

STEP 1 To quick check any washer system, make sure the reservoir has fluid and is not frozen. Then, disconnect the pump hose and operate the washer switch.

NOTE: Always use good-quality windshield washer fluid from a closed container to prevent contaminated fluid from damaging the washer pump. Radiator antifreeze (ethylene glycol) should never be used in any windshield wiper system.

● **SEE FIGURE 57–10.**



SCREW
CLIP
HOSE
RESERVOIR

FIGURE 57–10 A typical windshield washer reservoir and pump assembly.

STEP 2 If fluid squirts from the pump, the delivery system is at fault, not the motor, switch, or the electrical circuits (switch input, BCM, etc.).

STEP 3 If no fluid squirts from the pump, the problem is most likely a circuit failure, defective pump, or faulty switch.

STEP 4 A clogged reservoir screen also may be preventing fluid from entering the pump.

WINDSHIELD WASHER SERVICE

When a fluid delivery problem is indicated, check for:

- Blocked, pinched, broken, or disconnected hoses
- Clogged nozzles
- Blocked washer pump outlet

If the pump motor does not operate, check for battery voltage available at the pump while operating the washer switch.

- If voltage is available and the pump does not run, check for continuity on the pump ground circuit.
- If there is no voltage drop on the ground circuit, replace the pump motor. If battery voltage is not available at the motor, check for power through the washer switch.
- If voltage is available at and through the switch, there is a problem in the wiring between the switch and pump. Perform voltage drop tests to locate the fault. Repair the wiring as needed and retest.

Washer motors are not repairable and are replaced if defective. Centrifugal or positive-displacement pumps are located on or inside the washer reservoir tank or cover. ● **SEE FIGURE 57–11**.

RAIN-SENSE WIPERS

PARTS AND OPERATION

Rain-sense wiper systems use a sensor located on the inside and at the top of the windshield to detect rain droplets. This sensor is often called the *rain-sense module (RSM)*. It determines and adjusts the time delay of the wiper based on how much moisture it detects on the windshield. The wiper switch can be left on the sense position all the time, and if no rain is sensed, the wipers do not swipe. ● **SEE FIGURE 57–12**.

The control knob is rotated to the desired wiper sensibility level. The microprocessor in the RSM sends a command to the body control module. The rain-sense module is a triangle- or rectangle-shaped black plastic housing. Fine openings on the windshield side of the housing are fitted with eight convex clear plastic lenses. The unit contains four infrared (IR) diodes, two photocells, and a microprocessor.

The IR diodes generate IR beams that are aimed by four of the convex optical lenses near the base of the module through the windshield glass. Four additional convex lenses near the top of the RSM are focused on the IR light beam on the outside of the windshield glass and allow the two photocells to sense changes in the intensity of the IR light beam. When sufficient moisture accumulates, the RSM detects a change in the monitored IR light beam intensity. The RSM processes the rain intensity signal and sends it over the data BUS to the BCM, which then commands a swipe of the wiper. ● **SEE FIGURE 57–13**.

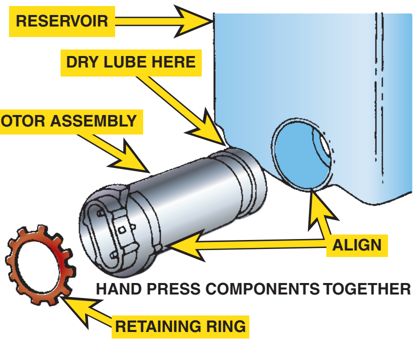


FIGURE 57–11 Washer pumps usually install into the reservoir and are held in place with a retaining ring.

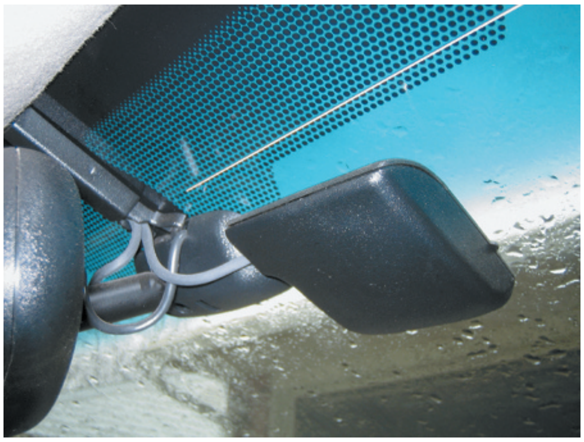

FIGURE 57–12 A typical rain-sensing module located on the inside of the windshield near the inside rearview mirror.

CASE STUDY

Intermittent Wipers Inoperative

The owner of a Chevrolet Tahoe LTZ complained the intermittent wipers did not work. On the initial selection of the wiper switch to one of the pulse positions, the wipers made one swipe and stopped working after that. The wipers would just sit in the park position. The low speed, high speed, and park positions worked fine.

This vehicle was equipped with rain-sense wipers. The wipers are not supposed to work in the pulse mode unless there is water on the windshield. In this case, the rain sensor at the top of the windshield was defective. The wipers would not come on because the body control module (BCM) was not being notified that there was a wipe pulse required. The rain sensor was replaced. After replacement of the sensor, with wipers in pulse mode, the windshield was sprayed with a spray bottle and the wipers operated correctly.

Summary:

Complaint—Intermittent wipers inoperative.
Cause—The rain senor on the inside of the windshield was defective.
Correction—The rain sensor was replaced and normal operation of the windshield wipers was restored.

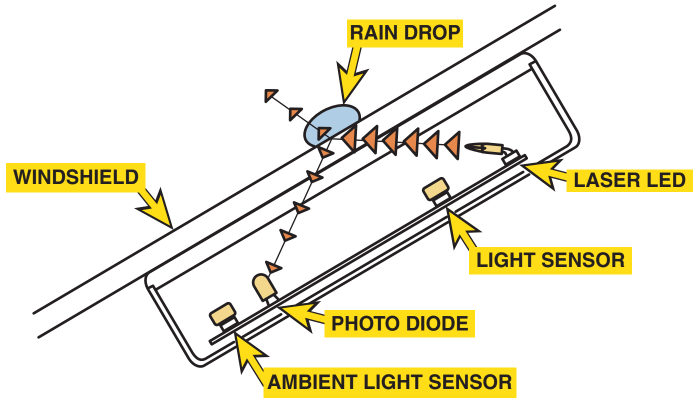

FIGURE 57–13 The electronics in the rain-sense wiper module can detect the presence of rain drops under various lighting conditions.

TECH TIP

Rain Sense and Cruise Control

The rain-sense wiper module communicates with the BCM over the data links and, if the rain is heavy, a signal is sent to deactivate the cruise control. A message is then displayed on the instrument panel warning that the cruise control is not available. This is normal operation and is used to help prevent the vehicle from hydroplaning during heavy rain. Normal cruise control operation resumes when the rain intensity is reduced. This is normal operation and not a fault with the cruise control system.

DIAGNOSIS AND SERVICE If there is a complaint about the rain-sense wipers not functioning correctly, check the owner's manual to be sure that they are properly set. Also, verify that the windshield wipers are functioning correctly on all speeds before diagnosing the rain-sensor circuits. Most rain-sensing wiper systems can be tested by misting water on the windshield in the area of the sensor. Always follow the vehicle manufacturer's recommended diagnosis and testing procedures.

BLOWER MOTOR

PURPOSE AND FUNCTION The same blower motor moves air inside the vehicle for:

1. Air conditioning
2. Heat
3. Defrosting
4. Defogging
5. Venting of the passenger compartment.

The motor turns a squirrel cage-type fan. A squirrel cage-type fan is able to move air without creating a lot of noise. The fan switch controls the path that the current follows to the blower motor. ● **SEE FIGURE 57–14.**

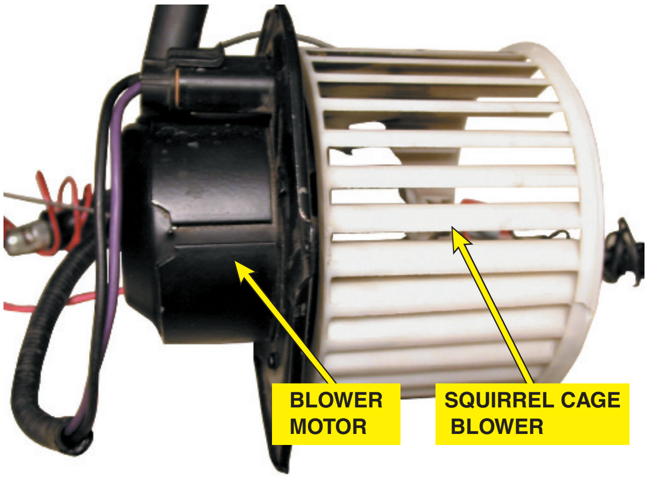

FIGURE 57–14 A squirrel cage blower motor. A replacement blower motor usually does not come equipped with the squirrel cage blower, so it has to be switched from the old motor.

PARTS AND OPERATION The motor is usually a permanent magnet, one-speed motor that operates at its maximum speed with full battery voltage. The switch gets current from the fuse panel with the ignition switch on, and then directs full battery voltage to the blower motor for high speed and to the blower motor through resistors for lower speeds.

VARIABLE SPEED CONTROL The fan switch controls the path of current through a resistor pack to obtain different fan speeds of the blower motor. The electrical path can be:

- Full battery voltage for high-speed operation
- Through one or more resistors to reduce the voltage and the current to the blower motor, which then rotates at a slower speed.

The resistors are located near the blower motor and mounted in the duct where the airflow from the blower can cool the resistors. The current flow through the resistor is controlled by the switch and often uses a relay to carry the heavy current (10 to 12 amperes) needed to power the fan. Normal operation includes

- Low speed. Current flows through three resistors in series to drop the voltage to about 4 volts and 4 amperes
- Medium-low speed. Current is directed through two resistors in series to lower the voltage to about 6 volts and 6 amperes
- Medium-high speed. Current is directed through one resistor resulting in a voltage of about 9 volts and 9 amperes
- High speed. Full battery voltage, usually through a relay, is applied to the blower motor resulting in a current of about 12 amperes. ● **SEE FIGURES 57–15 AND 57–16.**

Some blower motors are electronically controlled by the body control module and include electronic circuits to achieve a variable speed. ● **SEE FIGURE 57–17.**

BLOWER MOTOR DIAGNOSIS If the blower motor does not operate at any speed, the problem could be any of the following:

1. Defective ground wire or ground wire connection.
2. Defective blower motor (not repairable; must be replaced).
3. Open circuit in the power-side circuit, including fuse, wiring, or fan switch. If the blower works on lower speeds, but

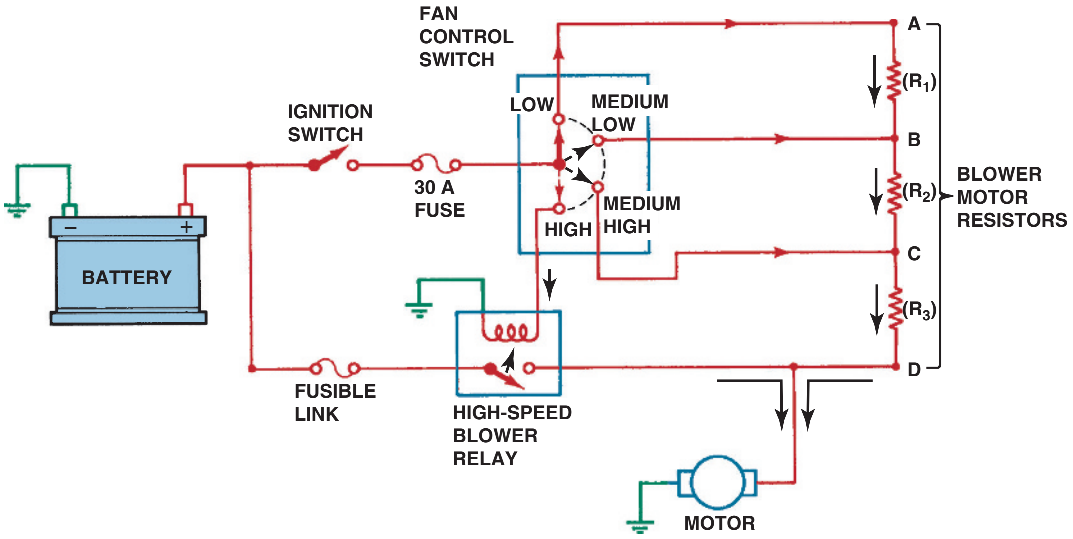

FIGURE 57–15 A blower motor circuit with four speeds controlled by resistors. The three lowest fan speeds (low, medium-low, and medium-high) use the blower motor resistors to drop the voltage to the motor and reduce current to the motor. On high, the resistors are bypassed. The "high" position on the fan switch energizes a relay, which supplies the current for the blower on high through a fusible link or maxi fuse.

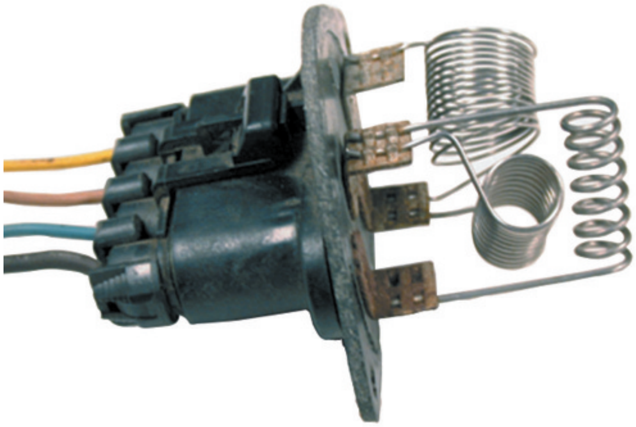

FIGURE 57–16 A blower motor resistor pack used to control blower motor speed. Some blower motor resistors are flat and look like a credit card and are called credit card resistors.

not on high speed, the problem is usually an in-line fuse or high-speed relay that controls the heavy current flow for high-speed operation.

The high-speed fuse or relay usually fails as a result of internal blower motor bushing wear, which causes excessive resistance to motor rotation. At slow blower speeds, the resistance is not as noticeable and the blower operates normally. The blower motor is a sealed unit and, if defective, must be replaced as a unit. The squirrel-cage fan usually needs to be removed from the old motor and attached to the replacement motor. If the blower motor operates normally at high speed, but not at any of the lower speeds, the problem could be melted wire resistors or a defective switch.

The blower motor can be tested using a clamp-on DC ammeter. ● **SEE FIGURE 57–18**.

Most blower motors do not draw more than 15 amperes on high speed. A worn or defective motor usually draws more current than normal and could damage the blower motor resistors or blow a fuse if not replaced.

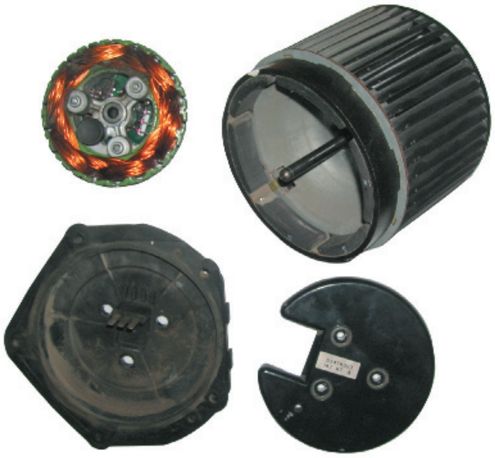

FIGURE 57–17 A brushless DC motor that uses the body computer to control the speed.

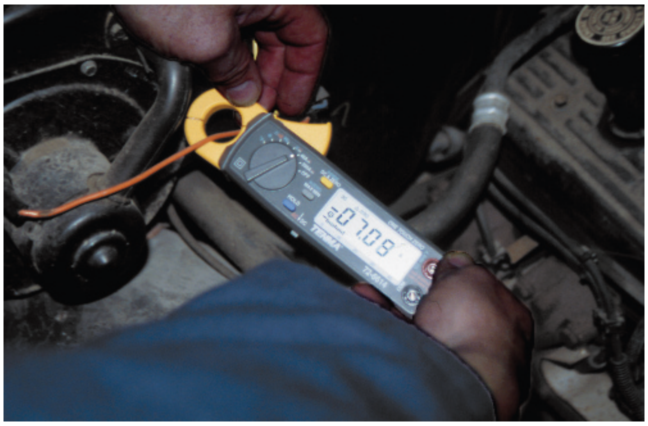

FIGURE 57–18 Using a mini AC/DC clamp-on multimeter to measure the current drawn by a blower motor.

CRUISE CONTROL

PURPOSE AND FUNCTION **Cruise control**, also called vehicle *speed control*, is used to maintain a preset vehicle speed, even up gentle grades. Some vehicles are programmed to downshift the transmission to maintain the vehicle speed when descending grades if the speed increases more than 5 MPH (7 km/h) faster than the preset speed. Using cruise control avoids the tendency to drive at varying speeds, helps to reduce driver fatigue, and allows for driver position changes when driving for a long period of time. Cruise control should be avoided if driving on curving roads or when it is raining.

CRUISE CONTROL OPERATION A typical cruise control system can be set only if the vehicle speed is 25 MPH (40 km/h) or more. Computer-controlled cruise control systems use the vehicle's speed sensor input to the powertrain control module (PCM) for speed reference. Older systems use a throttle actuator to control the throttle opening, control switches for driver control of cruise control functions, and electrical brake and clutch (if equipped) pedal-release switches. The typical actuator uses a stepper motor or vacuum to move the throttle linkage based on commands from the cruise control module, which is often inside the cruise control assembly. ● **SEE FIGURE 57–19**.

ELECTRONIC THROTTLE CRUISE CONTROL Many vehicles are equipped with an electronic throttle control (ETC) system. Vehicles equipped with such a system do not use throttle actuators for the cruise control, but instead use the electronic throttle to control vehicle speed. ● **SEE FIGURE 57–20**.

The cruise control on a vehicle equipped with an electronic throttle control system consists of a switch to set the desired

FIGURE 57–19 Circuit diagram of a typical electronic cruise control system.

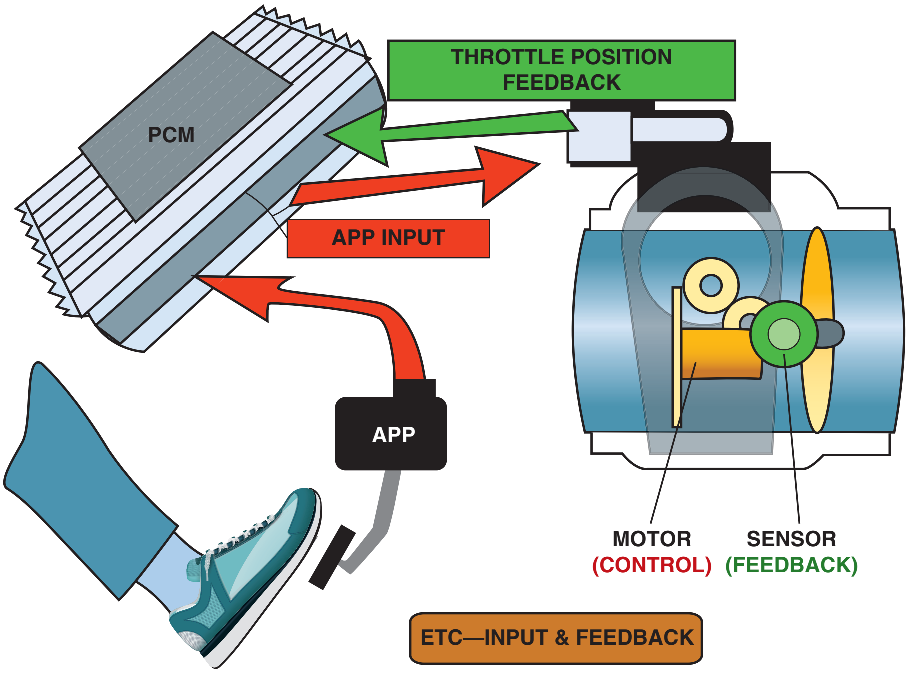

FIGURE 57–20 The electronic throttle control (ETC) system uses a sensor that measures the position and the speed of the driver's foot on the accelerator pedal. A throttle position sensor measures the throttle angle. An electric motor operates the movement of the throttle plate using commands from the PCM.

speed. The PCM receives the vehicle speed information from the vehicle speed (VS) sensor. The PCM then commands the ETC throttle to open or close the throttle valve as needed to maintain desired vehicle speed.

DIAGNOSIS AND SERVICE Any fault in the accelerator pedal position (APP) sensor, brake switch, or ETC system disables the cruise control function. Always follow the specified troubleshooting procedures, which usually include the use of a scan tool to properly diagnose the ETC system.

HEATED REAR WINDOW DEFOGGERS

PARTS AND OPERATION An electrically **heated rear window defogger** system uses an electrical grid baked on the glass that warms the glass to about 85°F (29°C) and clears it of fog or frost. The rear window is also called a *backlight*. The rear window defogger system is controlled by a driver-operated switch and a timer relay. ● **SEE FIGURE 57–21**.

The timer relay is necessary because the window grid can draw up to 30 amperes, and continued operation puts a strain on the battery and the charging system. Generally, the timer relay permits current to flow through the rear window grid for only 10 minutes. If the window is still not clear of fog after 10 minutes, the driver can turn the defogger on again, but after the first 10 minutes, any additional defogger operation is limited to 5 minutes.

The electrical current through the grids depends, in part, on the temperature of the conductor grids. As the temperature decreases, the resistance of the grids decreases and the current flow increases, helping to warm the rear glass. As the temperature of the glass increases, the resistance of the conductor grids increases and the current flow decreases. Therefore, the defogger system tends to self-regulate the electrical current requirements to match the need for defogging.

NOTE: Some vehicles use the wire grid of the rear window defogger as the radio antenna. Therefore, if the grid is damaged, radio reception can also be affected.

TECH TIP

Bump Problems

Cruise control problem diagnosis can involve a complex series of checks and tests. The troubleshooting procedures vary among manufacturers (and year), so a technician should always check service information for the exact vehicle being serviced. However, every cruise control system uses a brake safety switch and, if the vehicle has manual transmission, a clutch safety switch. The purpose of these safety switches is to ensure that the cruise control system is disabled if the brakes or the clutch are applied. Some systems use a redundant brake pedal safety switch. If the cruise control "cuts out" or disengages itself while traveling over bumpy roads, the most common cause is a misadjusted brake (and/or clutch) safety switch(es). Often, a simple readjustment of these safety switches cures the intermittent cruise control disengagement problems.

CAUTION: Always follow the manufacturer's recommended safety switch adjustment procedures. If the brake safety switch(es) is misadjusted, it could keep pressure applied to the master brake cylinder, resulting in severe damage to the braking system.

TECH TIP

Check the Brake Lights

On many vehicles, the cruise control does not work if the brake lights are not working. This includes the third brake light, commonly called the center high-mounted stop light (CHMSL). Always check for the proper operation of the brake lights first if the cruise control does not work.

TECH TIP

The Infrared Camera Test

It is difficult to test for the proper operation of all grids of a rear window defogger unless the rear window happens to be covered with fog. A common trick that works is to turn on the rear defogger and look at the outside of the rear window glass using an infrared camera. The image shows if all sections of the rear grids are working. ● **SEE FIGURE 57–22**.

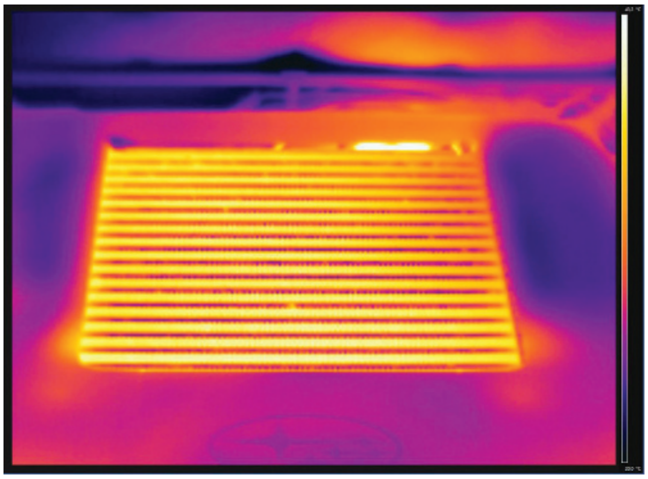

FIGURE 57–22 A typical image captured using an infrared camera of a rear defogger that is working as designed.

HEATED REAR WINDOW DEFOGGER DIAGNOSIS Troubleshooting a nonfunctioning rear window defogger unit involves using a test light or a voltmeter to check for voltage to the grid. If no voltage is present at the rear window, check for voltage at the

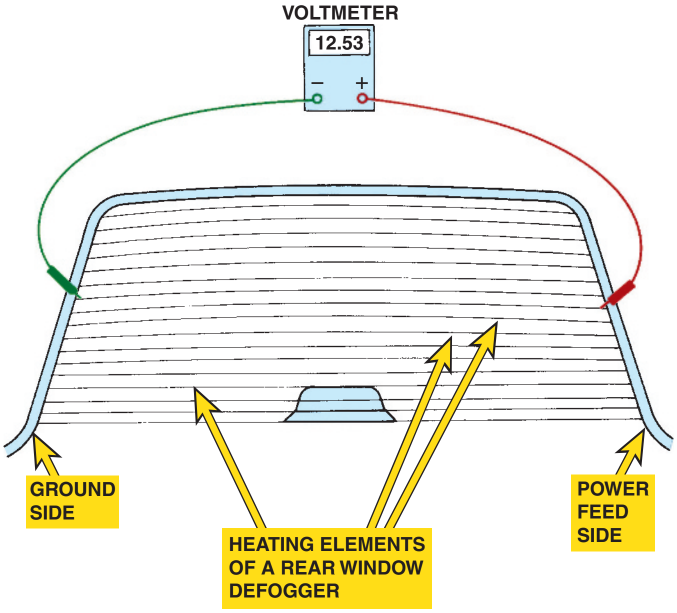

FIGURE 57–23 A rear window defogger electrical grid can be tested using a voltmeter to check for a decreasing voltage as the meter lead is moved from the power side toward the ground side. As the voltmeter positive lead is moved along the grid (on the inside of the vehicle), the voltmeter reading should steadily decrease as the meter approaches the ground side of the grid.

switch and relay timer assembly. A poor ground connection on the opposite side of the grid from the power side can also cause the rear defogger not to operate. Because most defogger circuits use an indicator light switch and a relay timer, it is possible to have the indicator light on, even if the wires are disconnected at the rear window grid. A voltmeter can be used to test the operation of the rear window defogger grid. ● **SEE FIGURE 57–23**.

With the negative meter lead attached to a good body ground, carefully touch the positive meter lead to the grid conductors. There should be a decreasing voltage reading as the meter lead is moved from the power ("hot") side of the grid toward the ground side of the grid.

REPAIR OR REPLACEMENT Electric grid-type rear window defoggers can be damaged easily by careless cleaning or scraping of the inside of the rear window glass. If there is a broken grid wire, it can be repaired using an electrically conductive substance available in a repair kit. Most vehicle manufacturers recommend that grid wire less than 2 inches (5 cm) long be repaired. If a bad section is longer than 2 inches, the entire rear window needs to be replaced.

POWER WINDOWS

SWITCHES AND CONTROLS **Power windows** use electric motors to raise and lower door glass. They can be operated by both a master control switch located beside the driver and additional independent switches located at each electric window. Some power window systems use a lockout/child safety switch located on the driver's controls to prevent operation of the power windows from the independent switches. Power windows are designed to operate only with the ignition switch in the on (run) position, although some manufacturers use a time delay for accessory power after the ignition switch is turned off. This feature permits the driver and passengers an opportunity to close all windows or operate other accessories for about 10 minutes or until a vehicle door is opened after the ignition has been turned off. This feature is often called *retained accessory power (RAP).*

POWER WINDOW MOTORS Most power window systems use permanent magnet (PM) electric motors. It is possible to run a PM motor in the reverse direction by reversing the polarity of the two wires going to the motor. Most power window motors do not require that the motor be grounded to the body (door) of the vehicle. The ground for all the power windows is most often centralized near the driver's master control switch. The up-and-down motion of the individual window motors is controlled by double-pole, double-throw (DPDT) switches. These DPDT switches have five contacts and permit battery voltage to be applied to the power window motor, as well as reverse the polarity and direction of the motor.

Each motor is protected by a positive temperature coefficient (PTC) electronic circuit breaker. These circuit breakers are built into the motor assembly and are not a separate replaceable part. ● **SEE FIGURE 57–24**.

The power window motors rotate a mechanism called a *window regulator*. The window regulator is attached to the door glass and controls opening and closing of the glass. Door glass adjustments, such as glass tilt and upper and lower stops, are usually the same for both power and manual windows. ● **SEE FIGURE 57–25**.

AUTO DOWN/UP FEATURES Many power windows are equipped with an auto down feature that allows windows to be lowered all the way if the control switch is moved to a detent or held down for longer than 0.3 second. The window then moves down all the way to the bottom, and then the motor stops.

Public Law 110-189, also known as the Cameron Gulbransen Kids Transportation Safety Act, mandated the use of power window **automatic reversal systems (ARS)**. The automatic reversal system is designed to prevent windows from causing injury when they are closing, if the vehicle is equipped with power windows. The Department of Transportation (DOT) established a limit of 136 ft-lb (100 N-m) of force be exerted by the window before the window retracts. There are two methods used for controlling ARS and auto up and auto down windows, including

1. An encoder wheel and position sensor are used to monitor the speed and position of the window as it travels up and down.
2. The current (amperes) required is measured by the power window control module.

The window direction reverses if the current draw exceeds a predetermined value. If an object is in the path of the window, the current draw and or slowing of the window causes the control module to reverse. The system is designed to expect increased current flow and slower window movement in cold weather conditions. However, sudden vehicle movement, such as hitting a bump in the road as the window is moving upward or a fault in the window track, can cause the window to reverse.

GLASS
MOTOR
GLASS GUIDE
GLASS GUIDE
REGULATOR ASSEMBLY

FIGURE 57–25 An electric motor and a regulator assembly raise and lower the glass on a power window.

A factory or factory-level scan tool is used to diagnosis this system, which can monitor switch operation and can be used to control the operation of the windows using bidirectional controls.

TROUBLESHOOTING POWER WINDOWS Before troubleshooting a power window problem, check for proper operation of all power windows. Also check that the child-proof switch is not in the disable position, which prevents the windows from being operated from any position except the driver's master control. Check service information for the exact procedure to follow. In a newer system, a scan tool can be used to perform the following:

- Check for B (body) or U (network) diagnostic trouble codes (DTCs)
- Operate the power windows using the bidirectional control feature
- Relearn or program the operation of the power windows after a battery disconnect

Always follow the diagnosis and repair procedures as specified in service information.

TECH TIP

Programming Auto Down/Up Power Windows

Many vehicles are equipped with automatic operation that can cause the window to go all the way down (or up) if the switch is depressed beyond a certain point or held for a fraction of a second. Sometimes this feature is lost if the battery in the vehicle has been disconnected. Although this programming procedure can vary depending on the make and model, many times the window(s) can be reprogrammed without using a scan tool by depressing and holding the down button for 10 seconds. If the vehicle is equipped with an auto up feature, repeat the procedure by holding the button up for 10 seconds. Always check exact service information for the vehicle being serviced.

ELECTRIC POWER DOOR LOCKS

PARTS AND OPERATION Electric power door locks use a permanent magnet (PM) reversible motor to lock or unlock all vehicle door locks from a control switch or switches. The electric motor uses a built-in circuit breaker and operates the lock-activating rod. PM reversible motors do not require grounding because, as with power windows, the motor control is determined by the polarity of the current through the two motor wires. ● **SEE FIGURES 57–26 AND 57–27**.

Some two-door vehicles do not use a power door lock relay because the current flow for only two PM motors can be handled through the door lock switches. However, most four-door vehicles and vans with power locks on rear and side doors use a relay to control the current flow necessary to operate four or more power door lock motors. The door lock relay is controlled by the door lock switch and is commonly the location of the one and only ground connection for the entire door lock circuit.

TECH TIP

Check the Glove Box Switch Position

A common customer complaint is that the trunk or lift gate can be opened manually, but it cannot be opened using the remote. Most vehicles are equipped with a lockout switch in the glove compartment (instrument panel compartment) that can be switched off, and the glove box door locked to limit access when the vehicle is parked, and the valet has the key to the ignition. If the switch is in the locked position, the trunk cannot be opened using the remote. Check that first before following the recommended diagnostic procedures found in service information. ● **SEE FIGURE 57–28**.

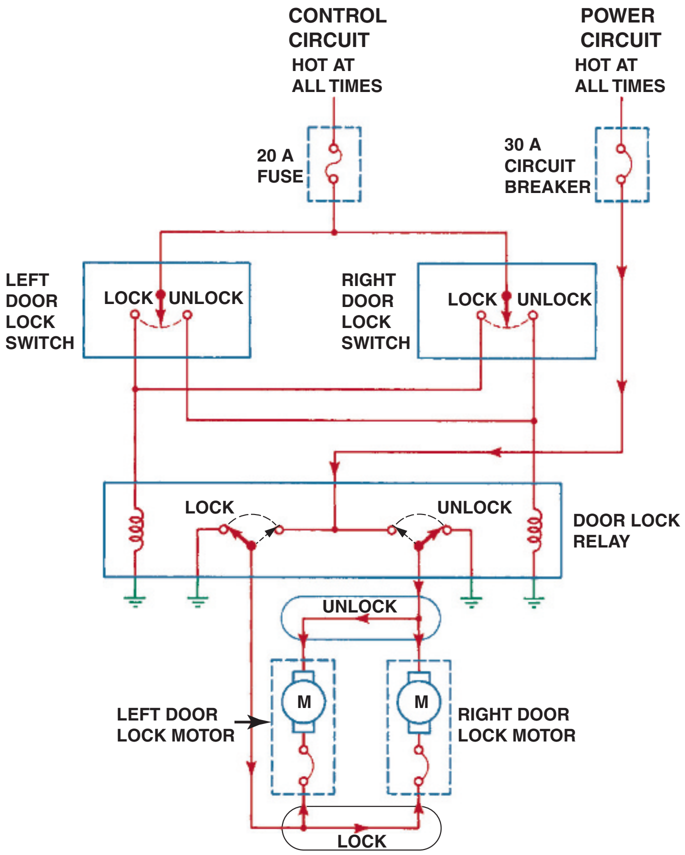

FIGURE 57–26 A typical electric power door lock circuit diagram. Note that the control circuit is protected by a fuse, whereas the power circuit is protected by a circuit breaker. As with the operation of power windows, power door locks typically use reversible permanent magnet (PM) non-grounded electric motors. These motors are geared mechanically to the lock–unlock mechanism.

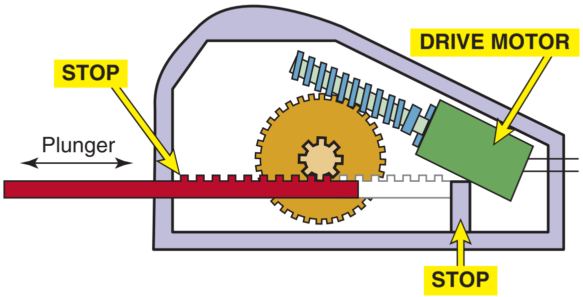

FIGURE 57–27 A typical power door lock mechanism showing a DC drive motor used to move the door lock plunger

TROUBLESHOOTING POWER LOCKS If all power door locks are inoperative, use a factory or factory-level aftermarket scan tool and try operating the locks using the bidirectional control. If the door locks do not operate using a scan tool, refer to service information for the exact procedure to follow.

If only the power door lock is inoperative, check for the power and ground, as well as possible physical binding of the lock mechanism. Repair or replace as needed.

TRUNK/LIFT GATE LOCKS The electric power trunk/lift gate lock uses a permanent magnet (PM) reversible motor to lock or

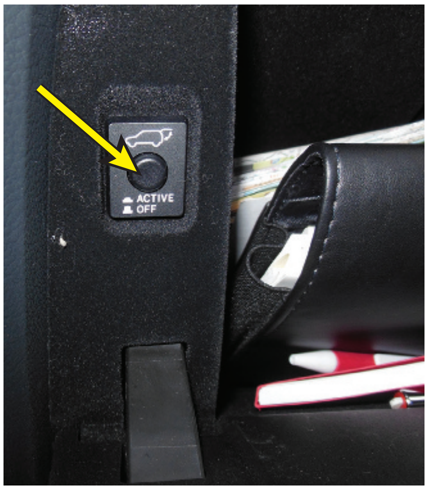

FIGURE 57–28 The switch to disable the outside opening of the trunk/lift gate is often in the glove box.

unlock the trunk/lift gate lock from a control switch or with the remote. The electric motor uses a built-in circuit breaker and operates the lock-activating rod. PM reversible motors do not require grounding because, as with power windows and door locks, the motor control is determined by the polarity of the current through the two motor wires.

POWER SUN ROOF/ MOON ROOF

DEFINITIONS While they are similar in nature and often used interchangeably, there is a difference between a sun roof and a moon roof.

- **Sun roof**—A sun roof is basically any kind of panel on the roof of a car that permits light, air, or both to come into a vehicle, but only if the panel is opened. A sunroof includes two types of panels:
    1. One panel may be made of either metal or the same material as the ceiling of the car and can be retracted to expose the glass panel above.
    2. The other panel is made of glass that can be either tilted open or completely retracted to essentially serve as an open window in the roof.
- **Moon roof**—A moon roof is made of a tinted glass panel that can be either tilted open or completely retracted to operate as an open window in the roof. Most new cars have moon roofs.

OPERATION Most moon or sun roof systems use permanent magnet (PM) electric motors to open and close the moveable glass panel. The open and close, or tilt up or down, motion of the moon roof motors is controlled by double-pole, double-throw (DPDT) switches. These DPDT switches have five contacts and permit battery voltage to be applied to the power moon roof motor, as well as reverse the polarity and direction of the motor. Each motor is protected by an electronic circuit breaker. These circuit breakers are built into the motor assembly and are not a separate replaceable part.

DIAGNOSIS AND SERVICE Always check service information for the exact procedure to use because the moon roofs have many different service items that are likely to need service or repair, including

- **Water leaks**—Engineers refer to water seals around moon roofs as "controlling the flow of water" and not necessarily trying to provide a water-proof seal. Because the roof of a vehicle flexes when the being driven, no seal can prevent water from leaking around the area around the moon roof. Instead, the water is directed to a tray under the outer seal and then tubes are installed at the four corners of the moon roof to drain the water from the tray to the ground. If water is entering the passenger compartment, make sure the drain tubes are not clogged. The tubes are routed though the two front "A" pillars and the two rear "C" pillars. ● **SEE FIGURE 57–29**.
- **Electrical/Mechanical issues—**Electrical or mechanical issues can prevent the moon roof from opening or closing. Most vehicle manufacturers include a crank or a way to close the roof if the roof fails to close due to an electrical fault.

Always follow the vehicle manufacturer's recommended service and repair instructions and procedures.

SUN SHADES **Sun shades** are fabric or screen-like material installed on the inside of the vehicle that can be raised, lowered, or moved to block the rays of the sun from entering the interior of the vehicle. Most of the sun shades used on the side windows are operated manually and either can be pulled down from the top of the inside of the door or up from the inner part of the door panel. Sun shades used to block the sun in the rear backlight or moon roof are often electrically powered and use a reversible PM motor to drive the roll holding the fabric. ● **SEE FIGURE 57–30**.

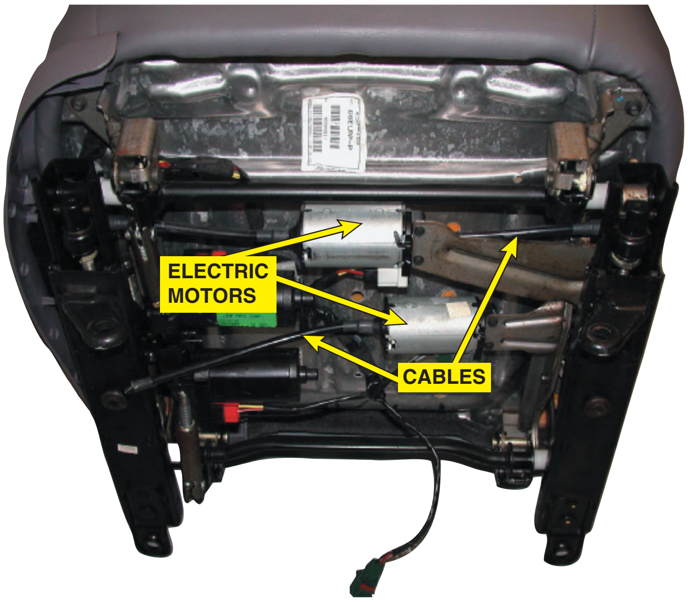
Sun shades are vehicle-specific, so check service information for the exact procedures to follow when servicing or repairing a sun shade.



ELECTRIC MOTORS
CABLES

FIGURE 57–31 A power seat uses electric motors under the seat, which drive cables that extend to operate screw jacks (up and down) or gears to move the seat forward and back.

POWER SEATS

PARTS AND OPERATION A typical power-operated seat includes a reversible electric motor and a transmission assembly that may have three solenoids or motors, and six drive cables that turn the six seat adjusters. A six-way power seat offers seat movement forward and backward, plus seat cushion movement up and down at the front and the rear. The drive cables rotate inside a cable housing and connect the power output of the seat transmission to a gear or screw jack assembly that moves the seat. ● **SEE FIGURE 57–31**.

A *screw jack assembly* is often called a *gear nut*. It is used to move the front or back of the seat cushion up and down. A rubber coupling, usually located between the electric motor and the transmission, prevents electric motor damage in the event of a jammed seat. This coupling is designed to prevent motor damage. Most power seats use a permanent magnet motor that can be reversed by reversing the polarity of the current sent to the motor by the seat switch. ● **SEE FIGURE 57–32**.

POWER SEAT MOTOR(S) Power seats use a PM motor to power the movement of the seat. Most PM motors have a built-in circuit breaker or PTC circuit protector to protect the motor from overheating. Some older Ford power seat motors use three separate armatures inside one large permanent magnet field housing. Some power seats use a series-wound electric motor with two separate field coils, one field coil for each direction of rotation. This type of power seat motor typically uses a relay to control the direction of current from the seat switch to the corresponding field coil of the seat motor. This type of power seat can be identified by the "click" heard when the seat switch is changed from up to down or front to back, or vice versa. The click is the sound of the relay switching the field coil current. Some power seats use as many as eight separate PM motors that operate all functions of the seat, including headrest height, seat length, and side bolsters, in addition to the usual six-way power seat functions.

NOTE: Some power seats use a small air pump to inflate a bag (or bags) in the lower part of the back of the seat, called the lumbar, because it supports the lumbar section of the lower back. The lumbar section of the seat can also be changed, using a lever or knob that the driver can move to change the seat section for the lower back.

MEMORY SEAT Memory seats use a potentiometer to sense the position of the seat. The seat position can be programmed into the BCM or memory seat module, and stored by position number 1, 2, or 3. The driver pushes the desired button and the seat moves to the stored position. On some vehicles, the memory seat position is also programmed into the remote keyless entry (RKE) key fob. ● **SEE FIGURE 57–33.**

Check service information for the exact procedure to follow when diagnosing power seats.

TECH TIP

Easy-Exit Seat Programming

Some vehicles are equipped with memory seats that allow the seat to move rearward when the ignition is turned off to allow easy exit from the vehicle. Vehicles equipped with this feature include an *exit/entry* button that is used to program the desired exit/entry position of the seat for each of two drivers. If the vehicle is not equipped with this feature and only one driver primarily uses the vehicle, the second memory position can be programmed for easy exit and entry. Set position 1 to the desired seat position and position 2 to the entry/exit position. When exiting the vehicle, press memory 2 to allow easy exit and easy entry the next time. Press memory 1 to return the seat memory to the desired driving position.

TECH TIP

What Every Driver Should Know about Power Seats

Power seats use an electric motor or motors to move the position of the seat. These electric motors turn small cables, gears, and/or shafts that operate mechanisms that move the seat. Never place rags, newspapers, or any other object under a power seat. Even ice scrapers can get caught between moving parts of the seat and can often cause serious damage or jamming of the power seat. In many cases, after the object is removed that caused the seat jam, the memory function needs to be relearned for proper operation to resume.

HEATED AND COOLED SEATS

HEATED SEATS **Heated seats** use electric heating elements in the seat bottom, as well as in the seat back, in many vehicles. The heating element is designed to warm the seat and/or back of the seat to about 100°F (38°C) or close to normal body temperature (98.6°F [37°C]). Many heated seats also include a high-position or a variable temperature setting, so the temperature of the seats can, therefore, be as high as 110°F (44°C).

A temperature sensor in the seat cushion is used to regulate the temperature. The sensor is a variable resistor, which changes with temperature and is used as an input signal to a heated seat control module. The heated seat module uses the seat temperature input, as well as the input from the high–low (or variable) temperature control, to turn the current on or off to the heating element in the seat. Some vehicles are equipped with heated seats in both the front and the rear seats.

When diagnosing a heated seat concern, start by verifying that the switch is in the on position and that the temperature of the seat is below normal body temperature. Using service information, check for power and ground at the control module and to the heating element in the seat. Most vehicle manufacturers recommend replacing the entire heating element if it is defective. ● **SEE FIGURE 57–34**.

HEATED AND COOLED SEATS Most electrically heated and cooled seats use a thermoelectric device (TED) located under the seat cushion and seat back. The thermoelectric device consists of positive and negative connections between two ceramic plates. Each ceramic plate has copper fins to allow the transfer of heat to or from air passing over the device and directed into the seat cushion. The thermoelectric device uses the Peltier effect, named after the inventor Jean C. A. Peltier (1785–1845), a French clockmaker. When electrical current flows through the module, one side is heated, and the other side is cooled. Reversing the polarity of the current changes the side to be heated. ● **SEE FIGURE 57–35**.

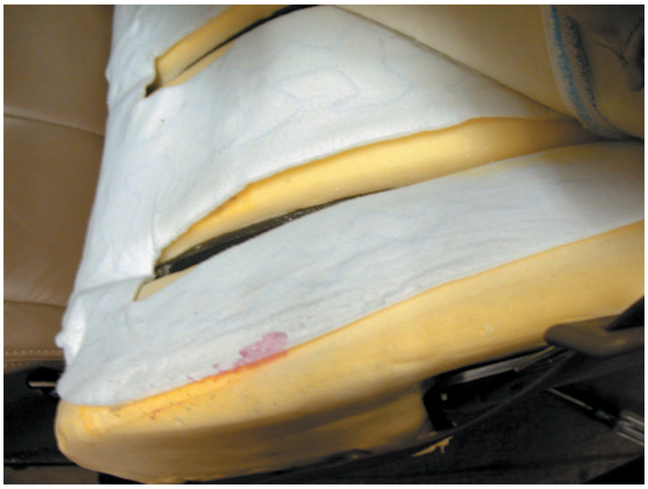

FIGURE 57–34 The heating element of a heated seat is a replaceable part, but service requires that the upholstery be removed. The yellow part is the seat foam material and the entire white cover is the replaceable heating element. This is then covered by the seat material.

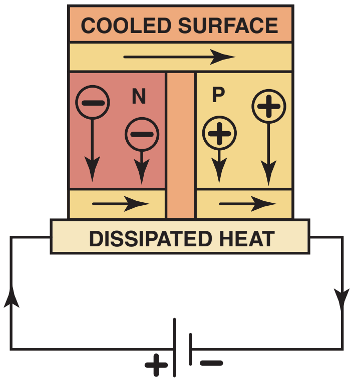

FIGURE 57–35 A Peltier effect device is capable of heating or cooling, depending on the polarity of the applied current.

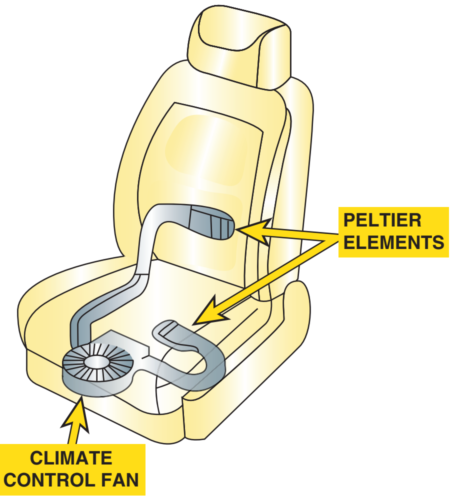

FIGURE 57–36 A fan is used to move the heated or cooled air to heat or cool the bottom or the back of the seat.

Most vehicles equipped with heated and cooled seats use two modules per seat, one for the seat cushion and one for the seat back. When the heated and cooled seats are turned on, air is forced through a filter and then through the thermoelectric modules. The air is then directed through passages in the foam of the seat cushion and seat back. Each thermoelectric device has a temperature sensor called a thermistor. The control module uses sensors to determine the temperature of the fins in the thermoelectric device so the controller can maintain the set temperature. ● **SEE FIGURE 57–36**.

TECH TIP

Check the Seat Filter

Heated and cooled seats often use a filter to trap dirt and debris to help keep the air passages clean. If a customer complains of a slow heating or cooling of the seat, check the air filter and replace or clean as necessary. Check service information for the exact location of the seat filter and for instructions on how to remove and/or replace it.

Always follow the vehicle manufacturer's recommended diagnosis and service procedures for the repair of heated and cooled seat systems.

HEATED STEERING WHEEL

PARTS INVOLVED A **heated steering wheel** usually consists of the following components:

- Steering wheel with a built-in heater in the rim
- Heated steering wheel control switch
- Heated steering wheel control module

OPERATION When the steering wheel heater control switch is turned on, a signal is sent to the control module and electrical current flows through the heating element in the rim of the steering wheel. ● **SEE FIGURE 57–37**.

The system remains on until the ignition switch is turned off or the driver turns off the control switch. The temperature of the steering wheel is usually calibrated to stay at about 90°F (32°C), and it requires three to four minutes to reach that temperature, depending on the outside temperature. Most heated steering wheels only heat a part and often not all the steering wheel. Before trying to repair a condition where just some sections of the steering wheel are being warmed, check service information for what parts are normally heated.

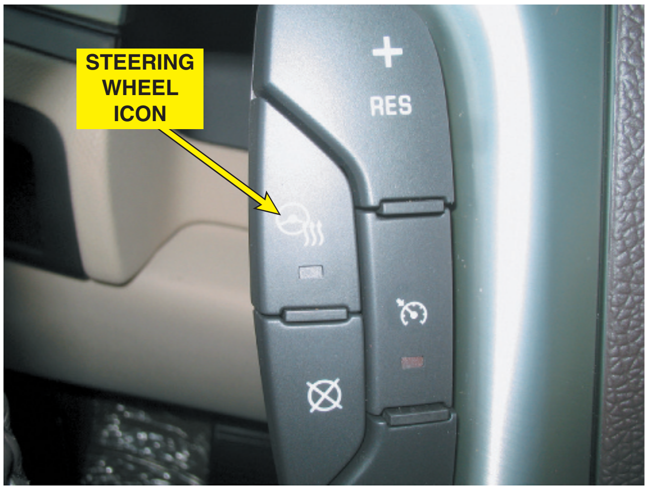

FIGURE 57–37 The heated steering wheel is controlled by a switch on the steering wheel in this vehicle.

Always follow the vehicle manufacturer's recommended diagnosis and testing procedures for heated steering wheel diagnosis and repair.

HEATED MIRRORS

PURPOSE AND FUNCTION The purpose and function of heated outside mirrors is to heat the surface of the mirror, which evaporates moisture on the surface. Heated mirrors may be an option for the left-side outside mirror or both the left- and right-side outside mirrors, depending on the vehicle. The heat helps keep ice and fog off the mirrors to allow for better driver visibility.

PARTS AND OPERATION Heated outside mirrors are often tied into the same electrical circuit as the rear window defogger. Therefore, when the rear defogger is turned on, the heating grid on the backside of the mirror is also turned on. On some vehicles, the heated mirrors are activated when the heating, ventilation, and cooling (HVAC) system is placed in the defrost mode. Some vehicles use a switch for each mirror.

DIAGNOSIS The first step in any diagnosis procedure is to verify the customer concern. Check the owner's manual or service information for the proper method to use to turn on the heated mirrors.

NOTE: Heated mirrors are *not* designed to melt snow or a thick layer of ice.

If a fault has been detected, check service information instructions for the exact procedure to follow. If the mirror itself is found to be defective, it is usually replaced as an assembly, instead of being repaired.

ADJUSTABLE PEDALS

PURPOSE AND FUNCTION Adjustable pedals, also called *pedal height* or **electric adjustable pedals (EAP)**, place the brake pedal and the accelerator pedal on movable brackets that are motor operated. The height of the accelerator pedal and the brake pedal are adjusted together and cannot be adjusted individually. A typical adjustable pedal system includes the following components:

- Adjustable pedal position switch: Allows the driver to position the pedals.
- Adjustable pedal assembly: Includes the motor, threaded adjustment rods, and a pedal position sensor. ● **SEE FIGURE 57–38**.

The position of the pedals, as well as the position of the seat system, is usually included as part of the memory seat function and can be set for two or more drivers.

DIAGNOSIS AND SERVICE The first step when there is a customer concern about the functioning of the adjustable pedals is to verify that the unit is not working as designed. Check the owner's manual or service information for the proper operation. Follow the vehicle manufacturer's recommended troubleshooting procedure. Many diagnostic procedures include the use of a factory scan tool with bidirectional control capabilities to test this system.

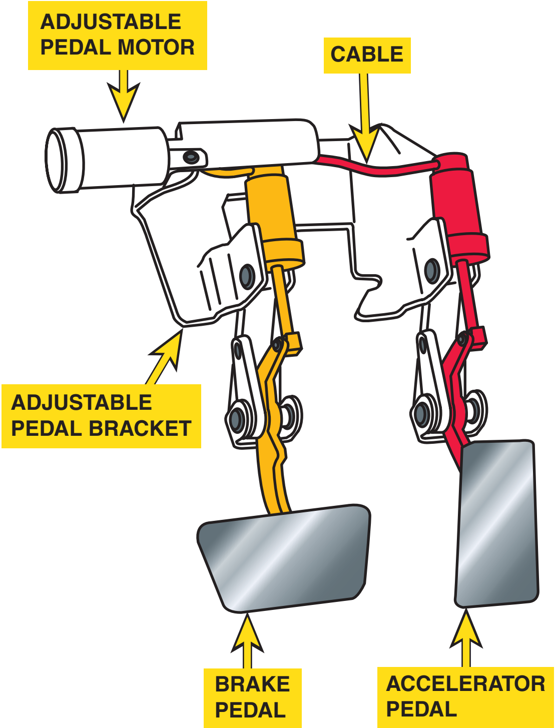

FIGURE 57–38 A typical adjustable pedal assembly. Both the accelerator and the brake pedal can be moved forward and rearward by using the adjustable pedal position switch.

TECH TIP

Check the Remote

The memory function may be programmed to a particular key fob remote, which commands the adjustable pedals to move to the position set in memory. Always check the settings of all remotes before attempting to repair a problem, which may not be a problem.

CASE STUDY

The Case of the Haunted Mirrors

The owner complained that while driving, either one or the other, outside mirror folded in without any button being depressed. Unable to verify the customer concern, the service technician looked at the owner's manual to find out exactly how the mirrors were supposed to work. In the manual, a caution statement said that if the mirror is electrically folded inward and then manually pushed out, the mirror does not lock into position. The power folding mirrors must be electrically cycled outward, using the mirror switches to lock them in position. After cycling both mirrors inward and outward electrically, the problem was solved. ● **SEE FIGURES 57–39 AND 57–40**.

Summary:

Complaint—Customer stated that the outside power folding mirror folded by itself at times.
Cause—The mirrors must be moved electrically, not manually, to work correctly.
Correction—Cycling the mirrors electrically restored proper operation.

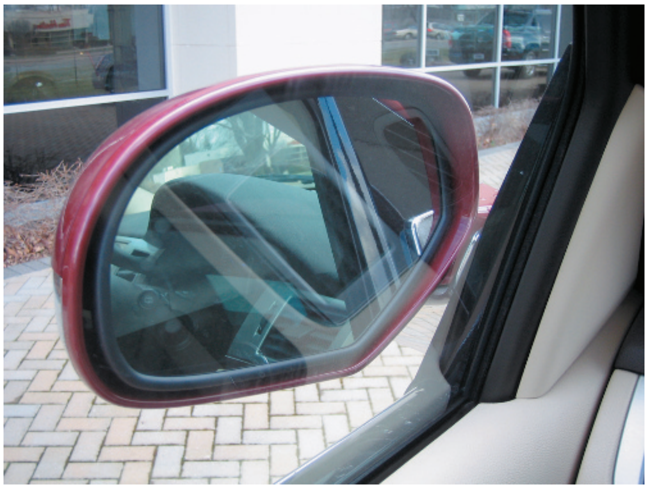

FIGURE 57–39 Electrically folded mirror in the folded position.

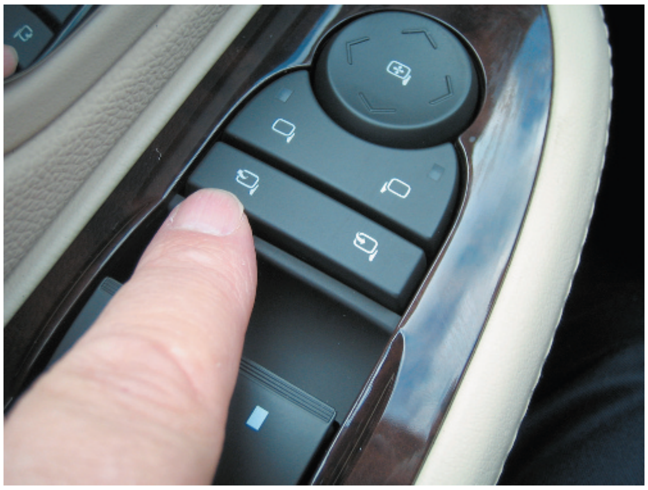

FIGURE 57–40 The electric mirror control is located on the driver's side door panel on this Cadillac Escalade.

FOLDING OUTSIDE MIRRORS Mirrors that can be electrically folded inward are a popular feature, especially on larger sport utility vehicles. A control inside is used to fold both mirrors inward when needed, such as when entering a garage or a tight parking spot. For diagnosis and servicing of outside folding mirrors, check service information for details.

KEYLESS ENTRY

SYSTEM DESCRIPTION Even though some Ford vehicles use a keypad located on the outside of the door, most keyless entry systems use a wireless transmitter built into the key fob or remote. A key fob is a decorative item on a key chain. ● **SEE FIGURE 57–41**.

FIGURE 57–41 A key fob remote.

LEFT REAR DOOR LOCK ACTUATOR/KNOB SWITCH
TRUNK KEY CYLINDER SWITCH
LEFT REAR DOOR SWITCH
TRUNK LATCH SWITCH

FIGURE 57–42 A typical vehicle showing the location of the various components of the remote keyless entry system.

The transmitter broadcasts a signal that is received by the electronic control module, which is generally mounted in the trunk or under the instrument panel. ● **SEE FIGURE 57–42**.

The electronic control unit sends a voltage signal to the door lock actuator(s) located in the doors. Generally, if the transmitter unlock button is depressed once, only the driver's door is unlocked. If the unlock button is depressed twice, then all doors unlock.

ROLLING CODE RESET PROCEDURE Many keyless remote systems use a rolling-code type of transmitter and receiver. In a conventional system, the transmitter emits a certain fixed frequency, which is received by the vehicle control module. This single frequency can be intercepted and rebroadcast to open the vehicle. A rolling-code type of transmitter emits a different frequency every time the transmitter button is depressed and then rolls over to another frequency so that it cannot be intercepted. Both the transmitter and the receiver must be kept in synchronized order so that the remote functions correctly. If the transmitter is depressed when it is out of range from the vehicle, the proper frequency may not be recognized by the receiver, which did not roll over to the new frequency when the transmitter was depressed. If the transmitter does not work, try to resynchronize the transmitter to the receiver by depressing and holding both the lock and the unlock button for 10 seconds when within range of the receiver.

PASSIVE KEYLESS ENTRY SYSTEM A passive system uses the key fob as a transmitter, which communicates with the vehicle as it comes close. The key is identified using one of several antennas around the body of the vehicle and a radio pulse generator in the key housing. Depending on the system, the vehicle is automatically unlocked when a button or sensor on the door handle or trunk release is depressed. ● **SEE FIGURE 57–43**.

A passive system can also be used to unlock and open a rear lift gate on an SUV if a foot is moved under the edge of the vehicle, allowing it to open the slider or the rear hatch. Vehicles with a passive (smart) key system can also have a mechanical backup, usually in the form of a key blade built into the key fob. Vehicles with a smart key system can be started without inserting a key in the ignition, provided the driver has the key fob inside the vehicle. On most vehicles, this is done most often by pressing a start button. When leaving a vehicle equipped with a smart key system, the vehicle is locked, depending on the make, model, and year of manufacture of vehicle, by:

- Pressing a button on one of the door handles
- Touching a capacitive area on a door handle
- Walking away from the vehicle and the door locks when the key fob is further away than 15 feet (5 m).

KEYLESS ENTRY DIAGNOSIS A small battery powers the transmitter, and a weak battery is a common cause of remote power locks failing to operate. If the keyless entry system fails to operate after the transmitter battery has been replaced, check the following items:

- Mechanical binding in the door lock
- Low vehicle battery voltage
- Blown fuse
- Open circuit to the control module

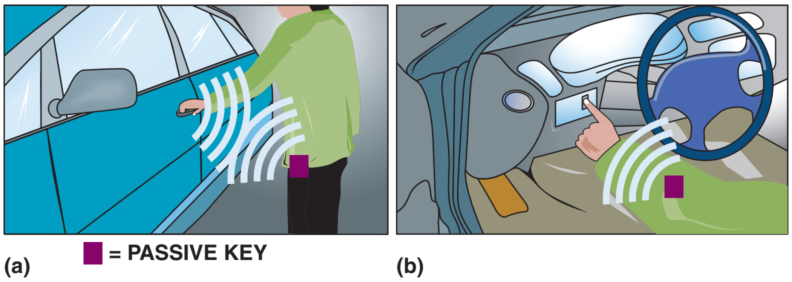

FIGURE 57–43 (a) If the passive key is within about 15 feet (5 m) of the vehicle when the door handle is touched, the door unlocks, allowing access to the interior. (b) The engine starts if the smart key is detected being inside the vehicle. This system is commonly called the **passive entry**, **passive starting (PEPS)** system.

- Defective control module
- Defective transmitter

PROGRAMMING A NEW REMOTE If a new or additional remote transmitter is to be used, it must be programmed to the vehicle. Generally, all remotes previously programmed to the vehicle must be present during the programming or they no longer work. The programming procedure varies and may require the use of a scan tool. Check service information for the exact procedure to follow.

GARAGE DOOR OPENER

OPERATION HomeLink or Car2U is a device installed in many new vehicles that duplicates the radio-frequency code of the original garage door opener. The frequency range is 288 to 418 MHz. The typical vehicle garage door opening system has three buttons that can be used to operate one or more of the following devices:

- Garage doors equipped with a radio transmitter electric opener
- Gates
- Entry door locks
- Lighting or small appliances

The devices include both fixed-frequency devices, usually in older units, and rolling (encrypted) code devices. ● **SEE FIGURE 57–44**.

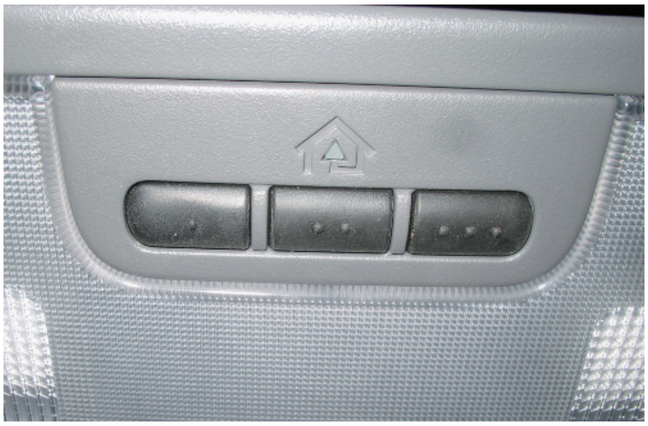

FIGURE 57–44 Typical HomeLink garage door opener buttons. Notice that three different units can be controlled from the vehicle using the HomeLink system.

PROGRAMMING A VEHICLE GARAGE DOOR OPENER When a vehicle is purchased, it must be programmed using the transmitter for the garage door opener or other device.

NOTE: The garage door opening controller can only be programmed by using a transmitter. If an automatic garage door system does not have a remote transmitter, the system cannot be programmed.

Normally, the customer is responsible for programming the garage door opener. However, some customers may find that help is needed from the service department. The steps that are usually involved in programming a garage door opener in the vehicle to the garage door opener are as follows:

STEP 1 Unplug the garage door opener during programming to prevent it from being cycled on and off, which could damage the motor.

STEP 2 Check that the frequency of the handheld transmitter is between 288 to 418 MHz.

STEP 3 Install new batteries in the transmitter to be assured of a strong signal being transmitted to the garage door opener module in the vehicle.

STEP 4 Turn the ignition on, engine off (KOEO).

STEP 5 While holding the transmitter 4 to 6 inches away from the opener button, press and hold the button while pressing and releasing the handheld transmitter every two seconds. Continue pressing and releasing the transmitter until the indicator light near the opener button changes from a slow blink to a rapid flash.

STEP 6 Verify that the vehicle garage door system (HomeLink or Car2U) button has been programmed. Press and hold the garage door button. If the indicator light blinks rapidly for two seconds and then comes on steady, the system has been successfully programmed using a rolling code design. If the indicator light is on steady, then it has been successfully programmed to a fixed frequency device.

DIAGNOSIS AND SERVICE If a fault occurs with the garage door opening system, first verify that the garage door opener is functioning correctly. Also, check if the garage door opener remote control can operate the door. Repair the garage door opener system as needed. If the problem still exists, attempt reprogramming the HomeLink/Car2U vehicle system, being sure that the remote has a newly purchased battery.

WARNING

Never use the remote start to start the engine if the vehicle is located inside a garage or an area without proper ventilation, or if a car cover is covering the body of the vehicle.

REMOTE START

PURPOSE AND FUNCTION A **remote start** is the ability to start the engine of the vehicle from a distance by using a remote control. This a popular option, especially in cold climates, which allows the driver to start the engine when inside the house or office to start the warm-up process before even entering the vehicle. It is also popular in the warm weather areas where the interior can be cooled by the air conditioning before entering the vehicle. Most factory-installed remote start systems use the same key fob that it used to unlock the doors.

PARTS AND OPERATION The remote start system uses a signal from the transmitter (usually the key fob on factory systems) to start the engine. The engine runs for about ten minutes, depending on the system, and then shuts off. The vehicle needs to be setup ahead of time with the HVAC system set to heat or A/C and the transmission gear selector in park, or in neutral on vehicles equipped with a manual transmission. Always check service information for the conditions that allow remote starting, which often includes the following:

- The keyless remote is not inside the vehicle.
- The gearshift lever is in the "P" (Park) position.
- The security warning system is not activated.
- The brake pedal is not depressed.
- The engine hood is closed.
- All the doors are closed and locked.
- The trunk or tailgate is closed.
- The ignition key is removed from the ignition switch.
- The vehicle battery is not low.

Check service information for the exact procedures to follow when diagnosing a fault with the remote engine start system.

BODY ELECTRICAL SYSTEMS DIAGNOSIS

BODY CONTROL MODULE COMMUNICATION The body control module (BCM) and other electronic modules are used to operate the various vehicle systems. The number of these modules and the purpose of them varies among the vehicle manufacturers. All these systems use the different controller area networks (CAN) to connect all these modules together. If there are communication errors on the various networks some or all of these modules may not function. Many communication errors will set a "U" DTC. If this network is active or partially active, a bidirectional factory level scan tool is needed to diagnose the diagnostic trouble code(s). A factory or factory-level aftermarket scan tool is also required to reprogram the current or new BCM with the latest operating software and calibrations.

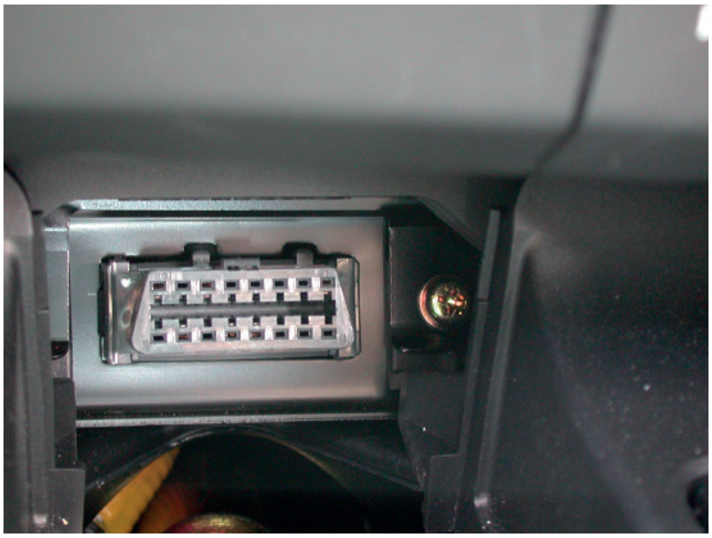

FIGURE 57–45 The data link connector is located under the dash.

STEPS INVOLVED The following steps are needed to be performed to access and determine module communications:

STEP 1 Connect a factory or factory-level scan tool to the DLC. ● **SEE FIGURE 57–45**.

STEP 2 Perform an all-module scan to check for any diagnostic trouble codes that may be stored in all of the modules.

STEP 3 Command the module using the scan tool to take the appropriate action and observe the response. If the component operates correctly, this means that there is nothing wrong on the output side of the circuit. If an incorrect response is shown, then refer to the service information for the specific diagnostic procedure.

SOFTWARE UPDATES TRANSFERS/FLASH PROGRAMMING When diagnosing and repairing many of these vehicles that use multiple electronic modules, it may be required to do a software transfer, update or flash reprogramming or relearning of the modules with the latest OEM update information. OEMs will periodically update the software for these modules to enhance vehicle operation or correct a fault. In many cases there will be a technical service bulletin (TSB) on these updates. Flash reprogramming tools are available to connect to the DLC to update the software. OEMs will make updates available over the Internet, generally using one of their subscription services like AC Delco.

REPROGRAMMING STEPS Before a data transfer is performed, connect a battery charger specifically designed to provide a clean direct current output to the battery. Using a conventional battery charger should be avoided because they often supply some alternating current (AC) that can disrupt the data transfer.

STEP 1 Download the latest vehicle software program updates from the OEM or a subscription website and load these updates onto the flash programmer or your factory level scan tool.

STEP 2 Locate the datalink connector and power on the flash programming tool, then turn on the ignition (KOEO).

STEP 3 Establish flash programming tool communication with the vehicle.

STEP 4 Identify the vehicle modules that will need to be updated, and use the flash programming tool (J2934) or the scan tool to perform software transfers updates or flash reprogramming. ● **SEE FIGURE 57–46**.

FIGURE 57–46 A laptop computer being used to download the latest software from the Internet, which needs to be transferred to a factory or factory-level scan tool that is connected to the vehicle at the DLC to perform the file transfer.

STEP 5 Disconnect the flash programmer or scan tool and then check the vehicle to see that the system is now functioning or functioning properly.

FREQUENTLY ASKED QUESTION

How Do Over the Air (OTA) Module Updates Work?

Electronic modules can be updated using **over the air (OTA)** on many vehicles. Tesla was the first to use OTA to update some of the electronic modules in 2012 on their Model S. Since then, many vehicle manufacturers are able to update the software of many electronic modules using OTA communication. Some use Wi-Fi whereas others use cellular systems to communicate with the vehicle.

REVIEW QUESTIONS

1. What are the advantages of using the BCM to able to operate the horns?
2. How do rain-sense wipers work?
3. How do power door locks work?
4. How can an infrared camera be used to test a rear window defogger?
5. What is meant by a “rolling code”?

CHAPTER QUIZ

1. In most recent-model vehicles, the horn button is an input to the _________, which then activates the horn circuit.
   a. horn relay
   b. instrument cluster
   c. BCM
   d. garage door opener
2. Technician A says that the cruise control on a vehicle that uses an electronic throttle control (ETC) system uses a servo to move the throttle. Technician B says that a blower motor speed can be controlled using resistors. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. Most vehicles use _________ to control the actual operation of the wipers.
   a. variable resistors
   b. changing the voltage to the brushes
   c. the BCM
   d. changing the position of the brushes
4. Technician A says that the automatic reversal system operates by detecting the force needed to close the window. Technician B says that rain sensing wipers use a water detection module attached to the inside of the windshield. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
5. What should be used during module reprogramming to maintain the vehicle voltage level?
   a. A 24-volt battery
   b. A charger that outputs clean DC voltage
   c. A memory saver
   d. Any of the above

6. When checking the operation of a rear window defogger, heated and cooled seats, heated steering wheel or heated mirrors, what can be used to check their operation?
   - **a.** A voltmeter
   - **b.** A scan tool
   - **c.** Infrared camera
   - **d.** Some or all may be used
7. PM motors used in power windows, mirrors, and seats can be reversed by __________.
   - **a.** sending current to a reversed field coil
   - **b.** reversing the polarity of the current to the motor
   - **c.** using a reverse relay circuit
   - **d.** using a relay and a two-way clutch
8. How is the panel of a sun roof opened and closed?
   - **a.** With a reversible PM motor
   - **b.** By way of vacuum actuators
   - **c.** With a handle and cables
   - **d.** None of these
9. A keyless remote start is not working. Technician A says the trunk of the vehicle may be open. Technician B says that the key fob may be too far away from the vehicle. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
10. Technician A says that adjustable pedals move both the accelerator pedal and the brake pedal. Technician B says that only the brake pedal moves when adjusting the pedals. Which technician is correct?
    - **a.** Technician A only
    - **b.** Technician B only
    - **c.** Both technicians are correct
    - **d.** Neither technician is correct

Chapter

ADVANCED DRIVER ASSIST SYSTEMS (ADAS)

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe the purpose and function of advanced driver assist systems.
- Discuss blind spot monitors.
- Discuss parking assist as well as self-parking systems.
- Explain lane departure warning systems.
- Explain lane keep assist systems.
- Describe how adaptive cruise control systems work.
- Discuss rear cross-traffic warning system operation.
- Explain automatic emergency braking.
- Explain pre-collision systems.
- Describe the operation of hill start assist.
- Describe the diagnostic procedures for advanced driver assist systems.
- Describe camera and radar sensor calibration.

KEY TERMS:

Adaptive cruise control (ACC) 695 • Automatic emergency braking (AEB) 697 • Blind spot monitor (BSM) 692 • Cross-traffic alert 694 • Electromagnetic parking sensors (EPS) 693 • Human–machine interface (HMI) 693 • Intelligent Speed Advice (ISA) 697 • Lane departure warning system (LDWS) 694 • Lane keep assist (LKA) 695 • Rear cross-traffic warning (RCTW) 697 • Self-parking 694 • Ultrasonic object sensors 693

ADVANCED DRIVER ASSIST SYSTEMS

PURPOSE The purpose of advanced driver assist systems (ADAS) is to provide the driver with systems that help the driver by doing the following:

- Alert the driver of a potential issue, such as getting too close to the center line or too far to the right of the roadway.
- Take the responsibility off the driver, such as maintaining an ensured clear distance from the vehicle in front while at the same time handling the accelerator pedal to maintain a set speed.
- Help the driver avoid a collision if a vehicle in front of the driver stops quickly.
- Make the parking safer through parking assist systems that use ultrasonic sensors to detect when the front or rear bumper is getting close to an object.

CAUTION: The advanced driver assist systems are designed as a driver aid and are not intended to replace the driver. It is the responsibility of the driver to be aware of the surroundings and be able to take control of the vehicle at all times.

BLIND SPOT MONITOR

FUNCTION AND TERMINOLOGY The **blind spot monitor (BSM)** is a vehicle-based sensor device that detects other vehicles located to the side and rear of the vehicle. Warnings can be any of the following:

- Visual—Usually a warning light in the outside rearview mirrors. ● **SEE FIGURE 58–1**.
- Audible—Usually a beep or buzzer sound.
- Vibrating (tactile)—A vibration is often created in the steering wheel or the driver's seat.

The term used varies with vehicle manufacturers and includes the following:

Acura—Blind Spot Information (BSI)
Audi—Side Assist
BMW—Active Blind Spot Detection
Buick—Side Blind Zone Alert
Cadillac—Side Blind Zone Alert
Chevrolet—Side Blind Zone Alert
Dodge—Blind Spot Monitoring
Fiat—Blind Spot Monitoring

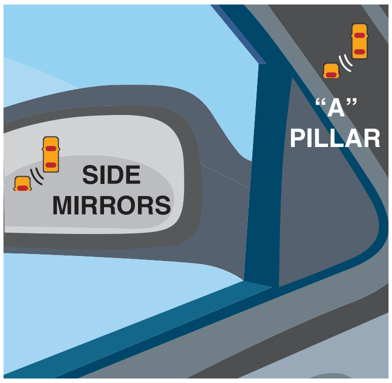

FIGURE 58–1 Blind spot monitoring systems usually use a warning system in the side-view mirror or in the "A" pillar near the side-view mirror to warn the driver that there is a vehicle in the potential blind spot.

FREQUENTLY ASKED QUESTION

What Is Meant by Human–Machine Interface (HMI)?

Human–machine interface (HMI) was very basic in the past because the vehicles were equipped with most of the following to let the driver know what the vehicle (the machine) was doing:

- Speedometers
- Fuel level gauge
- Engine coolant temperature
- Oil pressure (some vehicles)

Vehicles with advanced technology need to communicate to the driver or occupants using the following:

1. Visual displays
2. Sounds
3. Tactile (called "haptic" feedback vibrations of the seat or the steering wheel, which are created using a DC motor turning an offset weight to create the vibrations)

The hardware involved includes the following:

1. A display
2. Speakers
3. Input devices, such as a mouse or joystick
4. Microphone for voice commands

Behind the scenes, software is used to sort out the vast amount of information and reduce it to the levels where the driver can understand and react to situations as needed.

Ford—Blind Spot Information System (BLIS)
GMC—Side Blind Zone Alert
Honda—Lane Watch System
Hyundai—Blind Spot Detection
Infiniti—Blind Spot Intervention System
Jeep—Blind Spot Monitoring
Land Rover—Blind Spot Monitor
Lexus—Blind Spot Monitor
Mazda—Blind Spot Monitoring (BSM)
Mercedes-Benz—Active Blind Spot Assist
Mitsubishi—Blind Spot Warning (BSW)
Nissan—Blind Spot Warning
Porsche—Lane Change Assist
Subaru—Blind Spot Detection
Toyota—Blind Spot Monitor
Volvo—Blind Spot Information System (BSIS)

PARTS AND OPERATION When the vehicle is first started, the outside mirror displays will come on briefly indicating that the system is turned on and operating. The typical detection zone includes the following:

- Most systems are designed to detect objects that are as small as a motorcycle with rider.
- The detection zone extends out from the sides and behind the vehicle about 10 feet (3 m).
- It is capable of detecting objects that are about 2 to 6 feet (0.6 to 1.8 m) tall (above the ground).

NOTE: The blind spot monitoring system does not detect objects that are not moving, such as walls, curbs, bridges, or parked vehicles.

If the blind spot monitoring system fails to work as designed, check service information for the specified troubleshooting and repair procedure to follow.

PARKING-ASSIST SYSTEMS

FUNCTION AND COMPONENTS The parking-assist system is used to help drivers avoid contact with another object while moving slowly. When backing up at speed of less than 5 MPH (8 km/h), the system constantly monitors for objects located around the vehicle. The parking-assist system can usually detect objects that are greater than 3 inches (8 cm) wide and 10 inches (25 cm) tall, but the system cannot detect objects below the bumper or underneath the vehicle. As the vehicle gets closer to an object, there is an audible beep out of the speakers, and the time between the beeps becomes shorter, the closer to the object. The parking-assist system usually includes the following components:

- **Ultrasonic object sensors** are used to measure the distances to nearby objects and are built into the fender, and front and rear bumper assembly. The sensors send out acoustic pulses, and a control unit measures the return interval of each reflected signal, calculating object distances. ● **SEE FIGURE 58–2**.

  The system warns the driver with warning tones with the frequency indicating object distance. The faster the tone sounds, the closer is the vehicle to the object. A continuous tone indicates a minimal predefined distance. Systems may also include visual aids, such as LED or LCD readouts, to indicate object distance. A vehicle may include a vehicle pictogram on the infotainment screen. ● **SEE FIGURE 58–3**.
- **Electromagnetic parking sensors (EPS)** detect when a vehicle is moving slowly and toward an object. Once detected, the sensor continues to give signal of presence of the obstacle. If the vehicle then continues

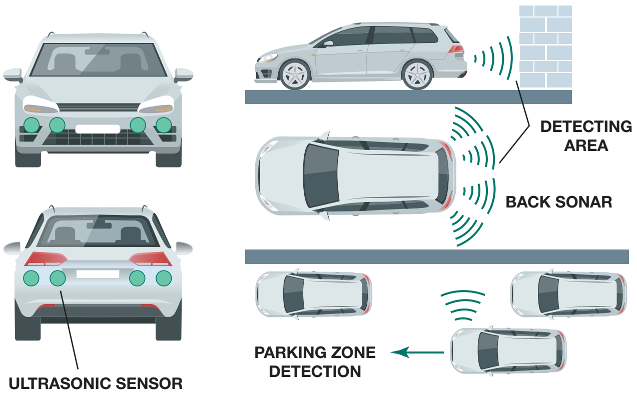

FIGURE 58–2 The small round buttons in the rear bumper are ultrasonic sensors used to sense distance to an object.

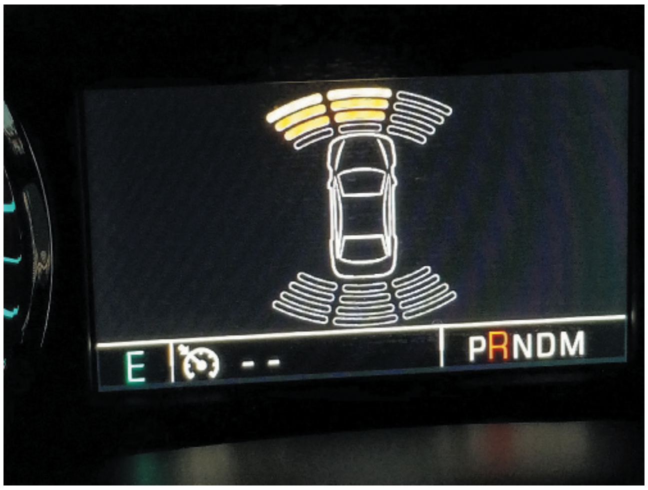

FIGURE 58–3 The dash display on a Chevrolet showing that an object is being detected at the front and left-front of the vehicle.

to move toward the object, the alarm signal becomes more and more impressive as the obstacle approaches. Electromagnetic parking sensors do not require any holes in the bumper and cannot be seen from the outside of the vehicle. A BSM is an option that may include more than monitoring the front, rear, and sides of the vehicle. It can include **cross-traffic alert**, which can sound an alarm when backing out of a parking space and traffic is approaching from either side.

TECH TIP

Check for Repainted Bumpers

The ultrasonic sensors embedded in the bumper are sensitive to paint thickness because the paint covers the sensors. If the system does not seem to be responding to objects, and if the bumper has been repainted, measure the paint thickness using a nonferrous paint thickness gauge. The maximum allowable paint thickness is 6 mils (0.006 inch or 0.15 millimeter).

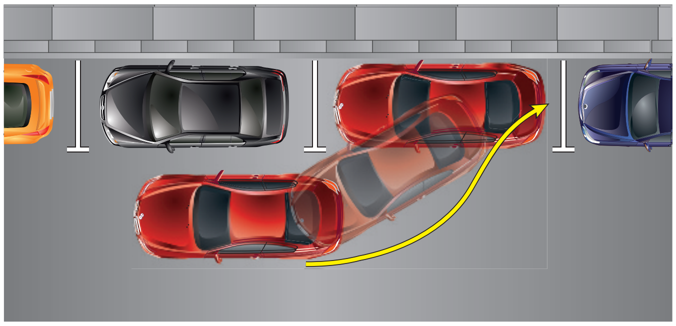

FIGURE 58–4 A self-parking-capable vehicle is able to parallel park or enter into a parking spot with little, or no input from the driver.

OPERATION The system is activated automatically when the vehicle is started. The indicator light on the dash or driver information center indicates the system is on. The parking-assist system is active from the time the engine is started until the vehicle exceeds a speed of approximately 6 MPH (10 km/h). It is also active when the vehicle is backing up. The parking-assist system is automatically reactivated the next time the engine is started, even if the system was turned off by the driver the last time the vehicle was driven.

DIAGNOSIS The parking-assist control module can detect faults and store diagnostic trouble codes. If a fault has been detected by the control module, the red lamp flashes and the system is disabled. Follow service information diagnostic procedures because the parking-assist module cannot usually be accessed using a scan tool.

SELF-PARKING **Self-parking** vehicles, also called *automatic parking vehicles*, use the camera(s) and control the electric power steering to guide the vehicle into a parking space. The driver may or may not have to add anything in many advanced systems, whereas the driver must control the throttle and the brakes in early systems. ● **SEE FIGURE 58–4**.

LANE DEPARTURE WARNING

PARTS AND OPERATION The **lane departure warning system (LDWS)** uses cameras to detect if the vehicle is crossing over lane marking lines on the pavement. Some systems use two cameras, one mounted on each outside rearview mirror. Some systems use infrared sensors located under the front bumper to monitor the lane markings on the road surface. The system names also vary according to vehicle manufacturers, including the following:

Honda/Acura: Lane Keep Assist System (LKAS)
Toyota/Lexus: Lane Monitoring System (LMS)
General Motors: Lane Departure Warning (LDW)
Ford: Lane Departure Warning (LDW)
Nissan/Infiniti: Lane Departure Prevention (LDP) System

If the cameras detect that the vehicle is starting to cross over a lane dividing line, a warning chime sounds or a vibrating mechanism mounted in the driver's seat cushion is triggered on the side where the departure is being detected. This warning does not

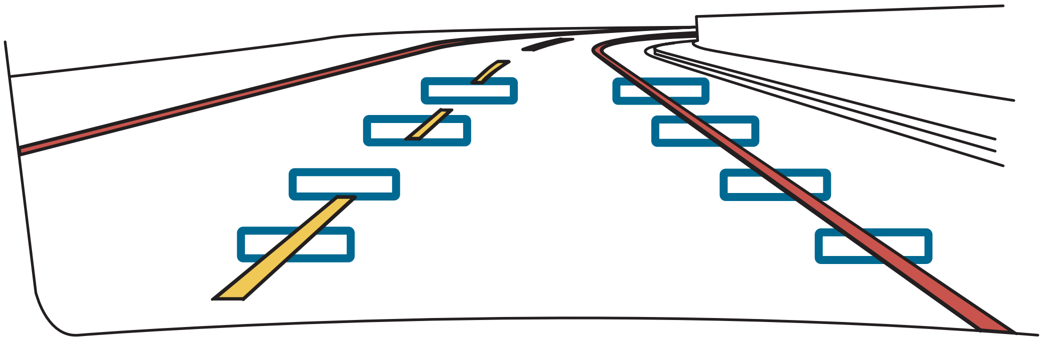

FIGURE 58–5 A lane departure warning system often uses cameras to sense the road lines and warns the driver if the vehicle is not staying within the lane, unless the turn signal is on.

occur if the turn signal is on in the same direction as detected. ● **SEE FIGURE 58–5**.

DIAGNOSIS AND SERVICE Before attempting to service or repair an LDWS fault, check service information for an explanation on how the system is supposed to work. If the system is not working as designed, perform a visual inspection of the sensors or cameras, checking for damage from road debris or evidence of body damage, which could affect the sensors. After a visual inspection, follow the vehicle manufacturer's recommended diagnosis procedures to locate and repair the fault in the system.

LANE KEEP ASSIST

PURPOSE AND FUNCTION The purpose of **lane keep assist (LKA)**, also called *lane keep assist system (LKAS)*, is not only to warn the driver if the vehicle is moving out of the lane of traffic, but when no response, it uses the electric power steering system to steer the vehicle back into the lane. ● **SEE FIGURE 58–6**.

PARTS AND OPERATION Most lane keep assist systems use a camera mounted in front of the inside rearview mirror with a clear view of the road ahead. A typical LKAS is able to monitor the road about 160 feet (50 m) ahead, and at vehicle speeds above 40 MPH (60 km/h) with the camera observing a 40-degree view ahead of the vehicle. The camera can detect the lane marking, which includes the center line and the right-side painted line, often called the fog line because it helps drivers see the right side of the road under poor or in foggy visibility.

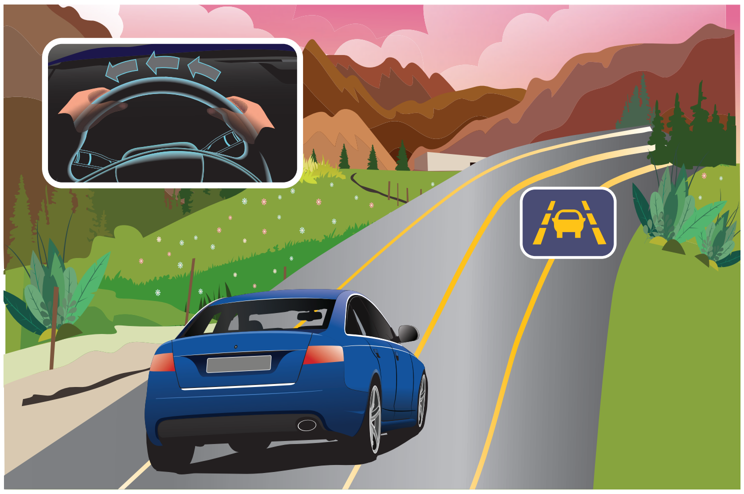
When the camera detects that the vehicle is starting to get close to either lane marking, the vehicle performs the following functions:

1. It warns the driver by a warning sound, and/or lights the LKA symbol on the dash. In some vehicles, the warning includes vibrating the steering wheel in an attempt to get the driver's attention.
2. If the warnings do not result in corrective action by the driver, the LKAS uses the electric power steering to steer the vehicle back into the lane between the two lane markings.

ADAPTIVE CRUISE CONTROL

PURPOSE AND FUNCTION **Adaptive cruise control (ACC)**, also called *radar cruise control*, gives the driver more control over the vehicle by keeping an assured clear distance behind the vehicle in front. If the vehicle in front slows, the ACC detects the slowing vehicle and automatically reduces the speed of the vehicle to keep a safe distance. Then, if the vehicle speeds up, the ACC also allows the vehicle to increase to the preset speed. This makes driving in congested areas easier and less tiring.

FIGURE 58–6 Lane keep assist systems not only warns the driver that the vehicle is not staying within the lane of traffic, but will also uses the electric power steering to actually move the steering wheel to bring the vehicle back into the lane. This action can startle a driver if the driver has never experienced the vehicle taking control of the steering before.



TERMINOLOGY Depending on the manufacturer, adaptive cruise control is also referred to as the following:

- **Adaptive cruise control** (Audi, Ford, General Motors, and Hyundai)
- **Dynamic cruise control** (BMW, Toyota/Lexus)
- **Active cruise control** (Mini Cooper, BMW)
- **Autonomous cruise control** (Mercedes)

It uses forward-looking radar to sense the distance to the vehicle in front and maintains an assured clear distance. This type of cruise control system works within the following conditions:

- Speeds from 20 to 100 MPH (30 to 161 km/h)
- Designed to detect objects as far away as 500 feet (150 m)

The cruise control system is able to sense both distance and relative speed. ● **SEE FIGURE 58–7**.

PARTS AND OPERATION Radar cruise control systems use long-range radar (LRR) to detect faraway objects in front of the moving vehicle. Some systems use a short-range radar (SRR) and/or infrared (IR) or optical cameras to detect when the distance between the moving vehicle and another vehicle in front is reduced. ● **SEE FIGURE 58–8**.

The radar frequencies include the following:

- 76 to 77 GHz (long-range radar)
- 24 GHz (short-range radar)

DIAGNOSIS AND SERVICE If the radar cruise control is not working properly, begin by making sure the sensor, which is usually behind the grille on most vehicles, is not covered. The system does not operate if the system is covered by heavy mud, ice, or snow. Additionally, some aftermarket vehicle front covers obstruct the sensor view. If the sensor is replaced, some systems require a re-alignment using special tools. Always refer to the manufacturer's service information for specific instructions.

CASE STUDY

The Case of The Inoperative Radar Cruise Control

The driver of a Lexus NX experienced a situation where the radar cruise control stopped working due to ice on the sensor after driving through light snow showers. When the front was checked, it was discovered that ice had accumulated on the front grille. Using an ice scraper brush, the grille was cleaned, which restored the proper operation of the radar cruise control. ● **SEE FIGURE 58–9**.

In automated vehicles, the sensors need to be heated, and maybe cleaned, so that they can operate under all driving conditions.

Summary:

Complaint—Radar cruise stopped working and a message appeared to clean the sensor.

Cause—Ice buildup on the grille.

Correction—Cleaning the front of the grille, using a brush restored the proper operation of the radar cruise control.

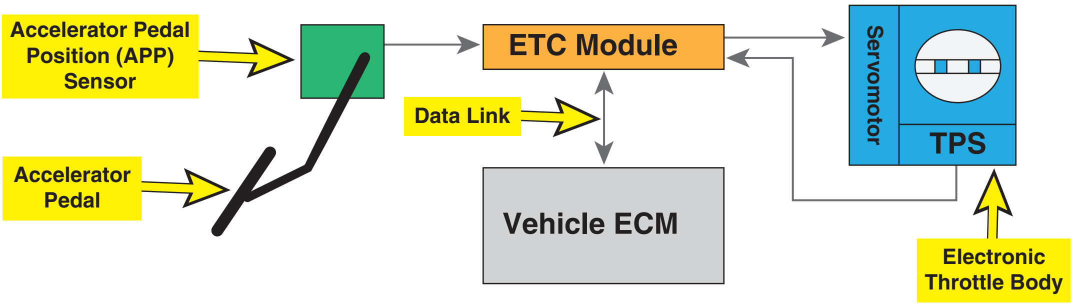


FIGURE 58–7 Adaptive cruise control can use radar to determine the distance of another vehicle in front. The control unit checks the driver's selected speed and sets the distance between the vehicles to determine what action is needed. The PCM then can operate the throttle or the brakes through the antilock brake/electronic stability control system to slow the vehicle, if needed, to maintain the set distance.

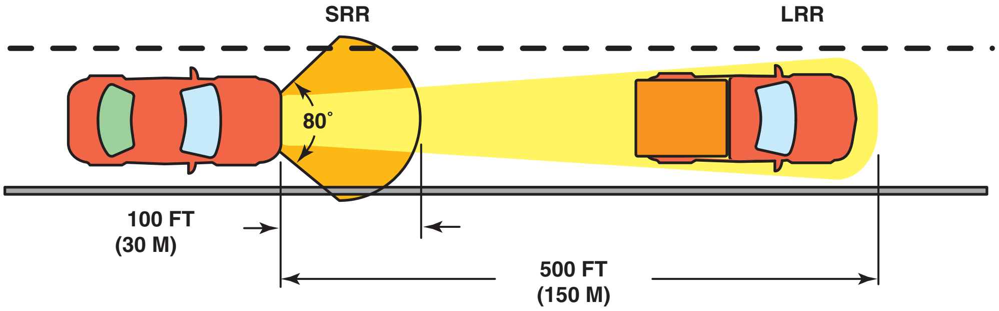

FIGURE 58–8 Most radar cruise control systems use radar, both long and short range. Some systems use optical or infrared cameras to detect objects.

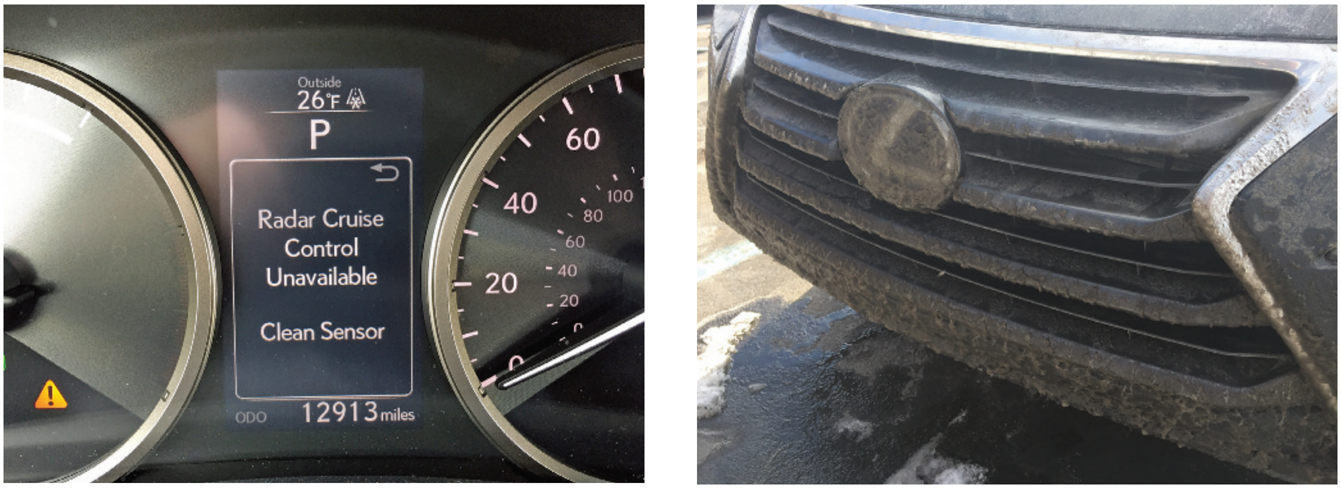

(a)

(b)

FIGURE 58–9 (a) This dash warning message appeared when the cruise control stopped working. (b) The front of a Lexus shows some ice buildup that was enough to block the radar signals needed for the radar cruise control to work.

FREQUENTLY ASKED QUESTION

What Is Intelligent Speed Advice (ISA)?

Intelligent Speed Advice (ISA) uses a sign recognition camera or a navigation system (GPS) to determine the speed limit, which is used to warn the driver of the posted speed limit. Some ISA systems automatically limit the speed of the vehicle by limiting engine power to prevent the vehicle from accelerating past the current speed limit unless overridden. The European New Car Assessment Program (Euro NCAP) is a European car safety performance assessment program which is awarding vehicle manufacturers if their vehicle is equipped with this system.

REAR CROSS-TRAFFIC WARNING (RCTW)

PURPOSE AND FUNCTION A **rear cross-traffic warning (RCTW)** system sounds an audible warning when a vehicle is crossing at the rear while backing. Some vehicles are capable of automatically braking to avoid a collision.

PARTS AND OPERATION Rear cross-traffic alert is used to warn the driver when backing from a parking space if there is a vehicle approaching from either side. The system uses radar sensors that are installed on both sides of the vehicle near the rear bumper. These sensors are able to detect vehicles approaching from the left or right side of the vehicle. These sensors activate when the vehicle is placed in reverse and can detect vehicles from up to 65 feet (20 m) on either side. The system is usually designed to function under the following conditions:

- When the vehicle is in reverse and your speed is less than 5 MPH (8 km/h)
- The system is designed to detect other vehicles approaching between 5 and 18 MPH (8 to 29 km/h).

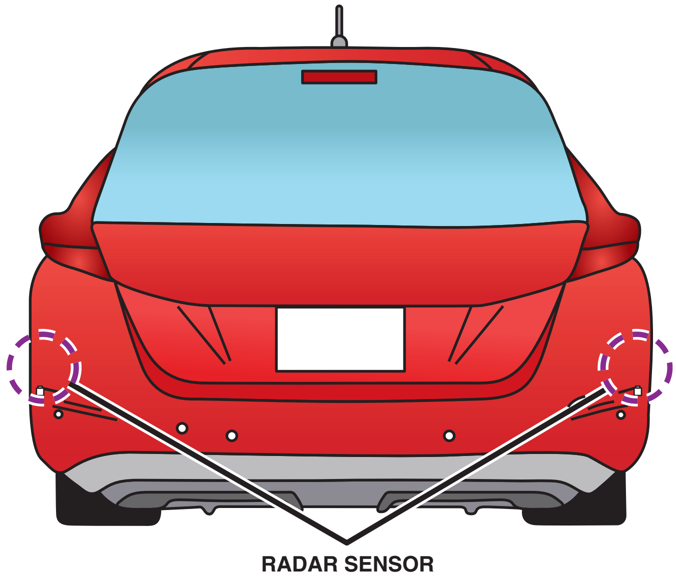

FIGURE 58–10 Rear cross-traffic warning systems use radar sensors at the rear corners of the vehicle which are able to detect a moving vehicle approaching from the sides.

- If a vehicle is detected, the system will sound a warning and often flash the side mirror indicators.
- Rear cross-traffic alert may not work if one of the rear sensors is blocked or during heavy rain or snow.

● **SEE FIGURES 58–10 AND 58–11**.

AUTOMATIC EMERGENCY BRAKING

PURPOSE AND FUNCTION An **automatic emergency braking (AEB)** system intervenes and automatically applies the brakes if needed. Automatic braking is often part of a safety package that includes radar cruise control, and will apply the brakes in the event of a possible collision. Sensors such as radar, sonar, and/or cameras are used depending on the system to

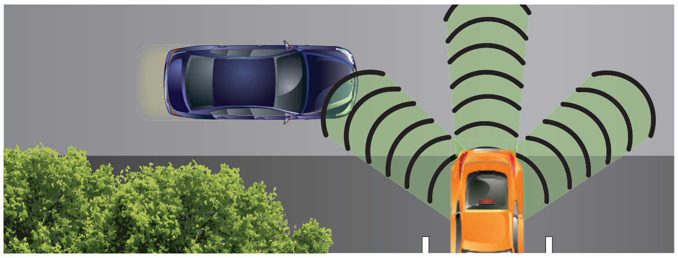

FIGURE 58–11 If a vehicle is approaching from the side when the gear selector is in reverse, a warning is sounded.

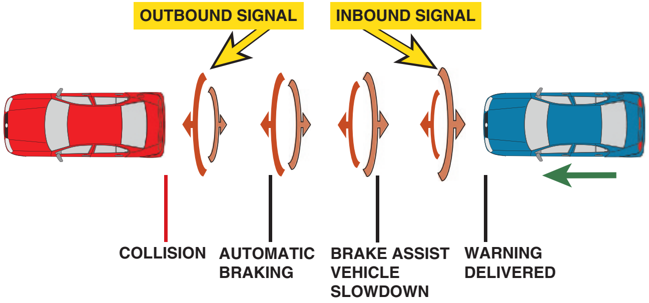

FIGURE 58–12 Sensors are used to detect when the distance is closing fast enough that a collision may be possible, and the system intervenes to automatically apply the brakes if needed.

detect the distance to another object. The controller, usually an antilock braking system (ABS) controller, then issues a warning if a collision is possible.

This warning can include one or more of the following:

1. A buzzer
2. A warning light flashing on the dash
3. A vibration of the driver's seat

If the warnings are ignored, the automatic braking system will intervene and either provide brake assist or apply the brakes autonomously (by itself) to achieve maximum braking in an effort to avoid a collision. ● **SEE FIGURE 58–12**.

PRE-COLLISION SYSTEM

PURPOSE AND FUNCTION The purpose and function of a pre-collision system is to monitor the road ahead and prepare to avoid a collision, and to protect the driver and passengers.

A pre-collision or a collision avoidance system uses the following systems:

1. The long-range and short-range radar or detection systems used by a radar cruise control system to detect objects in front of the vehicle
2. Antilock brake system (ABS)
3. Adaptive (radar) cruise control
4. Brake assist system

TERMINOLOGY Pre-collision systems can be called by various names, depending on the make of the vehicle. Some commonly used names for a pre-collision or pre-crash system include the following:

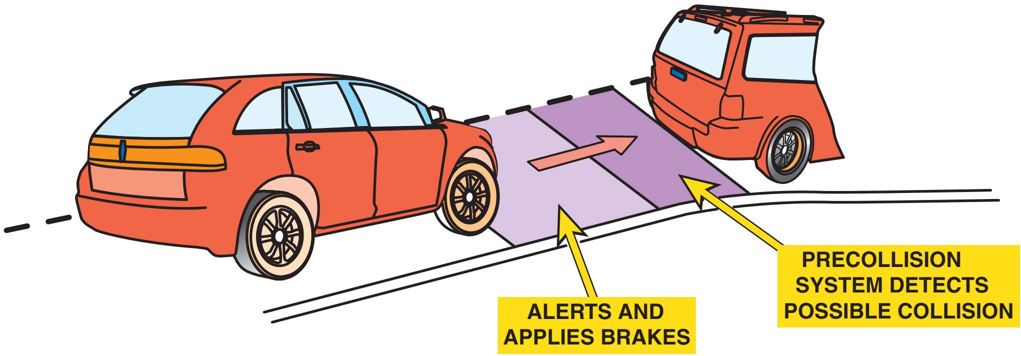
- **Ford/Lincoln:** Collision Warning with Brake Support
- **Honda/Acura:** Collision Mitigation Brake System (CMBS)
- **Mercedes-Benz:** Pre-Safe or Attention Assist
- **Toyota/Lexus:** Pre-Collision System (PCS) or Advanced Pre-Collision System (APCS)
- **General Motors:** Pre-Collision System (PCS)
- **Volvo:** Collision Warning with Brake Support or Collision Warning with Brake Assist Operation

The system functions by monitoring objects in front of the vehicle and can act to avoid a collision by the following actions:

- Sounds an alarm
- Flashes a warning lamp
- Applies the brakes and brings the vehicle to a full stop (if needed), if the driver does not react following actions:

1. Applies the brakes in full force to reduce vehicle speed as much as possible.
2. Closes all windows and the sunroof to prevent the occupants from being ejected from the vehicle.
3. Moves the seats to an upright position.
4. Raises the headrest (if electrically powered).
5. Pretensions the seat belts.
6. Airbags and seat belt tensioners function as designed during the collision.

● **SEE FIGURE 58–13**.



PRECOLLISION SYSTEM DETECTS POSSIBLE COLLISION
ALERTS AND APPLIES BRAKES

FIGURE 58–13 A pre-collision system is designed to prevent a collision first, and interacts to prepare for a collision, if needed.

HILL START ASSIST

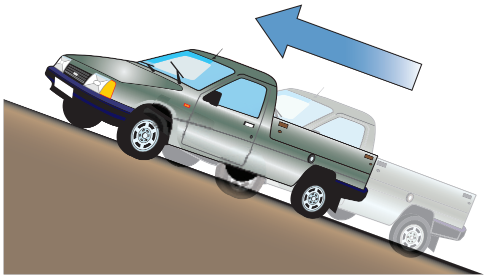
PURPOSE AND FUNCTION The hill start assist feature allows the driver to launch his vehicle without a rollback while moving the foot from the brake pedal to the accelerator pedal. The electronic brake control module calculates the brake pressure that is needed to hold the vehicle on an incline, and locks that pressure for a certain time by commanding the appropriate solenoid valves on and off when the brake pedal is released. Hill start assist is activated when the electronic brake control module determines that the driver wishes to move their vehicle uphill, either backward or forward. ● **SEE FIGURE 58–14**.

The following inputs are used for the hill start assist feature:

- Brake switch
- Brake pressure sensors
- Longitudinal acceleration sensor
- Engine torque
- Reverse gear information
- Clutch switch
- Accelerator pedal position
- Vehicle speed

Drivers of vehicles equipped with hill start assist systems are often not aware that the vehicle is equipped with this system. As a result, it is often a concern of drivers when the brake pedal is released when starting forward after being stopped on a hill (the brakes seem to be slow to release). This is normal and not a fault with the system.

WITH HILL START ASSIST



WITHOUT HILL START ASSIST

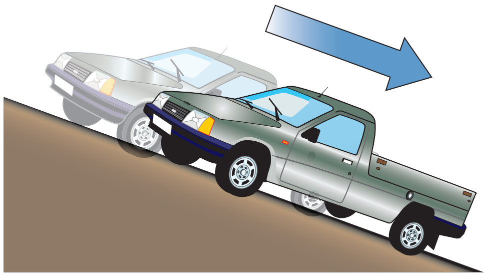


FIGURE 58–14 A hill start assist system applies the brakes when the system detects that the vehicle is stopped on a hill, either down or up. This system keeps the vehicle from rolling down the hill without requiring the driver to keep the brakes applied.

ADAS DIAGNOSIS

VIN DECODER To identify what ADAS a vehicle is equipped with, use the vehicle identification number (VIN), or the regular production order (RPO) for vehicles built by General Motors. There are many online VIN decoders available, including one on the National Highways Traffic Safety Administration (NHTSA) website. Visit https://vpic.nhtsa.dot.gov/decoder/

At this site, enter the VIN and select “decode.” The results will show all of the ADAS used on that specified vehicle.

DIAGNOSTIC STEPS Similar to troubleshooting any other system or fault, the steps in the diagnostic procedure include the following:

STEP 1 Verify the customer concern. Check the customer concern and determine that it is a true fault and not a misunderstanding on how the system is supposed to work.

STEP 2 Perform a visual inspection. Check for any physical faults that could affect the operation of the advanced driver assist system, such as road debris and/or minor collision damage.

STEP 3 Check for any stored or pending diagnostic trouble codes. Check all modules by performing a full module scan to check for faults in all of the modules.

STEP 4 Check service information for the specified procedure to follow to service or repair the verified fault.

STEP 5 Perform the specified procedure and static calibrations of the sensors as needed.

STEP 6 Perform the specified dynamic celebration of the sensors as needed.

STEP 7 Test drive the vehicle under the same operating conditions that were used to verify the fault to verify the repair.

STEP 8 Clear all advanced driver assist system-related diagnostic trouble codes (DTCs) and return the vehicle to the customer.

CAMERA AND RADAR SENSOR CALIBRATION

CAMERA CALIBRATION The operation of the camera can be affected by heavy rain, snow, or an accumulation of ice or mud. Before making any repairs, it is important to verify that the lens of the camera is free of anything that obstructs its view.

Calibration of the camera is required when one or more cameras are replaced on a mounting component, such as a windshield, bumper cover, mirror, or door. The calibration is an in-shop static process. Large patterned mats are placed around the vehicle at specific locations and the scan tool is used to initiate the process. ● **SEE FIGURE 58–15**.

TYPICAL PROCEDURE Some camera systems require a specific target so that the camera can be calibrated. Some vehicles that do not require a special target require a factory or factory-level

scan tool to imitate the learning process. They will often use lines that are taped to the floor around the vehicle to use as a target. ● **SEE FIGURE 58–16**.

Some systems also require that the vehicle be driven at slow speeds under specific operating conditions to complete the learning. This process is used to do the final accurate calibrations.

Refer to service information for specific diagnostic and calibration information for the vehicle being serviced.

RADAR CALIBRATION Calibration of the radar is required anytime the unit is replaced or reinstalled. In many cases, the calibration procedure must be performed anytime a grille or fascia is removed or replaced. The calibration process may be static (in the shop), or dynamic (on the road), or a combination of the two. The static process involves the use of a scan tool and an aiming procedure. The aiming procedure requires manufacturer-specific targets. ● **SEE FIGURES 58–17 AND 58–18**.

Check service information for specific diagnostic and calibration information for the vehicle being serviced.

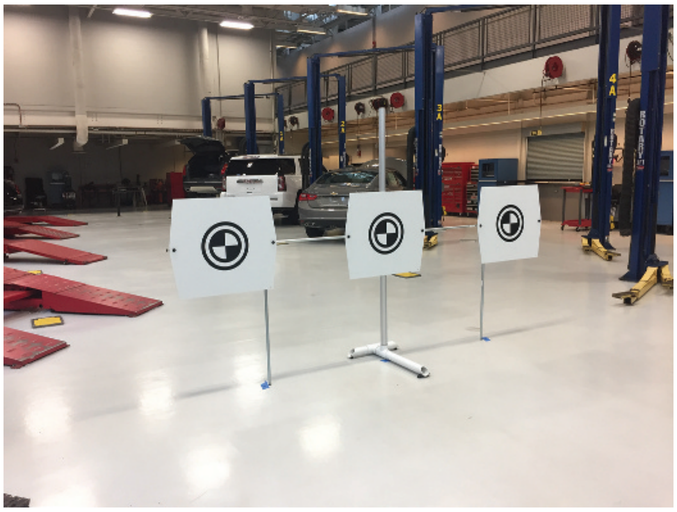

FIGURE 58–16 A typical target setup required to calibrate the camera on a vehicle equipped with an advanced driver assist system. Always follow the specified calibration procedure for the vehicle being serviced.

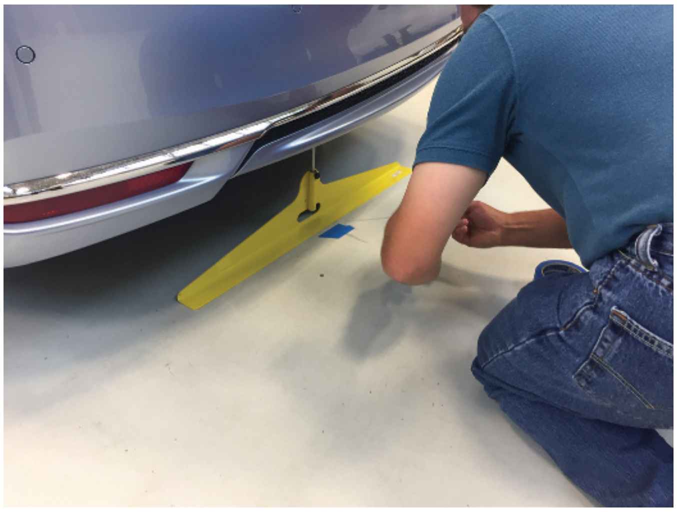

FIGURE 58–17 Before the radar sensor can be calibrated, the target must be installed at a very precise location at the front of the vehicle. The measurements involved include finding the exact center of the vehicle often using a special tool as shown.

REVIEW QUESTIONS

1. Parking-assist systems use what type of sensor?
2. What is the difference between a lane departure warning and a lane keep assist?
3. What type of sensors are used in adaptive cruise control systems?
4. What type of sensors are used in automatic emergency braking and pre-collision control systems?
5. What is the purpose and function of advanced driver assist systems?

CHAPTER QUIZ

1. What is *not* a function of advanced driver assist systems?
   - **a.** Self-drive capability
   - **b.** Take the load off the driver
   - **c.** Help the driver avoid a collision if a vehicle in front of them stops quickly
   - **d.** Alert the driver of a potential issue
2. Blind spot monitor (BSM) and lane departure warnings can be __________.
   - **a.** visual
   - **b.** audible
   - **c.** vibrating (tactile)
   - **d.** Any of the above
3. Self-parking vehicles use __________ and control the __________ to control the vehicle into a parking space.
   - **a.** radar; throttle
   - **b.** camera; electric power steering
   - **c.** sonic sensor; brakes
   - **d.** radar; electric power steering
4. The purpose of lane keep assist (LKA) is __________.
   - **a.** to warn the driver if moving out of a lane
   - **b.** used with adaptive cruise control to self-drive the vehicle without driver input or control
   - **c.** to use the electric power steering to keep the vehicle within the lane
   - **d.** Both a and c
5. A driver complains that the brakes seem to release slowly at times, usually when stopped on a hill. This is normal operation of the __________ system.
   - **a.** hill start assist
   - **b.** adaptive cruise control
   - **c.** pre-collision
   - **d.** automatic emergency braking
6. Adaptive cruise control systems can also be called __________.
   - **a.** dynamic cruise control
   - **b.** active cruise control
   - **c.** radar cruise control
   - **d.** Any of the above
7. Rear cross-traffic alert is used to warn the driver when backing out from a parking space if there is a vehicle approaching from either side. The system uses __________ installed on both sides of the vehicle near the rear bumper.
   - **a.** sonar
   - **b.** ultrasonic sensors
   - **c.** radar
   - **d.** cameras

8. Automatic braking uses a ___________ to warn of a possible collision.
- **a.** buzzer
- **b.** flashing light
- **c.** vibrating brake pedal
- **d.** Either a or b

9. A parking-assist system works to warn the driver if the vehicle is getting close to an object. What type of object *cannot* be detected by most systems?
- **a.** Objects larger than 3 inches (8 cm) wide
- **b.** Objects larger than 10 inches (25 cm) high
- **c.** Objects under the vehicle
- **d.** Any of the above

10. Calibrating radar and cameras involves all of the following *except* ___________.
- **a.** factory or factory-level scan tool
- **b.** special targets set at precisely specified location around the vehicle
- **c.** both static (stationary) and dynamic (moving) calibration is required
- **d.** driving the vehicle in a circle 10 times to calibrate the cameras

Chapter 59

AUDIO SYSTEM OPERATION AND DIAGNOSIS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss audio system fundamentals.
- Describe radios and receivers.
- Describe types of antennas and antenna testing.
- Discuss the purpose and function of speakers.
- Describe types of speakers.
- Explain the decibel scale.
- Discuss voice recognition systems.
- Explain how Bluetooth systems work.
- Explain how satellite radio systems work.

KEY TERMS:

AM 704 • Bluetooth 708 • Decibel (dB) 707 • FM 704 • Frequency 703 • Hertz (Hz) 704 • Modulation 704 • Radio frequency (RF) 703 • SDARS 708 • Speakers 705 • Voice recognition 707

AUDIO FUNDAMENTALS

INTRODUCTION The audio system of today's vehicles is a complex combination of antenna system, receiver, amplifier, and speakers, all designed to provide living room–type music reproduction while the vehicle is traveling in city traffic or at highway speed.

Audio systems produce audible sounds and include the following:

- Radio (AM, FM, and satellite)
- Antenna systems that are used to capture electronic energy broadcast to radios
- Speaker systems
- Aftermarket enhancement devices that increase the sound energy output of an audio system
- Diagnosis of audio-related problems

Many audio-related problems can be addressed and repaired by a service technician.

TYPES OF ENERGY There are two types of energy that affect audio systems:

- **Electromagnetic energy or radio waves.** Antennas capture the radio waves, which are then sent to the radio or receiver to be amplified.
- **Acoustical energy, usually called sound.** Radios and receivers amplify the radio wave signals and drive speakers, which reproduce the original sound as transmitted by radio waves.
● **SEE FIGURE 59–1**.

TERMINOLOGY Radio waves travel at approximately the speed of light (186,282,000 miles per second) and are electromagnetic. Radio waves are measured in two ways, wavelength and frequency. A radio wave has a series of high points and low points. A wavelength is the time and distance between two consecutive points, either high or low. Wavelength is measured in meters. **Frequency**, also known as **radio frequency (RF)**, is the number of times a particular waveform repeats itself in a

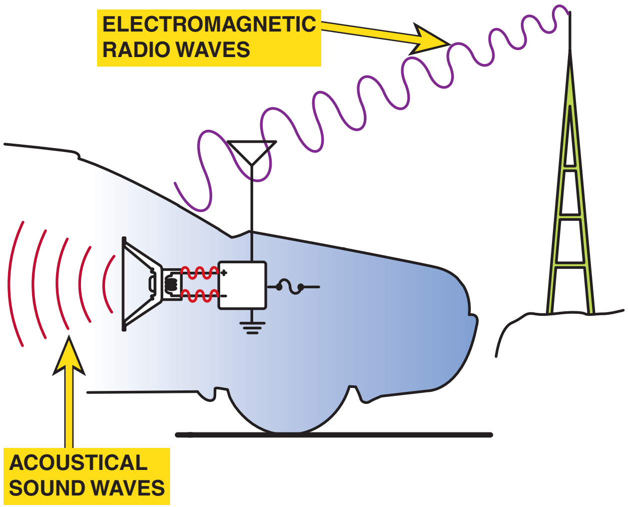

FIGURE 59–1 Audio systems use both electromagnetic radio waves and sound waves to reproduce sound inside the vehicle.

given amount of time and is measured in **hertz (Hz)**. A signal with a frequency of 1 Hz is one radio wavelength per second. Radio frequencies are measured in kilohertz (kHz), thousands of wavelengths per second, and megahertz (MHz), millions of wavelengths per second. ● **SEE FIGURE 59–2**.

- The higher the frequency, the shorter the wavelength.
- The lower the frequency, the longer the wavelength.

A longer wavelength can travel a further distance than a shorter wavelength. Therefore, lower frequencies provide better reception at further distances.

- AM radio frequencies range from 530 to 1,710 kHz.
- FM radio frequencies range from 87.9 to 107.9 MHz.

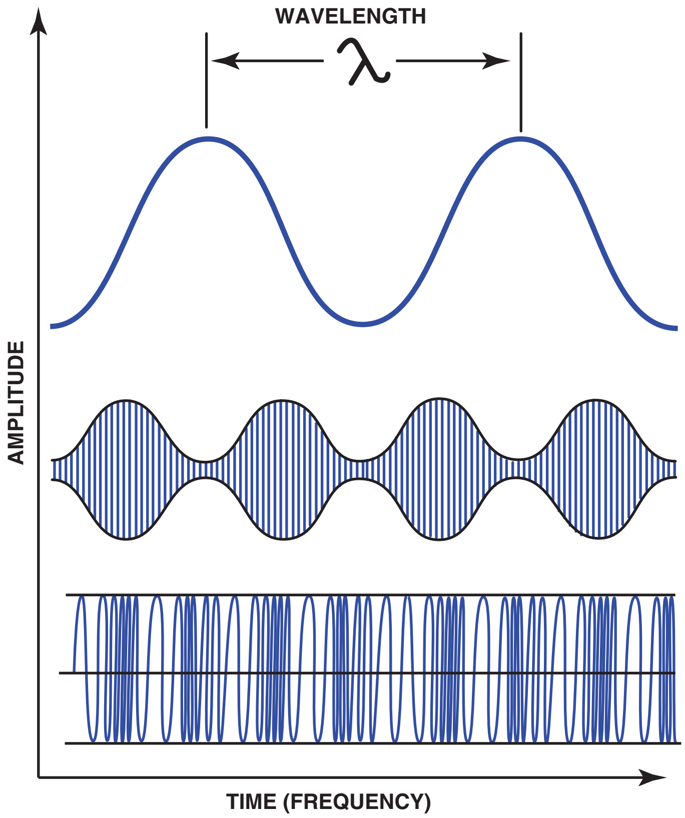

FIGURE 59–2 The relationship among wavelength, frequency, and amplitude.

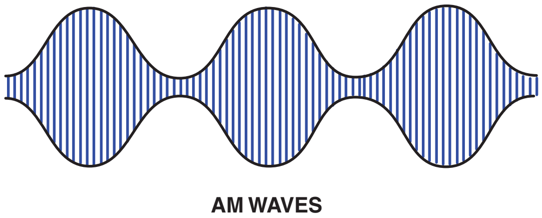

FIGURE 59–3 The amplitude changes in AM broadcasting.

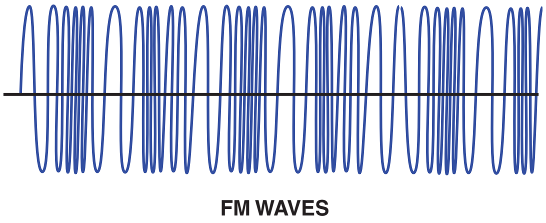

FIGURE 59–4 The frequency changes in FM broadcasting and the amplitude remains constant.

MODULATION **Modulation** is the term used to describe when information is added to a constant frequency. The base radio frequency used for RF is called the *carrier wave.* A carrier is a radio wave that is changed to carry information. The two types of modulation are:

- **Amplitude modulation (AM)**
- **Frequency modulation (FM)**

AM waves are radio waves that have amplitude that can be varied, transmitted, and detected by a receiver. Amplitude is the height of the wave as graphed on an oscilloscope. ● **SEE FIGURE 59–3**.

FM waves are also radio waves that have a frequency that can be varied, transmitted, and detected by a receiver. This type of modulation changes the number of cycles per second, or frequency, to carry the information. ● **SEE FIGURE 59–4**.

RADIO WAVE TRANSMISSION More than one signal can be carried by a radio wave. This process is called *sideband operation.* Sideband frequencies are measured in kilohertz. The amount of the signal above the assigned frequency is referred to as the upper sideband. The amount of the signal below the assigned frequency is called the lower sideband. This capability allows radio signals to carry stereo broadcasts. Stereo broadcasts use the upper sideband to carry one channel of the stereo signal and

FREQUENTLY ASKED QUESTION

What Does a “Capture” Problem Mean?

A capture problem affects only FM reception and means that the receiver is playing more than one station if two stations are broadcasting at the same frequency. Most radios capture the stronger signal and block the weaker signal. However, if the stronger signal is weakened due to being blocked by buildings or mountains, the weaker signal is then used. When this occurs, it sounds as if the radio is changing stations by itself. This is not a fault with the radio, but simply a rare occurrence with FM radio.

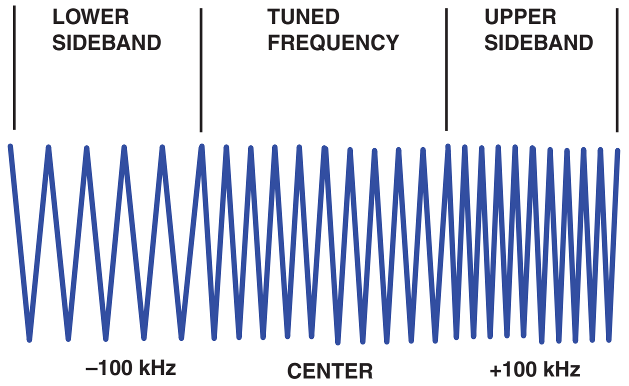

FIGURE 59–5 Using upper and lower sidebands allows stereo to be broadcast. The receiver separates the signals to provide left and right channels.

the lower sideband to carry the other channel. When the signal is decoded by the radio, these two signals become the right and left channels. ● **SEE FIGURE 59–5**.

NOISE Because radio waves are a form of electromagnetic energy, other forms of energy can impact them. For example, a bolt of lightning generates broad radio-frequency bandwidths known as radio-frequency interference (RFI). RFI is one type of electromagnetic interference (EMI) and is the frequency that interferes with radio transmission.

AM CHARACTERISTICS AM radio reception can be achieved over long distances from the transmitter because the waves can bounce off the ionosphere, usually at night. Even during the day, the AM signals can be picked up some distance from the transmitter. AM radio reception depends on a good antenna. If there is a fault in the antenna circuit, AM reception is affected the most.

FM CHARACTERISTICS Because FM waves have a high RF and a short wavelength, they travel only a short distance. The waves cannot follow the shape of the earth but instead travel in a straight line from the transmitter to the receiver. FM waves travel through the ionosphere and into space and do not reflect back to earth like AM waves.

MULTIPATH Multipath is caused by reflected, refracted, or line-sight signals reaching an antenna at different times. Multipath results from the radio receiving two signals to process on the same frequency. This causes an echo effect in the speakers. *Flutter,* or *picket fencing* as it is sometimes called, is caused by the blocking of part of the FM signal. This blocking causes a weakening of the signal resulting in only part of the signal getting to the antenna, causing an on-again off-again radio sound. Flutter also occurs when the transmitter and the receiving antenna are far apart.

RADIOS AND RECEIVERS

The antenna receives the radio wave where it is converted into very weak fluctuating electrical current. This current travels along the antenna lead-in to the radio that amplifies the signal and sends the new signal to the speakers where it is converted into acoustical energy.

Most late-model radios and receivers use five input/output circuits:

1. **Power.** Usually a constant 12 volt feed to keep the internal clock alive.
2. **Ground.** This is the lowest voltage in the circuit and connects indirectly to the negative terminal of the battery.
3. **Serial data.** Used to turn the unit on and off and provide other functions, such as steering wheel control operation.
4. **Antenna input.** From one or more antennas.
5. **Speaker outputs.** These wires connect the receiver to the speakers or as an input to an amplifier.

ANTENNAS

TYPES OF ANTENNAS The typical radio electromagnetic energy from the broadcast antenna induces a signal in the antenna that is very small, only about 25 microvolts AC (0.000025 volt AC), in strength. The radio contains amplifier circuits that increase the received signal strength into usable information.

For example, some types of antennas used on vehicles include the following:

- **Rear window defogger grid.** This type of system uses the heating wires to receive the signals and special circuitry to separate the RF from the DC heater circuit.
- **Fixed mast antenna.** The mast is simply a vertical rod. Mast antennas are typically located on the fender or rear quarter panel of the vehicle.
- **Integrated antenna.** This type of antenna is sandwiched in the windshield and an appliqué on the rear window glass. The antenna in the rear window is the primary antenna and receives both AM and FM signals. The secondary antenna is located in the front windshield typically on the passenger side of the vehicle. This antenna receives only FM signals.
- **Shark-fin antenna.** This type of antenna contains multiple antennas, including radio, GPS, and cellular system antennas.

ANTENNA HEIGHT The antenna collects all radio-frequency signals. An AM radio operates best with as long an antenna as possible, but FM reception is best when the antenna height is exactly 31 inches (79 cm). Most fixed-length antennas are, therefore, exactly this height. Even the horizontal section of a windshield antenna is 31 inches (79 cm) long.

A defective antenna:

- Greatly affects AM radio reception
- May affect FM radio reception

ANTENNA TESTING If the antenna or lead-in cable is broken (open), FM reception is heard but may be weak, and there is *no* AM reception. An ohmmeter should read infinity between the center antenna lead and the antenna case. For proper reception and lack of noise, the case of the antenna must be properly grounded to the vehicle body. ● **SEE FIGURE 59–6**.

SPEAKERS

PURPOSE AND FUNCTION The purpose of any **speaker** is to reproduce the original sound as accurately as possible. Speakers are also called *loudspeakers.* The human ear is capable of hearing sounds from a very low frequency of 20 Hz (cycles per seconds)

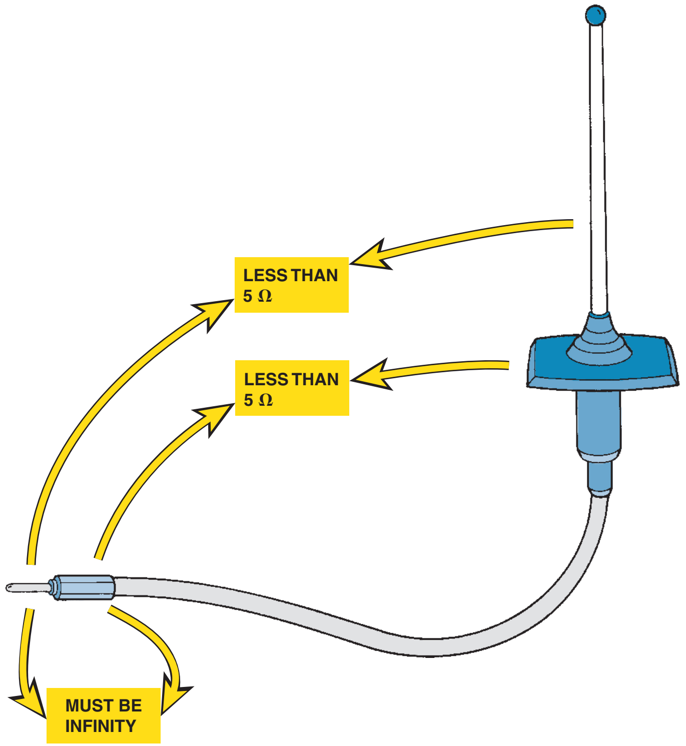

FIGURE 59–6 If all ohmmeter readings are satisfactory, the antenna is good.

to as high as 20,000 Hz. No one speaker is capable of reproducing sound over such a wide frequency range. ● **SEE FIGURE 59–7**.

Good-quality speakers are the key to a proper sounding radio or sound system. Replacement speakers should be securely mounted and wired according to the correct *polarity*. ● **SEE FIGURE 59–8**.

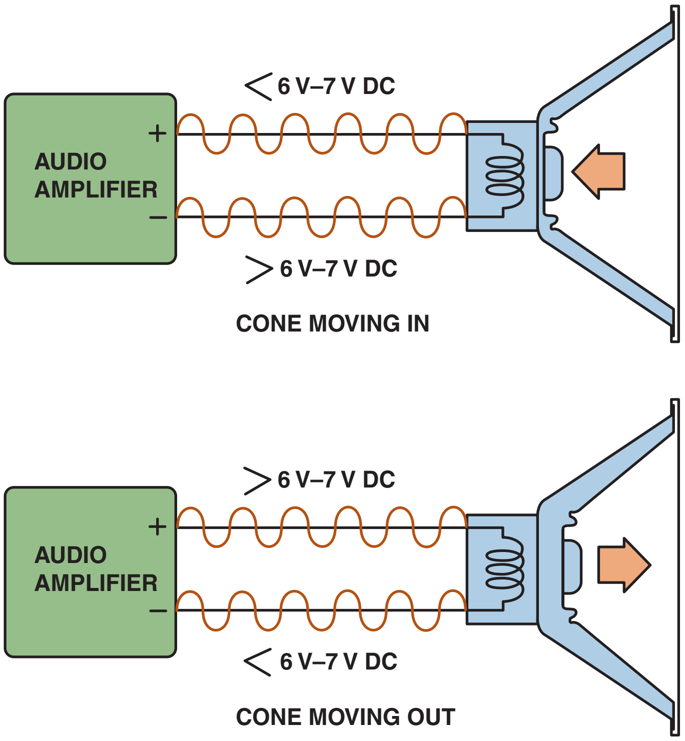

FIGURE 59–7 Between 6 and 7 volts is applied to each speaker terminal, and the audio amplifier then increases the voltage on one terminal and at the same time decreases the voltage on the other terminal, causing the speaker cone to move. The moving cone then moves the air, causing sound.

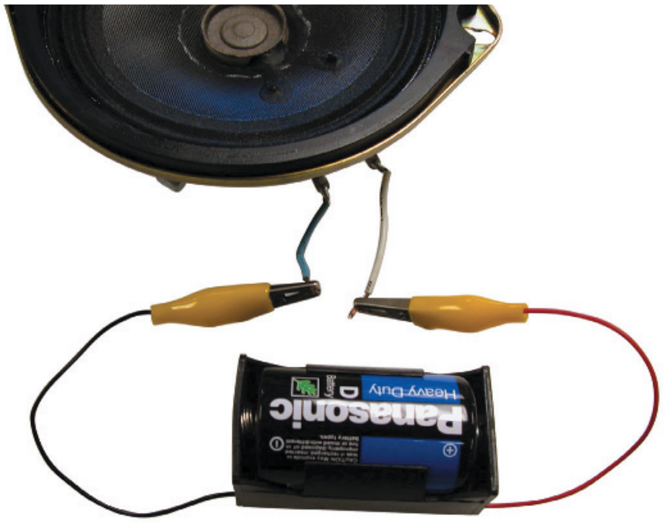

FIGURE 59–8 A typical automotive speaker with two terminals. The polarity of the speakers can be identified by looking at the wiring diagram in the service manual or by using a 1.5 volt battery to check. When the battery positive is applied to the positive terminal of the speaker, the cone moves outward. When the battery leads are reversed, the speaker cone moves inward.

SPEAKER WIRING The wire used for speakers should be as large a wire (as low an AWG number) as is practical in order to be assured that full power is reaching the speakers. Typical "speaker wire" is about 22 gauge (0.35 mm^2), yet tests conducted by audio engineers have concluded that increasing the wire gauge—up to 4 gauge (19 mm^2) or larger—greatly increases sound quality. All wiring connections should be soldered after making certain that all speaker connections have the correct polarity.

CAUTION: Regardless of radio speaker connections used, *never* operate any radio without the speakers connected, or the speaker driver section of the radio may be damaged as a result of the open speaker circuit.

SPEAKER TYPES

INTRODUCTION No one speaker is capable of reproducing sound over such a wide frequency range. Therefore, speakers are available in three basic types:

1. Tweeters are for high-frequency ranges.
2. Midrange are for mid-frequency ranges.
3. Woofers and subwoofers are for low-frequency ranges.

TWEETER A tweeter is a speaker designed to reproduce high-frequency sounds, usually between 4,000 and 20,000 Hz (4 and 20 kHz). Tweeters are very directional. This means that the human ear is most likely to be able to detect the location of the speaker while listening to music. This also means that a tweeter should be mounted in the vehicle where the sound can be directed in line of sight to the listener. Tweeters are usually mounted on the inside door near the top, windshield "A" pillar or similar locations.

MIDRANGE A midrange speaker is designed and manufactured to be able to best reproduce sounds in the middle of the

WARNING

Hearing loss is possible if exposed to loud sounds. According to noise experts (audiologists), hearing protection should be used whenever the following occurs:

1. You must raise your voice to be heard by others next to you.
2. You cannot hear someone else speaking who is less than 3 feet (1 m) away.
3. You are operating power equipment, such as a lawnmower.

human hearing range, from 400 to 5,000 Hz. Most people are sensitive to the sound produced by these midrange speakers. These speakers are also directional in that the listener can usually locate the source of the sound.

SUBWOOFER A subwoofer, sometimes called a *woofer,* produces the lowest frequency of sounds, usually 125 Hz and lower. A *midbass* speaker may also be used to reproduce those frequencies between 100 and 500 Hz. Low-frequency sounds from these speakers are *not* directional. This means that the listener usually cannot detect the source of the sound from these speakers. The low-frequency sounds seem to be everywhere in the vehicle, so the location of the speakers is not as critical as with the higher frequency speakers.

The subwoofer can be placed almost anywhere in the vehicle. Most subwoofers are mounted in the rear of the vehicle where there is more room for the larger subwoofer speakers.

SOUND LEVELS

DECIBEL SCALE A **decibel (dB)** is a measure of sound power, and it is the faintest sound a human can hear in the midband frequencies. The dB scale is not linear (straight line) but logarithmic, meaning that a small change in the dB reading results in a large change in volume of noise. An increase of 10 dB in sound pressure is equal to doubling the perceived volume. Therefore, a small difference in dB rating means a big difference in the sound volume of the speaker.

EXAMPLES Some examples of decibel sound levels include the following:

■ Quiet, faint	30 dB: whisper, quiet library
	40 dB: quiet room
■ Moderate	50 dB: moderate-range sound
	60 dB: normal conversation
■ Loud	70 dB: vacuum cleaner, city traffic
	80 dB: busy noisy traffic, vacuum cleaner
■ Extremely loud	90 dB: lawnmower, shop tools
	100 dB: chain saw, air drill
■ Hearing loss possible	110 dB: loud rock music

VOICE RECOGNITION

PARTS AND OPERATION **Voice recognition** is an expanding technology. It allows the driver of a vehicle to perform tasks, such as locate an address in a navigation system by using voice commands rather than buttons. In the past, users had to say the exact words to make it work such as the following examples listed from an owner's manual for a vehicle equipped with a voice-actuated navigation system:

"Go home"

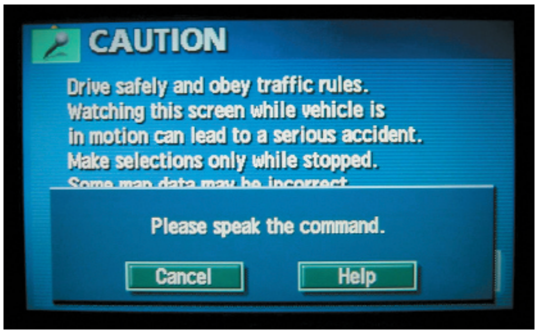
"Repeat guidance"

"Nearest ATM"

The problem with these simple voice commands was that the exact wording had to be spoken. The voice recognition software compares the voice command to a specific list of words or phrases stored in the system in order for a match to occur. Newer systems recognize speech patterns and take action based on learned patterns. Voice recognition can be used for the following functions:

1. Navigation system operation (● **SEE FIGURE 59–9**.)
2. Sound system operation
3. Climate control system operation
4. Telephone dialing and other related functions (● **SEE FIGURE 59–10**.)

A microphone is usually placed in the driver's side sun visor or in the overhead console in the center top portion of the windshield area.



CAUTION

Drive safely and obey traffic rules.
Watching this screen while vehicle is
in motion can lead to a serious accident.
Make selections only while stopped.
Some map data may be incorrect.

Please speak the command.

FIGURE 59–9 Voice commands can be used to control many functions, including navigation systems, climate control, telephone, and radio.

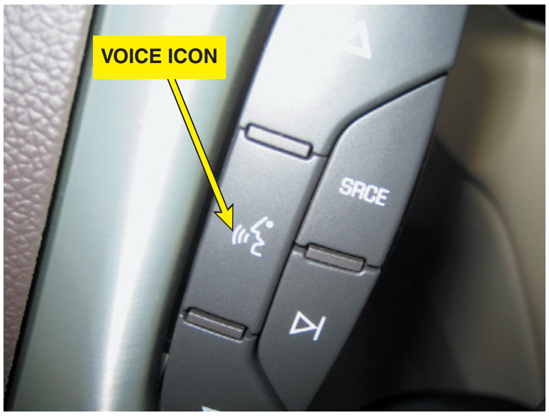


FIGURE 59–10 The voice command icon on the steering wheel of a Cadillac.

DIAGNOSIS AND SERVICE Voice recognition is usually incorporated into many functions of the vehicle. If a problem occurs with the system, perform the following steps:

1. Verify the customer complaint (concern). Check the owner's manual or service information for the proper voice commands and verify that the system is not functioning correctly.
2. Check for any aftermarket accessories that may interfere or were converted to components used by the voice recognition system, such as remote start units, MP3 players, or any other electrical component.
3. Check for stored diagnostic trouble codes (DTCs) using a scan tool.
4. Follow the recommended troubleshooting procedures as stated in service information.

BLUETOOTH

OPERATION **Bluetooth** is a (radio frequency) standard for short-range communications. The range of a typical Bluetooth device is 33 feet (10 m) and it operates in the ISM (industrial, scientific, and medical) band between 2.4000 and 2.4835 MHz.

Bluetooth is a wireless standard that works on two levels:

- It provides physical communication using low power, requiring only about 1 milliwatt (1/1,000 of a watt) of electrical power, making it suitable for use with small handheld or portable devices, such as an ear-mounted speaker/microphone.
- It provides a standard protocol for how bits of data are sent and received.

The Bluetooth standard is an advantage because it is wireless, low cost, and automatic. The automotive use of Bluetooth technology is in the operation of a cellular telephone being tied into the vehicle. The vehicle allows the use of hands-free telephone usage. A vehicle that is Bluetooth telephone equipped has the following components:

- A Bluetooth receiver can be built into the navigation or existing sound system.
- A microphone allows the driver to use voice commands as well as telephone conversations from the vehicle to the cell via Bluetooth wireless connections.

Many cell phones are equipped with Bluetooth, which may allow the caller to use an ear-mounted microphone and speaker. ● **SEE FIGURE 59–11**.

If the vehicle and the cell phone are equipped with Bluetooth, the speaker and microphone can be used as a hands-free telephone when the phone is in the vehicle. The cell phone can be activated in the vehicle by using voice commands.

FIGURE 59–11 Bluetooth earpiece that contains a microphone and speaker unit that is paired to a cellular phone. The telephone has to be within 33 feet (10 m) of the earpiece.

FREQUENTLY ASKED QUESTION

Where Did Bluetooth Get Its Name?

The early adopters of the standard used the term "Bluetooth," and they named it for Harold Bluetooth, the king of Denmark in the late 900s. The king was able to unite Denmark and part of Norway into a single kingdom.

FREQUENTLY ASKED QUESTION

Can Two Bluetooth Telephones Be Used in a Vehicle?

Usually, in order to use two telephones, the second phone needs to be given a name. When both telephones enter the vehicle, check which one is recognized. Say "phone status" and the system tells you to which telephone the system is responding. If it is not the one you want, simply say, "next phone" and it moves to the other one.

SATELLITE RADIO

PARTS AND OPERATION Satellite radio, also called **Satellite Digital Audio Radio Services** or **SDARS**, is a fee-based system that uses satellites to broadcast high-quality radio. SDARS broadcasts on the S-band of 2.1320 to 2.345 GHz.

SIRIUS/XM RADIO Sirius/XM radio is standard equipment but is optional in most vehicles. XM radio uses two satellites launched in 2001 called Rock (XM-2) and Roll (XM-1) in a geosynchronous orbit above North America. Two replacement satellites, Rhythm (XM-3) and Blues (XM-4), were launched in 2006. Sirius and XM radio combined in 2008 and now share some programming. The two types of satellite radios use different protocols and, therefore, require separate radios, unless a combination unit is purchased.

RECEPTION Reception from satellites can be affected by tall buildings and mountains. To help ensure consistent reception, both SDARS providers do the following:

- Include in the radio itself a buffer circuit that can store several seconds of broadcasts to provide service when traveling out of a service area
- Provide land-based repeater stations in most cities (● **SEE FIGURE 59–12**.)

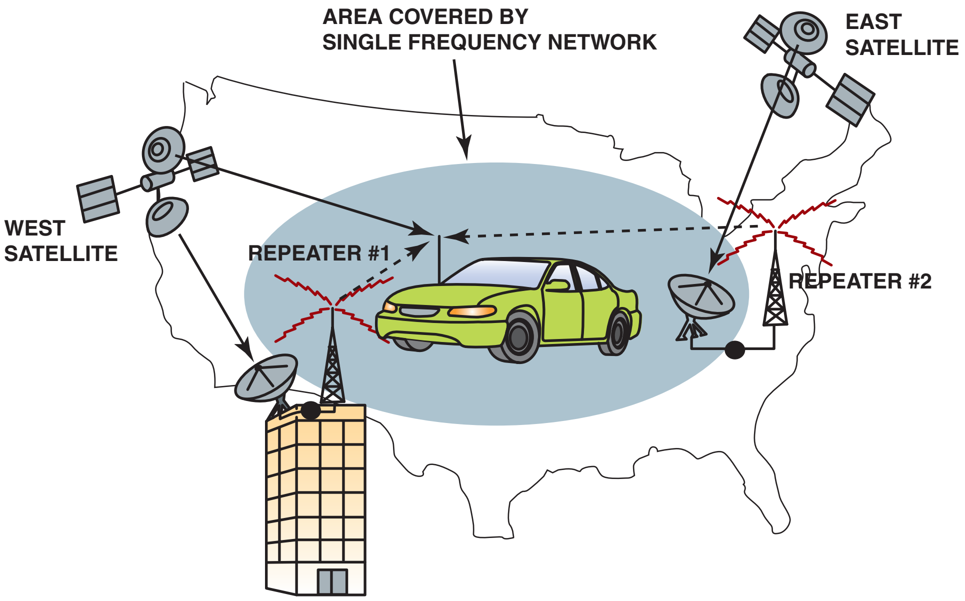

FIGURE 59–12 SDARS uses satellites and repeater stations to broadcast radio.

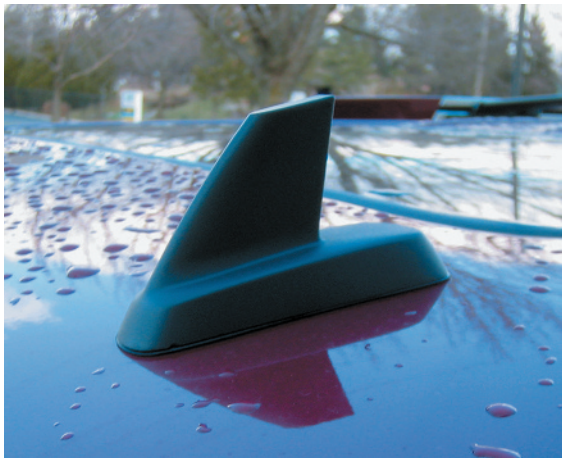

FIGURE 59–13 A shark-fin-type factory antenna used for both XM and OnStar.

ANTENNA To be able to receive satellite radio, the antenna needs to be able to receive signals from both the satellite and the repeater stations located in many large cities. There are various types and shapes of the antennas, ● **FIGURE 59–13**.

DIAGNOSIS AND SERVICE The first step in any diagnosis is to verify the customer complaint (concern). If no satellite service is being received, first check with the customer to verify that the monthly service fee has been paid and the account is up to date. If poor reception is the cause, carefully check the antenna for damage or faults with the lead-in wire. The antennas must be installed on a metal surface to provide the proper ground plane.

For all other satellite radio fault problems, check service information for the exact tests and procedures. Always follow the factory recommended procedures. Check the following websites for additional information:

- **www.xmradio.com**
- **www.sirius.com**
- **www.siriusxm.com**

FREQUENTLY ASKED QUESTION

What Does ESN Mean?

ESN means electronic serial number. This is necessary information to know when reviewing satellite radio subscriptions. Each radio has its own unique ESN, often found on a label at the back or bottom of the unit. It is also often shown on scan tools or test equipment designed to help diagnose faults in the units.

CASE STUDY

Lightning Damage

A radio failed to work in a vehicle that was outside during a thunderstorm. The technician checked the fuses and verified that power was reaching the radio. Then the technician noticed the antenna. It had been struck by lightning. Obviously, the high voltage from the lightning strike traveled to the radio receiver and damaged the circuits. Both the radio and the antenna were replaced to correct the problem. ● **SEE FIGURE 59–14**.

Summary:

Complaint—Customer stated that the radio did not work.
Cause—Visual inspection showed an antenna that had been stuck by lightning.
Correction—Replacing the radio and the antenna restored proper operation.

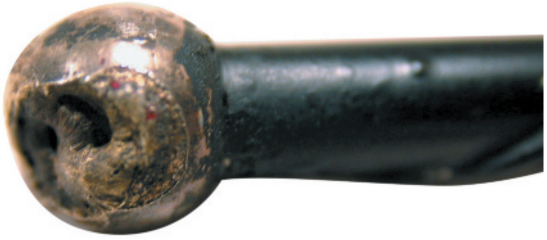

FIGURE 59–14 The tip of this antenna was struck by lightning.

REVIEW QUESTIONS

1. Why do AM signals travel farther than FM signals?
2. What is meant by the term modulation?
3. What is the typical range of Bluetooth?
4. What type of antenna is usually used for satellite radio reception?
5. What can affect the reception of a satellite radio signal?

CHAPTER QUIZ

1. Technician A says that a radio can receive AM signals, but not FM signals, if the antenna is defective. Technician B says that a good antenna should give a reading of about 500 ohms when tested with an ohmmeter between the center antenna wire and ground. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
2. An antenna lead-in wire should have how many ohms of resistance between the center terminal and the grounded outer covering?
   - **a.** Less than 5 ohms
   - **b.** 5 to 50 ohms
   - **c.** 300 to 500 ohms
   - **d.** Infinity (OL)
3. __________ is the term used to describe when information is added to a constant frequency.
   - **a.** Frequency
   - **b.** Modulation
   - **c.** Radio wave transmission
   - **d.** Any of the above
4. The number of times a particular waveform repeats itself in a given amount of time is measured in __________.
   - **a.** Hertz
   - **b.** AM
   - **c.** FM
   - **d.** RF
5. Receivers have what inputs/outputs?
   - **a.** Power and ground
   - **b.** Serial data
   - **c.** Antenna input
   - **d.** All of the above
6. Radio frequencies are measured in __________.
   - **a.** kHz
   - **b.** MHz
   - **c.** volts
   - **d.** Either a or b
7. What is a measure of sound power?
   - **a.** Amperes
   - **b.** Volts
   - **c.** Decibel (dB)
   - **d.** Any of the above
8. Bluetooth is a __________.
   - **a.** type of radio receiver
   - **b.** radio frequency standard for short-range communications
   - **c.** type of headphones
   - **d.** type of earpiece
9. Sirius/XM radio service uses __________ to transmit the audio signal.
   - **a.** satellites
   - **b.** repeater towers
   - **c.** Both a and b
   - **d.** Neither a nor b
10. Voice recognition can be used for __________.
    - **a.** navigation system operation
    - **b.** sound and climatic control system operation
    - **c.** telephone dialing and other related functions
    - **d.** Any of the above

HVAC

PURPOSE AND FUNCTION The **heating, ventilation, and air-conditioning (HVAC)** system of an automobile is designed to provide comfort for the driver and passengers. It is intended to maintain in-vehicle temperature and humidity within a range that is comfortable for the people inside and provide fresh, clean air. The air-conditioning system transfers the heat from inside the vehicle and moves it to the outside of the vehicle. The heater is needed in cold climates to prevent freezing or death.

PRINCIPLES INVOLVED On earth, matter is found in one of three different phases or states:

1. Solid
2. Liquid
3. Vapor (gas)

The state depends upon the nature of the substance, the temperature, and the pressure or force exerted on it. Water occurs naturally in all three states: solid ice, liquid water, and water vapor, depending upon the temperature and pressure. ● **SEE FIGURE 60–1**.

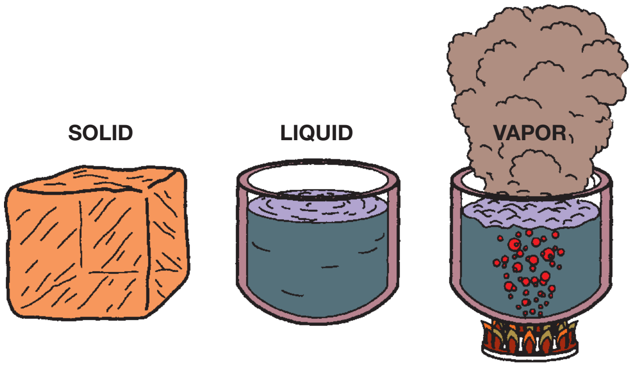

FIGURE 60–1 Water is a substance that can be found naturally in solid, liquid, and vapor states.

CHANGES OF STATE A solid is a substance that cannot be compressed and has strong resistance to flow. The molecules of a solid attract each other strongly, and resist changes in volume and shape.

- A substance is solid at any temperature below its melting point. Melting point is a characteristic of the substance, and is related to the temperature at which a solid turns

FREQUENTLY ASKED QUESTION

Why Is Liquid Sprayed from a Can Cold?

If a pressurized can of liquid is sprayed continuously, the can becomes cold, and so does the liquid being sprayed. The can becomes cold because the pressure in the can is reduced while spraying, allowing the liquid propellant inside the can to boil and absorb heat. The propellant vapor is further cooled as it decompresses when it hits the open air. Rapid decompression results in a rapid temperature drop.

to liquid. For water, the melting point is 32°F (0°C), which means that changes can be observed between liquid water and ice under normal weather conditions.

- A liquid is a substance that cannot be compressed. A substance in a liquid state has a fixed volume, but no definite shape.
- The boiling point is the temperature at which a liquid substance turns to vapor. For water at normal sea level conditions, the boiling point is 212°F (100°C). A vapor is a substance that can be easily compressed, has no resistance to flow, and no fixed volume. Since a vapor flows, it is considered a fluid just like liquids are.

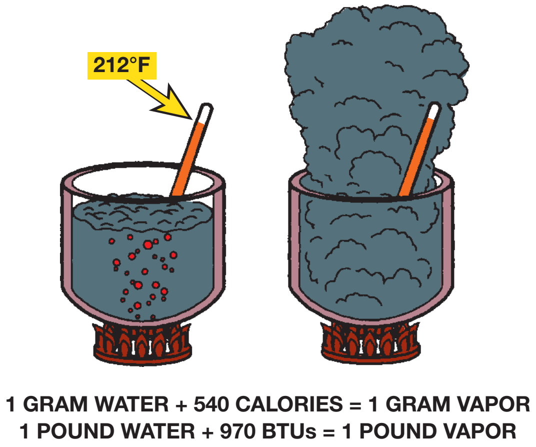
A vapor condenses to liquid if the temperature falls below the vaporizing temperature. Again, the difference is simply whether heat is being added or taken away. Boiling point and condensation point temperatures are not fixed because they vary with pressure.

HEAT AND TEMPERATURE Molecules in a substance tend to vibrate rapidly in all directions, and this disorganized energy is called heat. The intensity of vibration depends on how much kinetic energy, or energy of motion, the atom or molecule contains. Heat and temperature are not the same:

- **Temperature** is the measure of the level of energy. Temperature is measured in degrees.
- **Heat** is measured in the metric unit called **calorie** and expresses the amount of heat needed to raise the temperature of one gram of water one degree Celsius. Heat is also measured in **British Thermal Units (BTU)**. One BTU is the heat required to raise the temperature of one pound of water 1°F at sea level. One BTU equals 252 calories.

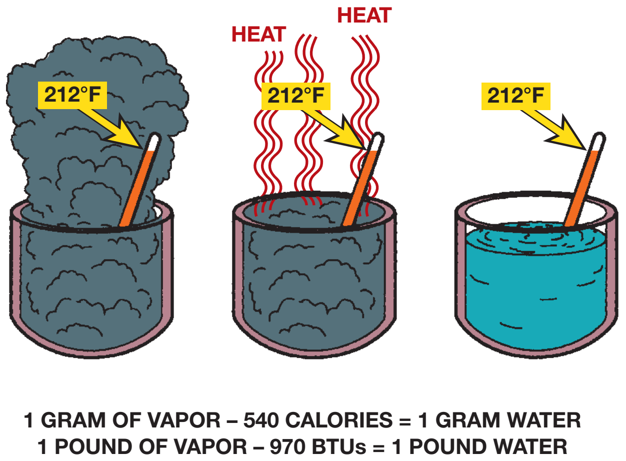
SENSIBLE HEAT Sensible heat makes sense because it can be felt and measured on a thermometer. If there is 1 lb. of water at 40°F and 1 BTU of heat is added to it, the temperature will increase to 41°F. Adding another BTU of heat will increase the temperature to 42°F and adding another 170 BTU (212 – 42) will increase the temperature to 212°F, the boiling point.

LATENT HEAT **Latent heat** is the "extra" heat that is needed to transform a substance from one state to another. Imagine that water is being heated on a stove. When water reaches its boiling point, the temperature stops rising. The water begins to boil. This occurs without any sensible change in temperature, even though heat is still being applied from the burner.



212°F
1 GRAM WATER + 540 CALORIES = 1 GRAM VAPOR
1 POUND WATER + 970 BTUs = 1 POUND VAPOR

FIGURE 60–2 The extra heat required to change a standard amount of water at its boiling point to vapor is called latent heat of vaporization.



HEAT
HEAT

212°F
212°F
1 GRAM OF VAPOR – 540 CALORIES = 1 GRAM WATER
1 POUND OF VAPOR – 970 BTUs = 1 POUND WATER

FIGURE 60–3 The latent heat of vaporization that water vapor stores is released when the vapor condenses to a liquid. The temperature stays the same.

The water in the container on the stove boils at a temperature of 212°F (100°C) at sea level, for as long as any liquid water remains. As heat is further added to the water, heat will be used in changing the state of the liquid to a vapor. This extra, hidden amount of energy necessary to change the state of a substance is called latent heat. ● **SEE FIGURES 60–2 AND 60–3**.

Latent heat is important in the operation of an air-conditioning system because the cooling effect is derived from changing the state of liquid refrigerant to vapor. The liquid refrigerant absorbs the latent heat of vaporization, making the air cooler. The cooler air is then blown into the passenger compartment.

TEMPERATURE, VOLUME, AND PRESSURE OF A VAPOR Unlike a solid, vapor has no fixed volume. Increasing the temperature of a vapor, while keeping the volume confined in the same space, increases the pressure. This happens as the vibrating vapor molecules collide more and more energetically with the walls of the container. Conversely, decreasing the temperature decreases the pressure. This relationship between temperature and pressure in vapor is why a can of nonflammable refrigerant can explode when heated by a flame—the pressure buildup inside the can will eventually exceed the ability of the can to contain the pressure. Increasing the pressure by compressing vapor increases the temperature. Decreasing the pressure by permitting the vapor to expand decreases the temperature.

HEAT INTENSITY Intensity of heat is important to us because if it is too cold, humans feel uncomfortable and is measured in degrees. Extremely cold temperatures can cause frostbite and hypothermia. The other end of the scale can also be uncomfortable and may cause heat stress and dehydration. Humans have a temperature **comfort zone** somewhere between 68°F and 78°F (20°C and 26°C). This comfort zone varies among individuals. ● **SEE FIGURE 60–4**.

RULES OF HEAT TRANSFER Heating and air conditioning must follow the basic rules of heat transfer. An understanding of these rules helps greatly in understanding the systems:

- Heat always flows from hot to cold. (From higher level of energy to lower level of energy.) ● **SEE FIGURE 60–5**.
- To warm a person or item, heat must be added.
- To cool a person or item, heat must be removed.
- A large amount of heat is absorbed when a liquid changes state to vapor.
- A large amount of heat is released when a vapor changes state to a liquid.
- Compressing a gas concentrates the heat and increases the temperature.

TECH TIP

Quick and Easy Temperature Conversion

Temperature in service information and on scan tools is often expressed in degrees Celsius, which is often confusing to those used to temperature expressed in Fahrenheit degrees. A quick and easy way to get an *approximate* conversion is to take the degrees in Celsius, double it, and add 25.

For example,

Celsius × 2 + 25 = approximate Fahrenheit degrees:

0°C × 2 = 0 + 25 = 25°F (actual = 32°F)

10°C × 2 = 20 + 25 = 45°F (actual = 50°F)

15°C × 2 = 30 + 25 = 55°F (actual = 59°F)

20°C × 2 = 40 + 25 = 65°F (actual = 68°F)

25°C × 2 = 50 + 25 = 75°F (actual = 77°F)

30°C × 2 = 60 + 25 = 85°F (actual = 86°F)

35°C × 2 = 70 + 25 = 95°F (actual = 95°F)

40°C × 2 = 80 + 25 = 105°F (actual = 104°F)

45°C × 2 = 90 + 25 = 115°F (actual = 113°F)

50°C × 2 = 100 + 25 = 125°F (actual = 122°F)

The simplest way to convert between the Fahrenheit and Celsius scales accurately is to use a conversion chart or use an app on a smartphone.

HUMIDITY Humidity refers to water vapor present in the air. The level of humidity depends upon the amount of water vapor present and the temperature of the air. The amount of water vapor in the air tends to be higher near lakes or the ocean, because more water is available to evaporate from their surfaces. In desert areas with little open water, the amount of water vapor in the air tends to be low.

- **Absolute humidity** is the measure of the amount of moisture (water vapor) in the air regardless of the temperature.

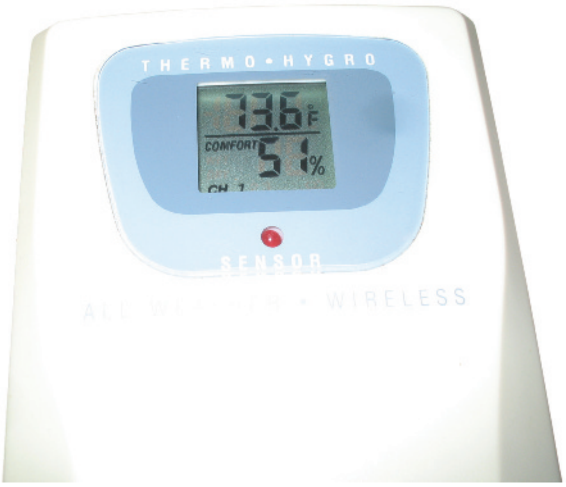

FIGURE 60–6 A combination meter that measures and displays both the temperature and the humidity is useful to use when working on air-conditioning systems.

- **Relative humidity (RH)** is the percentage of how much moisture is present in the air compared to how much moisture the air is capable of holding at that temperature.

Relative humidity is commonly measured with a *hygrometer* or a *psychrometer*. A hygrometer depends on a sensitive element that expands and contracts, based on the humidity. Hygrometers typically resemble a clock, with the scale reading from 0% to 100% relative humidity. ● **SEE FIGURE 60–6**.

FREQUENTLY ASKED QUESTION

What Is a Sling Pyschrometer?

A psychrometer is a measuring instrument used to measure relative humidity. It uses two thermometers, one of which has the bulb covered in a cotton wick soaked in distilled water from a built-in reservoir. The wick keeps the bulb of the "wet thermometer" wet so that it can be cooled by evaporation. Sling psychrometers are spun round in the air a certain number of times. Water evaporates from the cotton wick at a rate inversely proportional to the relative humidity of the air:

- Faster if the humidity is low.
- Slower if the humidity is high.

The "dry thermometer" measures the air temperature:

- The higher the relative humidity, the closer the readings of the two thermometers.
- The lower the humidity, the greater the difference in temperature of the two thermometers.

The different temperatures indicated by the wet and dry thermometers are compared to values given in a chart, which gives the relative humidity. While a sling psychrometer is still used, most technicians use an electronic instrument to measure relative humidity. ● **SEE FIGURE 60–7**.

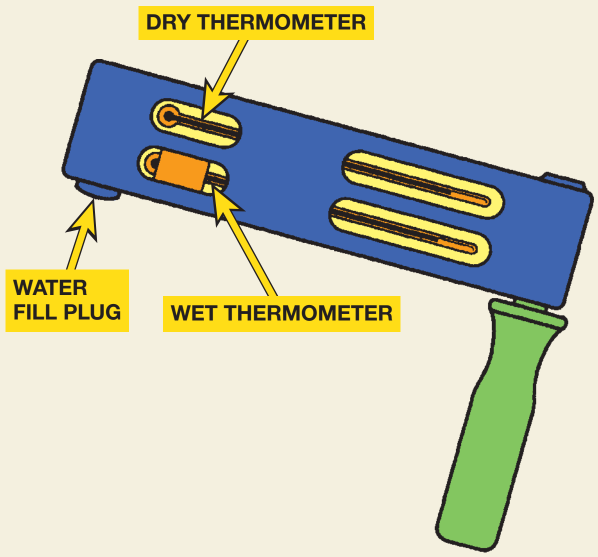

FIGURE 60–7 A sling psychrometer is used to measure relative humidity.

HEATING AND COOLING LOAD

HEATING LOAD **Heating load** is the term used when additional heat is needed. The actual load is the number of BTUs or calories of heat energy that must be added. In a home or office, burning fuel is the usual way to generate heat using coal, gas, or oil as a fuel. In most vehicles, the heat is provided by the heated coolant from the engine cooling system. This coolant is typically at a temperature of 190°F to 205°F (88°C to 98°C) when the engine reaches its normal operating temperature. ● **SEE FIGURE 60–8**.

In most vehicles, heated coolant is circulated through a heat exchanger, called a **heater core**. Air is circulated through the heater core, where it absorbs heat. Then it is blown into the passenger compartment, where the heat travels on to warm the car interior and occupants. The air from the blower motor moves the heat from the heater core to the passengers.

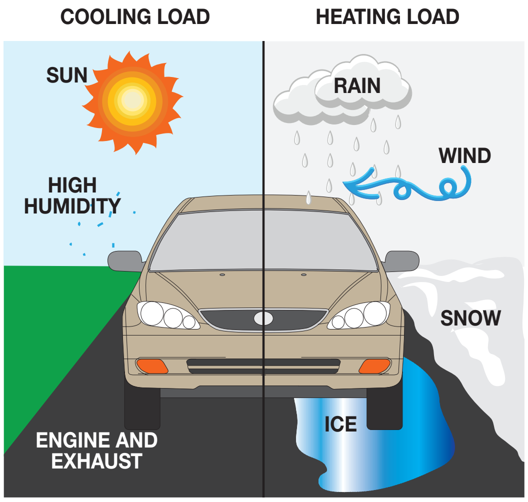

FIGURE 60–8 Cold temperatures present a heat load where heat must be added for comfort (right). Warm temperatures presents a cooling load.

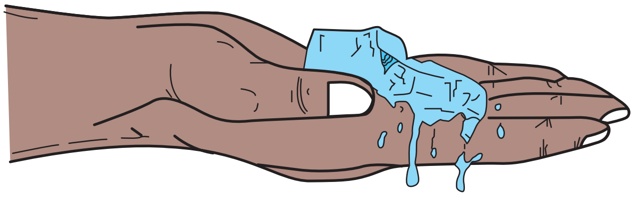

FIGURE 60–9 Ice has a cooling effect because of latent heat of fusion which means that it absorbs heat as it melts.

COOLING WITH ICE One way to move heat, called **cooling load**, is with a block of ice. A substantial amount of latent heat is required to change the state of the solid ice into a liquid:

- 144 BTU per lb. (80 calories per gram).
- A 50-lb. block of ice represents, or 7,200 BTU, of cooling power when it changes from 50 lb. of solid at 32°F to 50 lb. of liquid at 32°F.

In the early days of air conditioning, the term *ton* was commonly used. A ton of air conditioning was the amount of heat it took to melt a ton of ice, or 288,000 BTU. ● **SEE FIGURE 60–9**.

EVAPORATIVE COOLING A method of cooling that works well in areas of low humidity is evaporation of water, commonly called **evaporative cooling**. If water is spread thinly over the extremely large area of a meshed cooler pad and air is blown across it, the water evaporates. For every pound of water that evaporates, 970 BTU (540 calories per gram) of heat is absorbed. This is the latent heat of evaporation, just as when it is boiled. This is a natural process and uses only the energy required by the blower to circulate the air through the cooler pads and on to the space to be cooled. Disadvantages of evaporative coolers, often called "swamp coolers" include:

- increases the relative humidly
- not effective in areas of high humidity because the water does not evaporate rapidly enough to be efficient.

At one time, window-mounted evaporative coolers were used in cars. They were not very popular because they were unattractive and worked well only in dry areas. ● **SEE FIGURE 60–10**.

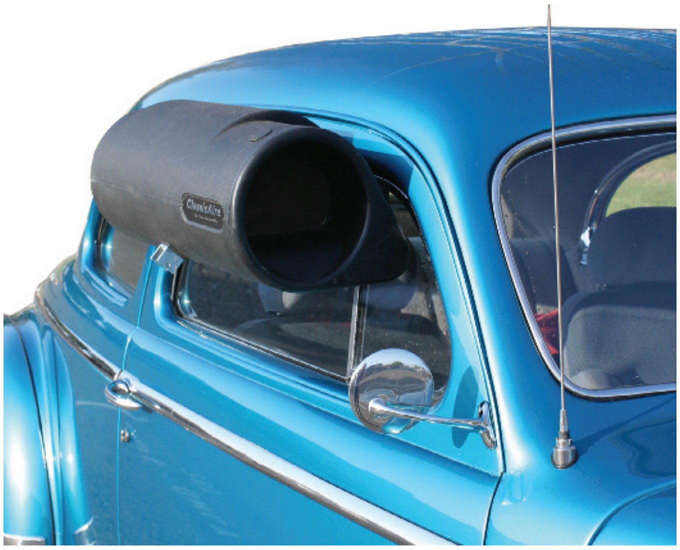

FIGURE 60–10 At one time, evaporative coolers were used to cool car interiors. Air forced through a water-wetted mesh produces evaporation and a cooling effect.

MECHANICAL COOLING A third way to handle a cooling load is by the use of **mechanical refrigeration**, which is called air conditioning. This system also uses evaporation of a liquid and the large amount of heat required for evaporation. The refrigerant boils so that it changes from liquid to gas, but it is condensed back to gas using an engine or electrically powered compressor to move the refrigerant and to increase its pressure in the system. ● **SEE FIGURE 60–11**.

HEAT MOVEMENT

Heat can travel through one or more of three paths as it moves from hot to cold:

1. conduction
2. convection
3. radiation ● **SEE FIGURE 60–12**.

CONDUCTION The simplest heat movement method is conduction, by which heat travels through a medium such as a solid or liquid, moving from one molecule of the material to the next. For example, if one end of wire is heated, the heat will travel through the material itself and will be transferred through to the other end of the wire. Some materials (most of the metals) are good heat conductors. Copper and aluminum are among the best of the commonly used metals, so most heat exchangers (radiators, evaporators, and condensers) use copper or aluminum.

- Some materials, such as wood, are poor heat conductors.
- Some materials, such as Styrofoam, conduct heat so poorly that they are called insulators. Most good insulators incorporate a lot of air or gaseous material in their structure because air is a poor conductor of heat.

CONVECTION Convection is a process of transferring heat by moving the heated medium, usually air or a liquid. An example of convection is the engine cooling system. Coolant is heated in the water jackets next to the cylinders and combustion chambers. Then the coolant is pumped to the radiator, where the heat is transferred to the air traveling through the radiator. Convection also occurs in the interior of the vehicle when air is circulated past the driver and passengers to pick up heat and moved to the evaporator, where the heat is transferred to the evaporator fins. The evaporator fins are cooler, so heat is transferred easily.

RADIATION Heat can travel through heat rays and pass from one location to another without warming the air through which it passes. The best example of this is the heat from the sun, which passes through cold space and warms our planet and everything it shines on. Radiant heat can pass from any warmer object through air to any cooler object. It is affected by the color and texture of the heat emitter, where the heat leaves, and the collector, where the heat is absorbed. Dark, rough surfaces make better heat emitters and collectors than light-colored, smooth surfaces.

NOTE: At one time, California Highway Patrol cars were painted all black. Painting the tops white benefited the patrol officers by lowering the in-vehicle temperature significantly.

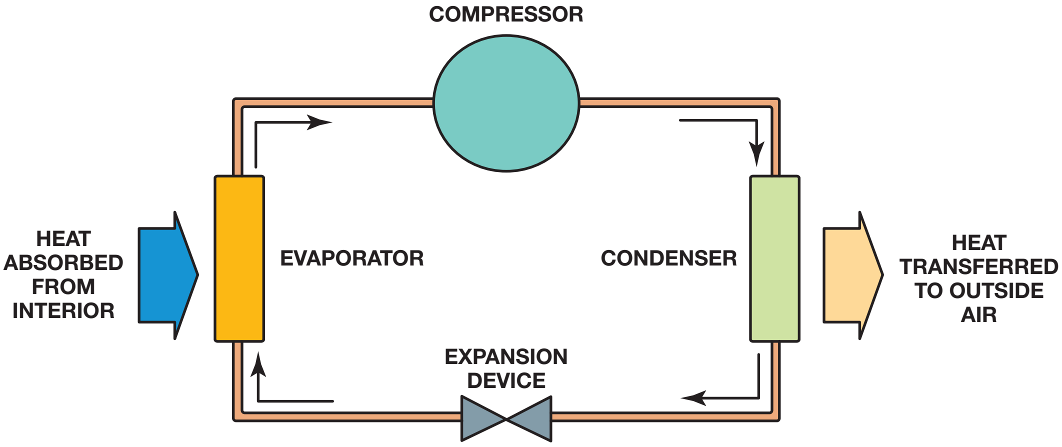

FIGURE 60–11 Heat, from in-vehicle cabin air, causes the refrigerant to boil in the evaporator (left). The compressor increases the pressure and moves refrigerant vapor to the condenser, where the heat is transferred to ambient air. This also causes the vapor to return to liquid form.

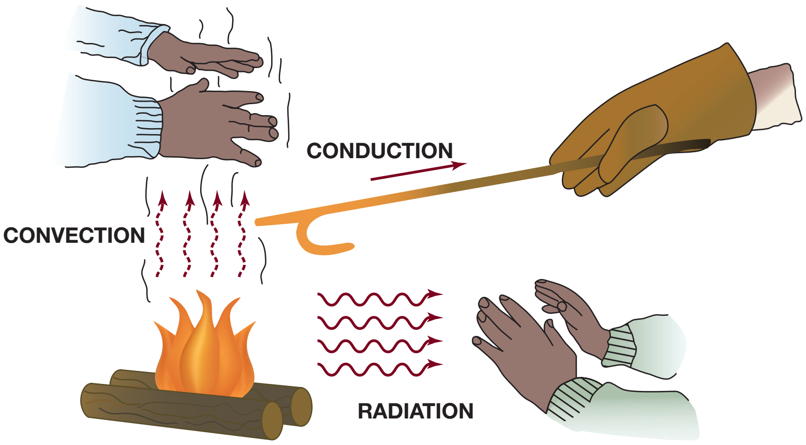

FIGURE 60–12 Heat can be moved from the source by convection, conduction, or radiation.

AIR-CONDITIONING PROCESS

CHANGING THE STATE OF THE REFRIGERANT The air-conditioning process works using a fluid, called *refrigerant,* which continuously changes state from liquid to gas and back to liquid.

Most states of matter can be changed from one state to another by adding or removing heat. ● **SEE FIGURE 60–13**.

Molecules are the building blocks for all things that can be seen or felt. Molecules are combinations of atoms, which are in turn made up of electrons, neutrons, and protons. The protons are in the center, or nucleus, of the atom and the electrons travel in an orbit around them. There are about 100 basic elements or atoms, each having a different atomic number, that combine with other elements to make the many, varied molecules. The atomic number of an element is based on the number of electrons and protons in that element. The periodic table of elements seen in most chemistry laboratories shows the relationship of these elements.

Water molecules, for example, are called H_2O. This is a combination of a single oxygen atom and two hydrogen atoms. Hydrogen has an atomic number of 1 (1 proton and 1 electron), and oxygen has an atomic number of 8 (8 electrons and 8 protons). ● **SEE FIGURE 60–14**. The three states of water are well known and include:

1. Solid ice
2. Liquid water
3. Vapor (gaseous)

SOLID Solid matter has a definite shape and substance. Solids exert pressure in only one direction, and that is downward because of gravity. For example, ice is the solid form of water, and will hold its shape, and is cold. Water is normally a solid at temperatures below 32°F (0°C), which is the normal freezing point. The electrons in the molecule's atoms are still orbiting around the protons, but the movement has been slowed because much of the heat energy has been removed. ● **SEE FIGURE 60–15**.

LIQUID Adding heat to most solids causes them to reach their melting point. It is the same material, but heat energy has broken the molecular bond and the matter becomes fluid. Fluid has no shape and it takes the shape of its container. Liquids can flow through a pipe or hose and can be pumped such as by the air-conditioning compressor.

Water is normally a liquid between 32°F and 212°F (0°C and 100°C). The molecules are same as ice, but heat energy has increased the movement of the electrons. ● **SEE FIGURE 60–16**.

GAS When heat is added to most liquids, it produces gas as the liquids boil. It is the same material, but the heat energy has broken the molecular bonds still further so that the molecules have no shape at all and have expanded so much that they have very little weight. A gas molecule exerts pressure in every direction. Gases can also be pumped through hoses and pipes, making them easy to move through the air-conditioning (A/C) system.

PURPOSE OF AN HVAC SYSTEM

CONTROL OF TEMPERATURE The goal in heating and air conditioning is to maintain a comfortable in-vehicle temperature and humidity. An air-conditioning system cools the interior of the vehicle by moving the heat from inside the vehicle to outside the vehicle. The internal body temperature of humans is about 98.6°F (37°C), which seems odd when our most comfortable temperature is 68°F to 78°F (20°C to 26°C). This means that in the summer heat must be continually given off to be comfortable, but in the cold weather suitable clothing is needed to maintain warmth. Body comfort is also affected by radiant heat.

The velocity of air past our bodies is another factor in human comfort. Air movement is an important part of heating and air-conditioning systems.

CONTROL OF HUMIDITY Humid cold air feels much colder than dry air at the same temperature.

- Humid hot air slows down our natural body cooling system (evaporation of perspiration), so it can make a day feel much hotter.
- Air that is too dry also tends to make people feel uncomfortable.
- As with temperature, a range of humidity that most people feel comfortable in a relative humidity of about 45% to 55%.

As the air-conditioning system operates, it dehumidifies (removes moisture) from the air. Water vapor condenses on the cold evaporator fins just as it would on a glass holding a cold drink. This condensed water then drops off the evaporator and runs out the drain at the bottom of the evaporator case. In-vehicle humidity is reduced to about 40% to 45% on even the most humid days if the A/C is operated long enough. A good example of this dehumidification process occurs when a vehicle's A/C is operated on cold days when the windows are fogged up. It usually takes only a short time to dry the air and remove the fog from the windows. ● **SEE FIGURE 60–18**.

CLEANLINESS A side effect of air conditioning is the cleaning of the air coming into the vehicle as it passes through the cooling ductwork. The act of cooling and dehumidifying air at the A/C evaporator causes water droplets to form on the evaporator fins. Dust and other contaminants in the air that come into contact with these droplets become trapped and are flushed out of the system as the water drops drain from the evaporator. Most recent vehicles use a **cabin filter** in the A/C and heating systems to clean the air by trapping dust and pollen particles before they enter the passenger compartment. ● **SEE FIGURE 60–19**.

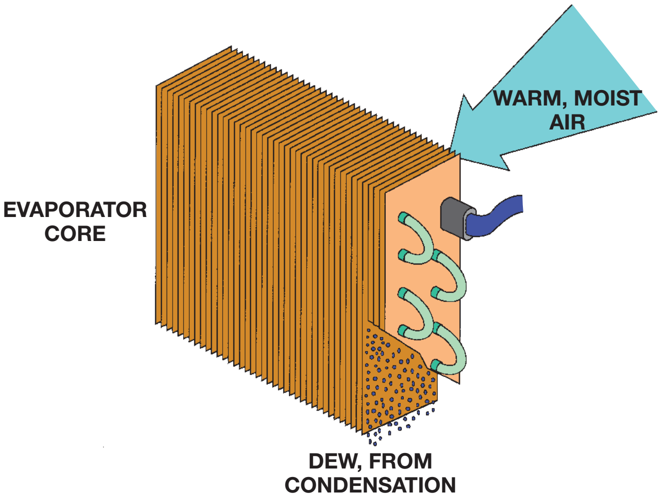

FIGURE 60–18 When air comes into contact with the cold evaporator, excess moisture forms dew. This condensed moisture leaves the car through the evaporator drain.

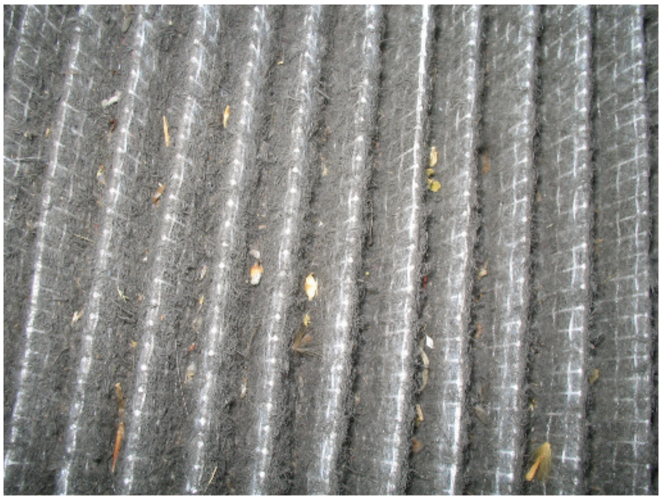

FIGURE 60–19 A cabin filter especially those that are impregnated with charcoal (carbon) are able to filter out dirt, dust, and odors from the outside air before entering the passenger compartment.

REVIEW QUESTIONS

1. Is it possible for heat to be added to water without causing the temperature to increase?
2. What are the three states of matter?
3. What is the difference between heat and temperature?
4. How is relative humidity measured?
5. How does heat move?

CHAPTER QUIZ

1. The three different phases or states of matter include __________.
   - **a.** solid, water, and steam
   - **b.** ice, liquid, and gas
   - **c.** solid, liquid, and gas
   - **d.** liquid, water, and steam
2. An air-conditioning system cools the interior of the vehicle by __________.
   - **a.** moving the heat from inside the vehicle to outside the vehicle
   - **b.** blowing cold air into the interior
   - **c.** moving heat from inside of the vehicle to the engine cooling system
   - **d.** using the engine to move air
3. Twenty degrees Celsius is about how many degrees Fahrenheit?
   - **a.** 25
   - **b.** 45
   - **c.** 65
   - **d.** 85
4. Heat intensity is measured in __________.
   - **a.** BTUs
   - **b.** degrees
   - **c.** RH
   - **d.** calories
5. A psychrometer measures __________.
   - **a.** temperature
   - **b.** relative humidity
   - **c.** amount of heat
   - **d.** radiation
6. A BTU is a measure of __________.
   - **a.** temperature
   - **b.** relative humidity
   - **c.** amount of heat
   - **d.** radiation
7. Heat transferred through the air is called __________.
   - **a.** radiation
   - **b.** insulation
   - **c.** convection
   - **d.** conduction
8. The air conditioning process works through a fluid, called a/an __________ that continuously changes state from liquid to gas and back to liquid.
   - **a.** element
   - **b.** conductor
   - **c.** insulator
   - **d.** refrigerant
9. Humans prefer temperatures that are between __________ and __________.
   - **a.** 55°F; 65°F
   - **b.** 60°F; 70°F
   - **c.** 68°F; 78°F
   - **d.** 76°F; 86°F
10. Humans prefer relative humidity that is between __________ and __________.
    - **a.** 10%; 20%
    - **b.** 20%; 30%
    - **c.** 30%; 40%
    - **d.** 45%; 55%

Chapter

A/C SYSTEM COMPONENTS, OPERATION, AND SERVICE

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to:

- Discuss the purpose and function of compressors and condensers.
- Describe the operation of thermal expansion valves.
- Explain the construction and operation of orifice tubes.
- Explain the purpose and function of evaporators.
- Explain the purpose and function of accumulators.
- Discuss the use of lines and hoses in refrigeration.
- Describe electrical switches and evaporator temperature controls used in A/C systems.
- Describe rear A/C systems.
- Explain component replacement procedures.

KEY TERMS

Barrier hoses 728 • Captive O-ring 729 • Discharge line 728 • H-block 722 • Liquid line 728 • Sight glass 726 • Suction line 728 • Thermistor 731 • Transducer 731

COMPRESSORS AND CONDENSERS

COMPRESSORS The compressor is the pump in the system that circulates the refrigerant. The pressure must be increased until the refrigerant temperature is above ambient air temperature so the condenser can get rid of all the heat absorbed in the evaporator.

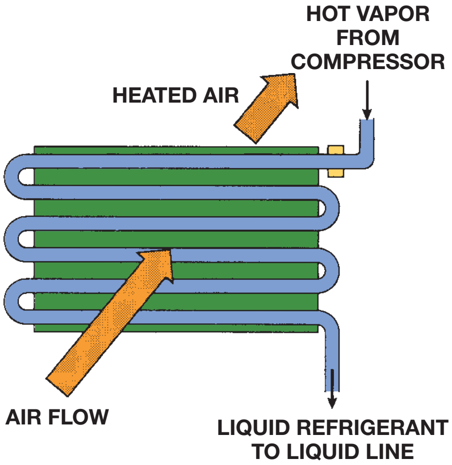

FIGURE 61–1 A condenser is a heat exchanger that transfers heat from the refrigerant to the air flowing through it.

CONDENSERS The condenser is a heat exchanger that is used to get rid of the heat removed from the passenger compartment. The condenser cools the hot refrigerant vapors, which while passing through the condensing tubes condense into high pressure liquid. The condenser of most vehicles is mounted in front of the radiator through which air is forced when the vehicle is moving forward. ● **SEE FIGURE 61–1**.

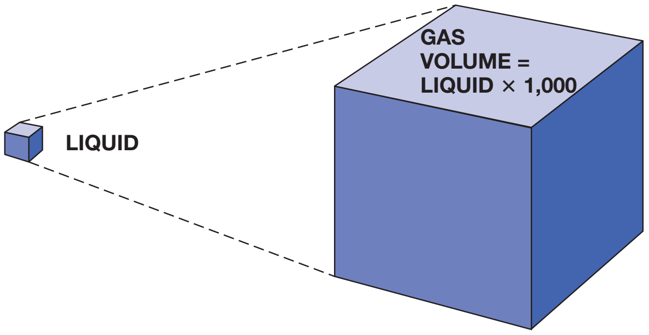
On most vehicles, the condenser is part of a *cooling module* that can combine the following:

- Condenser
- Radiator
- Automatic transmission fluid cooler
- Power steering pump oil coolers
- An intercooler for engine intake air on turbocharged engines.

Air flow through the condenser is increased by the use of a cooling fan.

- Many rear-wheel-drive (RWD) vehicles use a fan driven by a fan clutch mounted on the water pump. Some RWD vehicles use both an engine-driven fan with a clutch and an electric fan.
- Front-wheel-drive (FWD) vehicles normally use an electric motor to drive the fan(s).

This motor is controlled by relays that are controlled by the powertrain control module (PCM) using temperature information from the engine coolant temperature (ECT) sensor.



GAS
VOLUME =
LIQUID × 1,000
LIQUID

FIGURE 61–2 The volume of gas that enters a condenser is about 1,000 times the volume of liquid leaving it.

FREQUENTLY ASKED QUESTION

Why Is Sub-Cooling Necessary in Some Condensers?

Condenser sub-cooling makes sure that there is a liquid seal at the bottom of the condenser so the liquid line or receiver will not have any vapors. Some vehicles use a second condenser to make sure that the refrigerant has condensed into liquid before it exits. These secondary condensers can be called:

- *Dual condenser*
- *Secondary condenser*
- *Sub-condenser*
- *Modulator* ● **SEE FIGURE 61–3**.

FIGURE 61–3 (a) A dual condenser is a condenser where the refrigerant flows from the condenser portion through the modulator portion and then through the sub-cooling part. (b) The modulator is built as part of the condenser and often includes a removable plug that allows desiccant replacement.

CONDENSER CONSTRUCTION Automotive condensers are heat exchangers that are made in several designs, including the following:

- Older *tube-and-fin* condensers are merely a tube bent back and forth into a *serpentine shape* with fins attached. After the tubes are pressed through the fins, return bends or manifolds are used to connect the tubes to give the desired flow pattern.
- Newer condensers use a *flattened tube* with fins between the tubes. The tubing is formed in either *serpentine* or *parallel-flow* arrangement.
- Many condensers use a flattened, extruded aluminum tube that is divided into small refrigerant passages, 13–16 passages in a tube that is 0.875 inch (24 mm) wide.
- The numerous fins provide the large amount of contact area needed with the airstream. Newer flat-tube, parallel-flow condensers are more efficient and transfer heat much better and therefore allows for a smaller and lighter component.

As the gas condenses to a liquid, the volume is reduced because a gas has about 1,000 times the volume of the same liquid. As the latent heat of condensation is transferred to the airstream, the refrigerant vapor transforms into a liquid state. ● **SEE FIGURE 61–2**.

THERMAL EXPANSION VALVES

PURPOSE AND FUNCTION A thermal expansion valve (TXV) senses both temperature and pressure and controls the flow of refrigerant into the evaporator. ● **SEE FIGURE 61–4**.

CONSTRUCTION AND OPERATION In most TXV systems, the evaporator outlet is connected to the compressor inlet by the suction line with an internal diameter (ID) of about 5/8 inch or 3/4 inch (16 mm or 19 mm). The key to the operation of the expansion valve is the variable orifice. In these systems, the outlet from the high-pressure side to the low-pressure side is a variable-diameter hole. A pintle valve is a ball-and-seat valve used to increase or decrease the size of the opening. The expansion valve uses the pintle valve to control how rapidly refrigerant enters the evaporator. The expansion valve controls the refrigerant flow in response to the temperature of the evaporator outlet, measured by the remotely mounted sensing bulb and capillary tube.

- At room temperature, a TXV is open because the gas pressure in the capillary tube exerts a high pressure, greater than the spring pressure.
- As the system cools, the temperature of the sensing bulb and capillary tube drops, and the pressure on the diaphragm drops with it.
- When the pressure at the diaphragm drops below the spring pressure, the valve closes.
- If an excess amount of refrigerant enters the evaporator, high refrigerant pressure can act through the balance passage to close the TXV. ● **SEE FIGURE 61–5**.

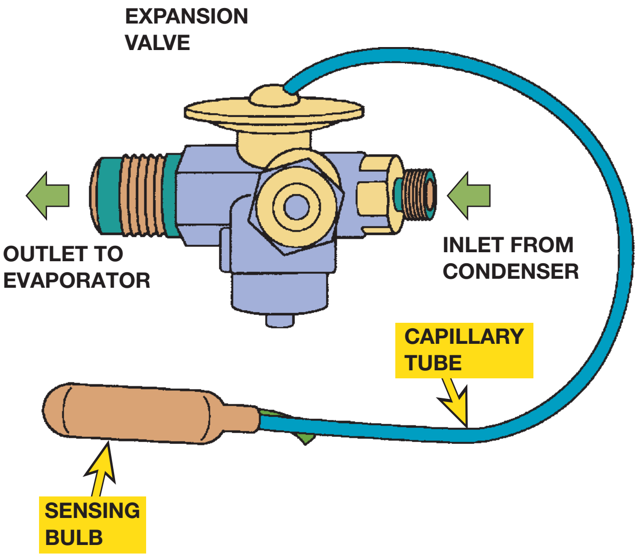

FIGURE 61–4 A typical expansion valve uses an inlet and outlet attachment for the evaporator, and a temperature-sensing bulb that is attached to the evaporator outlet tube.

TYPES OF TXVS Thermal expansion valves come in many types. Most of the early valves were threaded onto the evaporator inlet, and the liquid line threaded onto the valve. The thermal bulb, or end of the capillary tube, was clamped onto the evaporator tailpipe or inserted into a well in it. The thermal bulb has to be clamped tightly and should be well insulated so that it can transmit an accurate temperature signal. If used, the external equalizer line is threaded onto a fitting on the tailpipe. Most TXVs have a small, very fine screen at their inlet. This screen traps debris that can plug the valve, and it can be removed for cleaning or installing a replacement.

H-BLOCKS The thermal expansion block valve is another type of TXV. It is called an **H-block** or an *H-valve.* The H-block design uses four passages and controls the refrigerant flow using opposing pressures. These valves are connected with both the liquid and suction lines and the evaporator inlet and outlet. Some block valves use threaded fittings, and some are bolted between manifolds and are sealed using O-rings. ● **SEE FIGURE 61–6**.

ORIFICE TUBE SYSTEMS

TERMINOLOGY An orifice tube (OT), also called an *expansion tube*, is a fixed-diameter orifice that the refrigerant must flow through. The diameter varies between systems and is about 1/16 inch (0.065 inch or 1.6 mm). ● **SEE FIGURE 61–7**.

CONSTRUCTION AND OPERATION Most orifice tubes are a thin brass tube that is a couple of inches long and has a plastic filter screen around it. This tube is sized to flow the proper amount of refrigerant into the evaporator for maximum cooling loads. Some orifice tubes use a filter made up of many small plastic beads in place of the screen. The orifice tube floods the evaporator during light cooling loads, so a low-side accumulator is always used with an orifice. The flow through an orifice tube is also affected by pressure, and excessive high-side pressure can cause evaporator pressure and temperature to become too high.

TO EVAPORATOR

FIGURE 61–7 A typical orifice tube. The refrigerant flow is from the left toward the right.

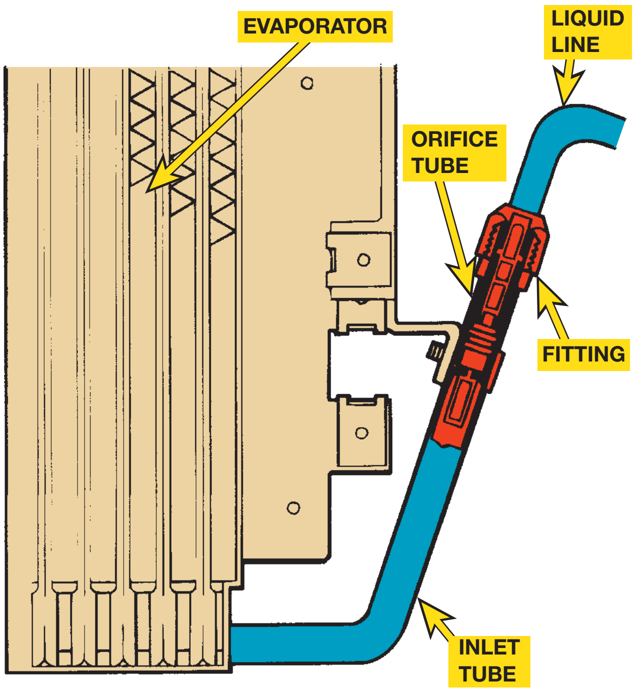
ORIFICE TUBE SIZES Manufacturers color-code orifice tubes to identify the car make and model for which a tube is made. There are at least eight different sizes of orifice tubes that have similar appearance, but the size ranges from 0.047 inch to 0.072 inch (1.19 mm to 1.8 mm). An R-134a system uses a larger orifice tube than a similar R-12 system.

ORIFICE TUBE LOCATION Some orifice tubes are placed into the evaporator inlet tube. An O-ring was fitted around it to stop refrigerant from flowing past the outside of the orifice tube. Several small indentations, or dimples, were put in the tubing wall to keep the orifice tube from moving too far into the evaporator. ● **SEE FIGURE 61–8**.

TECH TIP

How to Locate the Orifice Tube

In an operating system, the orifice tube position can be located by finding the point where the liquid line changes temperature from hot to cold. If the system is not operating, the dimples in the line show the orifice tube location.



EVAPORATOR
LIQUID LINE
ORIFICE TUBE
FITTING
INLET TUBE

FIGURE 61–8 The orifice tube is usually located at the inlet tube to the evaporator.

Many newer vehicles place the orifice tube in the liquid line farther away from the evaporator, close to the condenser outlet. This is done because of complaints of hissing noises that occur after the vehicle is shut off and high-side pressure bleeds down through the orifice tube.

VARIABLE ORIFICE VALVES (VOVs) One type uses a variable orifice valve (VOV) that senses temperature to change the size of the orifice. A bimetal coil spring senses the temperature of the liquid refrigerant, and when the temperature increases, the spring moves the variable port to a closed position. This increases the restriction at the VOV and reduces the flow to the evaporator. ● **SEE FIGURE 61–9**.

A VOV is similar to a fixed orifice tube but contains an internal valve. Installation of the VOV is simply a matter of removing the orifice tube and installing the VOV. Always follow the instructions for the variable orifice valve if installing it in place of a fixed orifice tube.

EVAPORATORS

PURPOSE AND FUNCTION An evaporator, sometimes called the *evaporator core*, is a heat exchanger. The purpose and function of the evaporator is to remove heat from the air being forced through it to cool the inside of the vehicle. ● **SEE FIGURE 61–10**.

CONSTRUCTION Most evaporators are a series of plates sandwiched together to form both the refrigerant and air passages. ● **SEE FIGURE 61–11**.

Evaporators are normally made from aluminum because it has good thermal properties and is lightweight. Evaporators have at least two line connections:

1. The smaller inlet line (liquid line) connects to the TXV or orifice tube.
2. The larger outlet line connects to the suction line and to the compressor or accumulator on orifice tube systems. ● **SEE FIGURE 61–12**.

RECEIVER–DRIERS AND ACCUMULATORS

PURPOSE AND FUNCTION The purpose of refrigerant storage is to compensate for volume changes due to temperature change or refrigerant loss. Desiccant is needed to remove moisture or water, which can cause rusting or corrosion.

DESICCANT The desiccant is a chemical drying agent called "molecular sieve" and its job is to remove all traces of water vapor from a system. Water can mix with refrigerant to form acids, which cause rust and corrosion of metal parts. Water can also freeze and form ice at the TXV or OT, which can block the flow of refrigerant into the evaporator. ● **SEE FIGURE 61–13**.

ACCUMULATORS The accumulator serves three major functions:

1. Prevents liquid refrigerant from passing to the compressor.
2. Holds the desiccant, which helps remove moisture from the system.
3. Holds a reserve of refrigerant.

An accumulator is a container that holds about 1 quart (1 L) or less in volume. The inlet line from the evaporator enters near the top of the accumulator and then drops downward to the bottom, and then exits the accumulator at the top. This routing of the outlet tube separates the refrigerant vapor at the top from the liquid at the bottom so that only vapor will leave the accumulator. A small opening for oil bleed is at the lowermost point and this opening usually has a filter so debris will not block it. A small amount of liquid refrigerant and oil also leaves through the bleed hole. The oil ensures that the compressor is lubricated. ● **SEE FIGURE 61–14**.

The accumulator of some R-134a systems has an insulating jacket to help reduce the heat absorption and lower the air temperature at the discharge ducts. The accumulator or receiver–drier is normally replaced if a system has been opened to the atmosphere for a period of time because the desiccant is probably saturated with moisture. It is also standard practice to replace the accumulator or receiver–drier whenever major service work is done on a system, especially if the compressor is replaced.

The accumulator inlet on many vehicles is connected directly to the evaporator, whereas on other vehicles it is mounted separately with a metal tube or rubber hose to connect it to the evaporator. The outlet of the accumulator is connected to

the compressor inlet through the flexible suction line. ● **SEE FIGURE 61–15**.

RECEIVER–DRIER The receiver–drier is used with TXV systems and is normally found in the high-side liquid line, somewhere between the condenser and the TXV.

The receiver–drier inlet dumps incoming refrigerant into the container so that the refrigerant passes through a filter pad and the desiccant. The outlet, often called a *pickup tube,* begins near the bottom and usually exits at the top. A fine-mesh filter screen is used at the inner opening to stop debris from passing out of the receiver–drier and on to the TXV. The receiver–drier is usually about half full of liquid refrigerant. ● **SEE FIGURE 61–16**.

SIGHT GLASS A receiver–drier can contain a sight glass, pressure release plug or valve, or switch. The **sight glass** allows observation of the refrigerant flow as it leaves the receiver–drier. The flow of R-12 should be invisible because R-12 is clear, and the oil is dissolved in the liquid refrigerant. Bubbles or foam in the sight glass can indicate abnormal operation. R-134a would appear cloudy in a sight glass, so sight glasses are not commonly used in R-134a systems. The pressure relief switch is used to sense high-side pressure. It can be used to prevent compressor operation if the pressure is either too low or too high.

LINES AND HOSES

PURPOSE AND FUNCTION The various system components must be interconnected so that refrigerant can circulate through the system. The components are connected using hoses and tubing (also called pipes).

HOSE CONSTRUCTION Both flexible rubber and rigid metal tubing are used to link the components. The connections to the compressor must be flexible to allow for engine and compressor movement. ● **SEE FIGURE 61–17**.

- Early R-12 hoses were made from rubber with one or two layers of braided reinforcing material. Over time refrigerants could permeate most of these flexible hose materials and slowly escape from the system. This design hose worked with R-12, but R-134a (smaller molecule) would permeate (leak through) R-12 hoses.
- Refrigerant hoses designed for R-134a are made with one or two nonpermeable inner layers with internal reinforcement and an outer layer for protection.

FIGURE 61–17 Rigid lines and flexible hoses are used throughout the A/C system. The line to and from the compressor must be flexible because it is attached to the engine, which moves on its mounts during normal vehicle operation.

The nonpermeable nylon layer forms a leak-proof barrier commonly called **barrier hoses**. The materials for the various layers are developed to keep refrigerant loss to a minimum.

METAL LINES Metal tubing (usually aluminum) is used in many systems to connect stationary components, such as a condenser, to the receiver–drier or OT.

- Metal tubing is sized by its outside diameter (OD).
- Pipes and hoses are sized by the inside diameter (ID) and these sizes are often nominal (approximate) sizes.

A number sizing is often used for refrigerant hose and fittings, with the most popular sizes being #4, #6, #8, #10, and #12.

- #4 equals 1/4 inch (6 mm)
- #6 equals 3/8 inch (10 mm)
- #8 equals 1/2 inch (13 mm)
- #10 equals 5/8 inch (16 mm)
- #12 equals 3/4 inch (19 mm)

Although metal aluminum tubing does not have permeation problems, corrosion caused by battery spillage or water can create holes in the tubing and produce leakage.

The lines in a system are named for their function or what they contain. Starting at the compressor, the **discharge line**, sometimes called the *hot gas line,* connects the compressor to the condenser inlet. The **liquid line** connects the condenser outlet to the receiver–drier and TXV or OT. A TXV system can have two liquid lines, one on each side of the receiver–drier. The **suction line** connects the evaporator outlet to the accumulator or compressor and has the largest diameter because it transfers a low-pressure vapor. ● **SEE FIGURE 61–18**.

HOSE SIZES

- The suction line has an ID of 1/2 inch or 5/8 inch (12.7 mm to 15.9 mm) (a #10 or #12 hose). The liquid line has the smallest diameter, usually an ID of 5/16 inch (7.9 mm) (#6 hose).

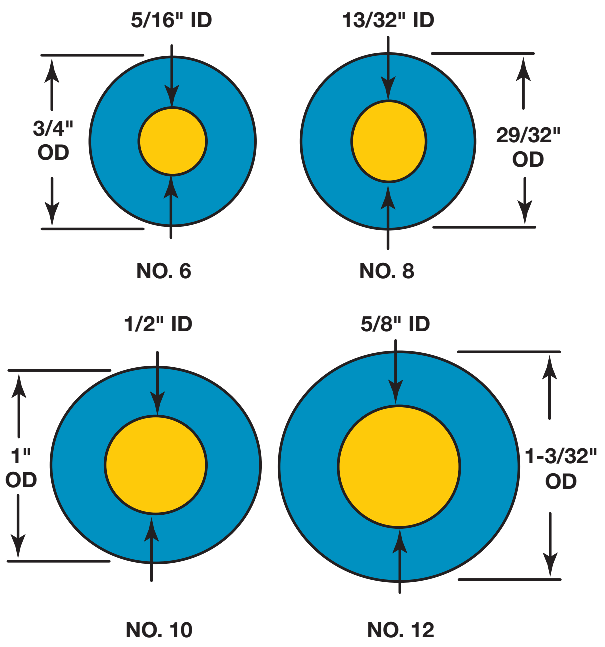

FIGURE 61–19 Most systems use three of these four refrigerant hose sizes. Metal tubing is sized by its outside diameter (OD) and hoses are sized by the inside diameter (ID).

- The discharge line has an ID of 13/32 inch or 1/2 inch (10.3 mm or 12.7 mm) (#8 hose). Metric sizes are also used. ● **SEE FIGURE 61–19**.

CONNECTIONS The lines and hoses are connected to the major components using fittings of several different styles. ● **SEE FIGURE 61–20**.

These fittings allow the lines to be disconnected and are designed to keep refrigerant leakage to a minimum. Most new fittings use an O-ring seal that can be replaced during service. A variety of quick-connect couplers are used to hold two lines together and seal the joint between them. Some of these are held together by one of at least two styles of plastic couplers. One

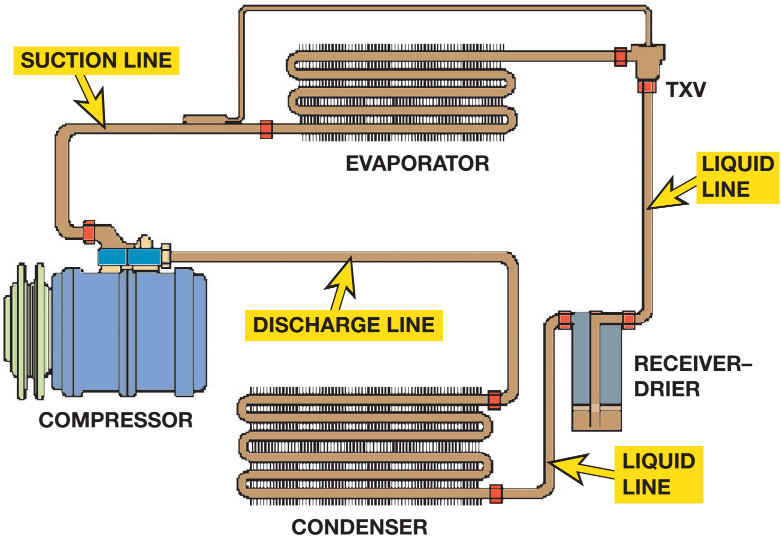

FIGURE 61–18 The three major hoses/lines are the discharge, liquid, and suction lines. A system can have two liquid lines.

QUICK DISCONNECT
TOOL

FIGURE 61–23 A quick disconnect tool being used to remove the connections at the evaporator.

style was held together using a garter spring and was called a *spring-lock fitting*. ● **SEE FIGURE 61–21**.

Spring-lock fittings are connected by pushing one line over the other until the garter spring moves into position. A special tool is inserted into the fitting to expand the garter spring and release the fitting. ● **SEE FIGURE 61–22**.

A spring-lock fitting is a type of quick-disconnect fitting. One portion of this fitting has a flare-like ridge at the end and is gripped by a garter spring when connected. One or two O-rings form the seal between the two fitting parts. These O-rings must be resilient enough to compensate for slight movement between the two parts. ● **SEE FIGURE 61–23**.

O-RINGS O-ring fittings squeeze a rubber O-ring between the two parts being connected to make the seal. In most cases, the O-ring is slid over the end of the metal tube and is located by a raised metal ring or bead. Some manufacturers use a **captive O-ring**, also called *captured O-ring*, which locates the O-ring more positively in a shallow groove. Captive O-rings use a larger-diameter cross section than standard O-rings. Some designs use two O-rings for a better seal.

O-rings made from Buna or nitrile is commonly used in R-12 systems, but these materials are not compatible with R-134a. High-grade neoprene O-rings (HSN or HNBR), often tinted blue or green, are used in R-134a systems. There is no color standard for O-rings but most manufacturers use the following color designations:

- Black indicates nitrile or neoprene.
- Blue indicates neoprene or nitrile.
- Green indicates HNBR and is generally used in R-134a systems.

ELECTRICAL SWITCHES AND EVAPORATOR TEMPERATURE CONTROLS

CONTROL SWITCHES Various electrical switches are used in A/C systems to prevent evaporator icing, protect the compressor, and control fan motor. Control switches can be located anywhere in the system, such as at the

- compressor discharge
- suction cavities
- receiver–drier
- accumulator

Some recent systems use a variable displacement compressor to prevent icing. A valve that senses evaporator pressure is used in the compressor, and compressor displacement is reduced in response to that pressure.

At one time, the A/C electrical circuit was rather simple:

- A typical circuit connects the evaporator blower motor and compressor clutch at one main switch.
- The power to the compressor clutch passes through a temperature switch that opens the circuit to cycle the clutch when the evaporator gets too cold.
- The power to the blower motor passes through a speed control switch so that the blower speed can be changed. ● **FIGURE 61–24**.

Today various switches, sensors, and relays are used. A sensor is usually an input to an electronic control module (ECM) or body control module (BCM). Many sensors provide a variable signal, so the ECM/BCM will know the actual temperature or pressure at a given point. A relay is essentially a magnetic switch that is controlled by another switch. A relay is used to control a greater amount of current than a switch can handle. Relays also allow computer control modules to control electrical circuits. Any one A/C system will have some of these, but not all of the following, depending on the type of system and manufacturer:

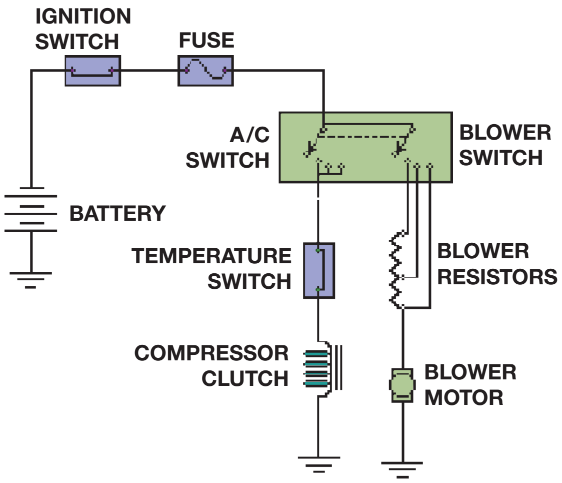

FIGURE 61–24 Many early A/C systems used a simple electrical circuit.

- **A/C clutch relay.** Controls current to compressor clutch and is used to turn the compressor on or off
- **Ambient sensor or switch.** Senses outside temperature and is designed to prevent compressor operation when ambient temperature is below a certain point, about 35°F to 40°F (2°C to 4°C)
- **Compressor high-pressure sensor or switch.** Mounted in compressor discharge cavity and senses high-side pressure and is used to cut out the compressor clutch if pressure is too high or too low, or provides a signal to another device that pressure is too high
- **Compressor low-pressure sensor or switch.** Mounted in compressor suction cavity, this switch or sensor detects low-side pressure and is used to cut out the compressor clutch if pressure is too low
- **Compressor RPM sensor.** Provides input to the ECM/BCM that the compressor is running. The ECM/BCM will cut out compressor if RPM is low (possible belt slippage or impending compressor lockup)
- **Compressor superheat sensor or switch.** Function is similar to compressor low-pressure switch
- **Compressor high-temperature switch.** Mounted on the compressor and shuts off the compressor if the temperature of the compressor gets too hot
- **Power steering compressor cutoff switch.** Mounted at power steering gear, this switch senses pressure in that system and is used to stop the compressor when the pressure in the power steering rises to a high level which increases the load on the engine. The A/C compressor clutch is then disengaged to help remove some of the load from the engine so it does not stall
- **Engine coolant temperature (ECT).** Mounted near the engine thermostat and senses engine temperature for ECM/BCM and is also used to turn on cooling fan(s)
- **Evaporator pressure sensor.** Provides input to the ECM/BCM as to the operating pressure in the evaporator
- **Evaporator temperature sensor.** Mounted at the evaporator, it senses temperature and is used to cycle compressor clutch to prevent icing
- **High-pressure cutout switch.** Mounted at receiver–drier or liquid line, it senses high-side pressure and is used to cut out the compressor clutch if high-side pressure is too high
- **High-temperature cutoff sensor or switch.** Mounted at the condenser outlet, this switch or sensor measures condenser temperature and is used to cut out the compressor clutch if the temperature is too high
- **Low-pressure cutout sensor or switch.** Mounted in receiver–drier or liquid line, it senses low pressure and is used to cut out the compressor clutch with low refrigerant charge
- **Main switch.** Mounted at control head, this switch can be operated by the driver to turn the system on or off

- **Pressure cycling switch.** Mounted at accumulator, it senses low pressure and cycles the compressor clutch to prevent evaporator icing
- **Thermostatic cycling switch.** Mounted at evaporator, it senses air temperature and cycles the compressor clutch to prevent evaporator icing
- **Trinary pressure switch.** Mounted at receiver–drier, this switch senses high-side pressure and cuts out compressor clutch if pressure is too high or too low. It can also be used to control radiator shutters or fan motor
- **Blower relay.** Can be used to turn blower on or off and provide high blower speed
- **Clutch cutoff relay.** Can be used to interrupt compressor clutch
- **Condenser fan relay.** Used to turn condenser fan motor on or off
- **Radiator fan relay.** Used to turn radiator fan motor on or off

THERMOSTATIC CYCLING SWITCH

Evaporator temperature in a cycling clutch system is sometimes controlled by either a thermostatic (thermal) switch or pressure switch. A bellows switch uses a capillary tube inserted into the evaporator fins. As with a TXV, the gas pressure in the capillary tube is exerted on the bellows. In a thermal switch, the bellows acts on a set of contact points:

- A warm evaporator produces a higher bellows pressure, which keeps the points closed.
- A cold evaporator reduces the pressure, which causes the points to open.

A bimetal switch has a contact arm that is laminated from two metals with very different thermal expansion rates:

- When the switch is warm, the metals expand to close the contact points.
- When the switch cools, the metals in the arm contract to open the contacts.

Both of these switch styles are calibrated so they are closed at temperatures above 32°F (0°C) and open at temperatures below 32°F (0°C). When the switch opens, the compressor clutch is turned off. This causes the evaporator to begin warming, and after a few degrees of temperature increase, the switch closes to cycle the compressor in again. Recent systems use thermistors to sense temperature instead of thermostatic cycling switches.

PRESSURE CYCLING SWITCHES

A pressure cycling switch is mounted to sense low-side pressure, usually on the accumulator. Ice begins to form when evaporator pressure drops below 30 PSI in an R-12 system or slightly less in an R-134a system.

- When evaporator pressure is above 30 PSI, the switch contacts close so the compressor will operate.
- When the pressure drops below 30 PSI, the switch opens and cycles the compressor out.
- After the compressor stops, evaporator pressure will increase and after an increase of about 10 PSI to 20 PSI, the pressure switch contacts close to cycle the compressor in again. This switch also prevents the compressor from operating if the pressure is too low from a refrigerant loss. ● **SEE FIGURE 61–25**.

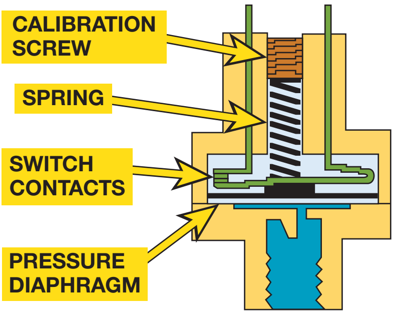

FIGURE 61–25 A pressure switch is either on or off. The contacts are closed by gas pressure on the diaphragm; they are opened by the spring.

LOW-PRESSURE SWITCH

Many systems include a low-pressure switch, located in a low-pressure line or the accumulator to prevent compressor operation if there is loss of refrigerant. Damage will occur if the compressor is operated without the refrigerant or the oil through which the refrigerant circulates.

THERMISTORS AND TRANSDUCERS

Recent systems use solid-state sensors that do not use switch contacts. The most common sensors are thermistors and transducers and these provide a variable output instead of just being on or off like a switch.

- A **thermistor** is commonly used to sense temperatures. It is basically an electrical resistor that changes resistance in inverse relationship to its temperature. Most automotive thermistors are of the negative temperature coefficient (NTC) type. The resistance will increase as the temperature drops and vice versa.
- A **transducer** senses pressure and changes a variable pressure signal into a variable electrical signal. A transducer can let the ECM/BCM know the actual pressure in the low and/or high side of the system. Sensors provide an electrical signal to a control module that, in turn, controls compressor clutch or condenser fan operation.

REAR A/C SYSTEMS

PARTS AND OPERATION

Some larger vehicles (vans and small buses) have dual heat and A/C assemblies, with the rear unit mounted in a rear side panel or in the roof. The rear A/C unit consists of an evaporator and a TXV that operates in parallel flow with the front unit. ● **SEE FIGURE 61–26**.

Tee fittings are placed in the liquid and suction lines so that refrigerant can flow through both units, with the flow through the rear unit dependent on the cooling load. Many dual systems use an orifice tube to control the refrigerant flow into the front

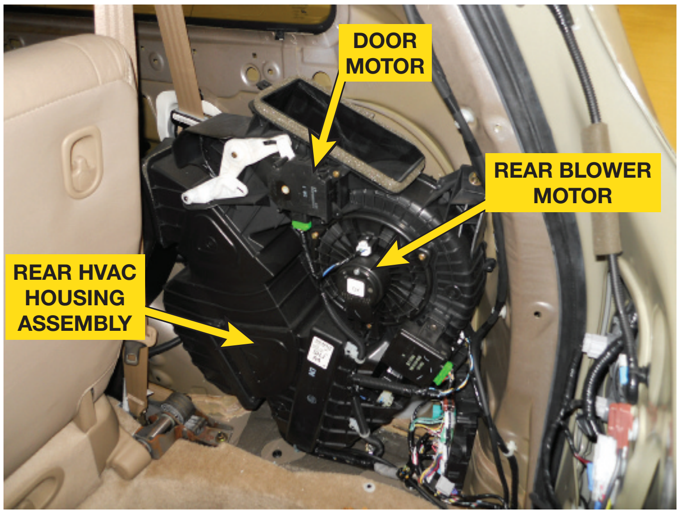

FIGURE 61–26 The rear HVAC module assembly used on a Honda Odyssey minivan.

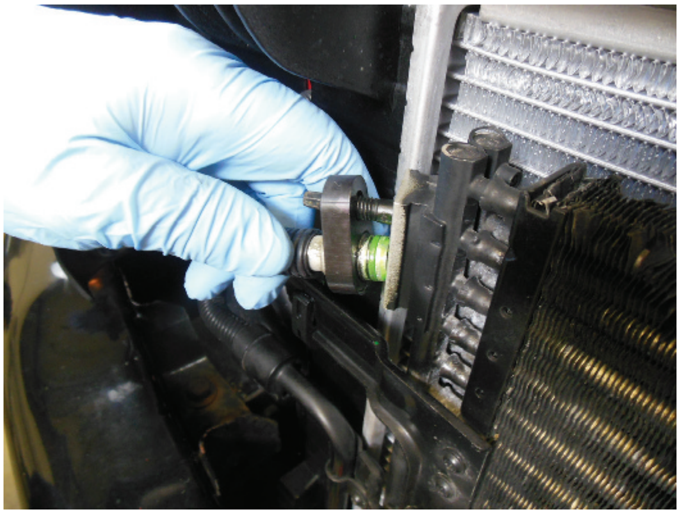

FIGURE 61–27 The line to the condenser from the compressor includes a flange mount with an O-ring. This line is being replaced with a new original equipment line as a result of an accident, which caused the line to be kinked.

evaporator and a TXV with the rear evaporator. The rear evaporator is normally mounted in an assembly that includes a blower, heater core, and doors to control the air temperature and where the air returns to the passenger compartment.

COMPONENT REPLACEMENT PROCEDURES

FITTING REPAIR If the fitting is tight and still leaks, it must be taken apart and inspected for damage and a new O-ring must be installed. Torque specifications for the various line fittings are provided by the vehicle manufacturer. Always use two wrenches when servicing fittings.

LINE REPLACEMENT A faulty hose or metal line is often repaired by replacing it with a new or repaired line. This normally involves disconnecting each end of the line at a fitting. Some hoses, like the suction and discharge, are combined with another line, making a double connection at the compressor, condenser, or evaporator. A manifold-type connector sealed with a pair of O-rings is commonly used at these connections. Some aftermarket suppliers can custom make hoses with fittings. ● **SEE FIGURE 61–27**.

A/C COMPONENT REPLACEMENT Inside-out failure is caused by acids inside of the system, and the accumulator or receiver–drier must be replaced and the refrigerant recycled to remove these acids.

- When the compressor, evaporator, or TXV is replaced, the receiver–drier or accumulator should also be replaced. These failures were possibly caused by system contamination. This contamination will probably have loaded the desiccant capacity with moisture.
- It is good practice to keep the plastic caps in place on the new components until just before installation to keep as much moisture out of the system as possible.
- Removal of an accumulator, condenser, evaporator, or receiver–drier also removes a certain amount of oil from the system, and new oil should be added to the new part. The actual amount is usually specified in service information. ● **SEE CHART 61–1**.

COMPONENT	FLUID OZ.	CC
Accumulator	2	60
Condenser	1	30
Evaporator	2	60
Each hose	0.3	10
Receiver–drier	0.5	15

CHART 61–1

When an A/C component is removed, a certain amount of oil is also removed. These are typical amounts. Check service information for the exact amount to add to each component if it is replaced.

If faulty, a major A/C component (the accumulator, condenser, evaporator, OT, receiver–drier, or TXV) is repaired by replacing it with a new one. At one time, replacement of these components was relatively easy because there was good access, except when working with evaporators. In most cases, getting the evaporator case out of the vehicle is tedious and time consuming, sometimes requiring the vehicle or evaporator case to be cut. Many technicians will not change an evaporator without consulting service information for the exact procedure to follow.

To remove and replace a major A/C component, locate, read, understand, and follow the specified repair procedure found in service information, which usually includes the following steps:

STEP 1 Recover the refrigerant from the system.

STEP 2 Disconnect and cap the refrigerant lines to the component.

STEP 3 Disconnect any mounting brackets and wires connected to the component and remove it.

STEP 4 Install the new part and attach any mounting brackets and wires.

STEP 5 Remove the line caps, pour the proper amount of the correct refrigerant oil into the component or line, and connect the refrigerant lines.

STEP 6 Evacuate and recharge the system and test for leaks.

ORIFICE TUBE REPLACEMENT A special puller that attaches to the orifice tube or needle-nose pliers is normally used to remove it. ● **SEE FIGURE 61–28**.

TXV REPLACEMENT When replacing a TXV (other than a H-block-type TXV), the thermal bulb must be securely attached to the evaporator outlet tube. This area must be clean to ensure good heat transfer. After attaching the thermal bulb, it must be wrapped with insulating refrigerant tape. This thick, pliable tape is used to keep outside heat from reaching the thermal bulb.

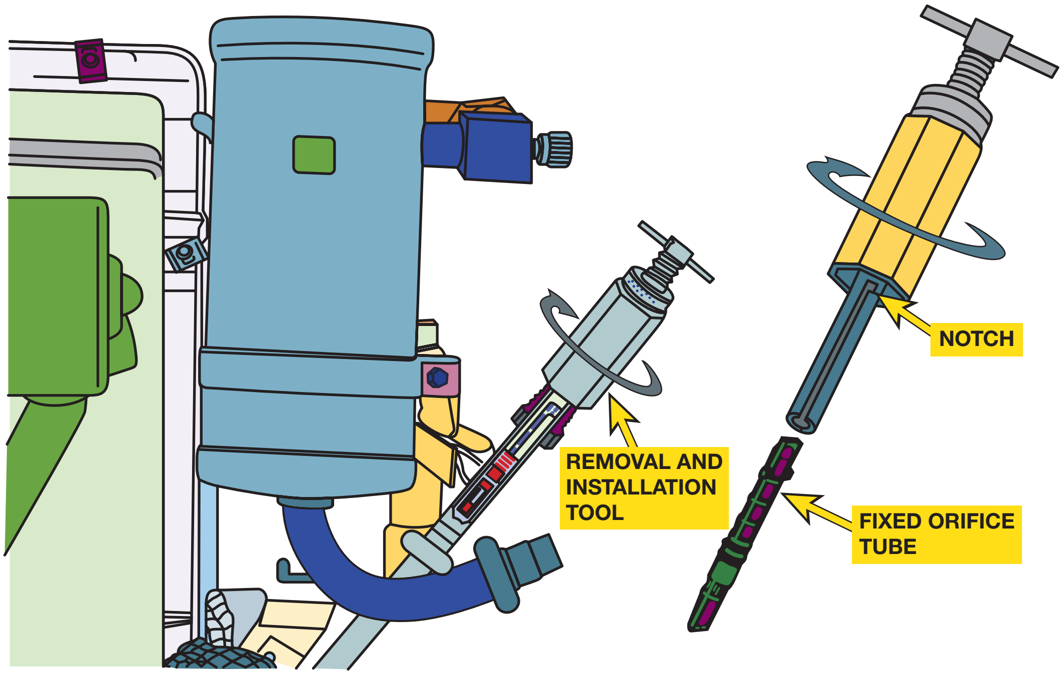

FIGURE 61–28 Needle-nose pliers can sometimes be used to remove an orifice tube, but it requires this special tool in most cases.

REVIEW QUESTIONS

1. Why is sub-cooling necessary in some condensers?
2. Where is the thermal expansion valve located in the refrigeration system?
3. Where is the orifice tube located in the refrigeration system?
4. What is the difference between an accumulator and a receiver–drier?
5. Why does refrigerant oil need to be added to a new component such as a condenser?

CHAPTER QUIZ

1. A cooling module usually includes what components?
   - **a.** Radiator
   - **b.** Automatic transmission fluid cooler
   - **c.** A/C condenser
   - **d.** All of the above
2. As the latent heat of condensation is transferred to the airstream in the condenser, the refrigerant changes into ___________.
   - **a.** liquid
   - **b.** vapor
   - **c.** gas
   - **d.** solid
3. Newer condensers use a ___________ tube design, with fins between the tubes.
   - **a.** copper
   - **b.** flattened
   - **c.** rubber
   - **d.** None of the above
4. What is the purpose of the compressor in a refrigeration system?
   - **a.** Circulates the refrigerant
   - **b.** Raises the pressure of the refrigerant
   - **c.** Raises the temperature of the refrigerant
   - **d.** All of the above

5. The orifice tube is usually located at the inlet tube to the ____________.
    - **a.** condenser
    - **b.** compressor
    - **c.** evaporator
    - **d.** receiver–drier
6. Two technicians are discussing A/C systems. Technician A says that the TXV system uses a receiver–drier mounted in the suction line. Technician B says that the orifice tube system uses an accumulator in the suction line. Which technician is correct?
    - **a.** Technician A only
    - **b.** Technician B only
    - **c.** Both Technicians A and B
    - **d.** Neither Technician A nor B
7. The liquid line ____________.
    - **a.** connects the condenser to the receiver–drier and TXV or OT
    - **b.** is smaller than the suction line
    - **c.** is larger in diameter than the suction line
    - **d.** Both a and b
8. O-rings used in R-134a systems are usually ____________.
    - **a.** green
    - **b.** black
    - **c.** red
    - **d.** orange
9. Various electrical switches used in A/C systems ____________.
    - **a.** prevent evaporator icing
    - **b.** protect the compressor
    - **c.** control fan motors
    - **d.** All of the above
10. Rear A/C systems use ____________.
    - **a.** an orifice tube to control the refrigerant flow into the front evaporator and a TXV with the rear evaporator
    - **b.** an orifice tube to control the refrigerant flow into the front evaporator and the rear evaporator
    - **c.** a TXV to control the refrigerant flow into the front evaporator and an orifice tube with the rear evaporator
    - **d.** a TXV to control the refrigerant flow into the front evaporator and the rear evaporator

Chapter 62

AIR MANAGEMENT SYSTEM

LEARNING OBJECTIVES

After studying this chapter, the reader should be able to:

- Discuss the different components of an air management system.
- Explain airflow control in an A/C system.
- Explain air temperature control in an A/C system.
- Describe air filtration in an A/C system.
- Describe housing and ducts in an A/C system.
- Discuss plenum and control doors.
- Explain nonelectrical and electronic HVAC controls.
- Describe the blower motor.

KEY TERMS

Air doors 735 • Air inlet door 736 • Air management system 735 • Cabin filter 738 • Dual-zone 741 • Inside air 735 • Mode door 736 • Outside air 735 • Plenum 739 • Recirculation 735 • Temperature-blend door 736

TERMINOLOGY

AIR MANAGEMENT A system that contains the HVAC plenum, ducts, and **air doors** is called the **air management system**, or *air distribution system,* and controls the airflow to the passenger compartment. ● **SEE FIGURE 62–1**.

Air flows into the case that contains the evaporator and heater core from two possible inlets:

1. **Outside air**, often called *fresh air*
2. **Inside air**, usually called **recirculation**.

Proper temperature control to enhance passenger comfort during heating should maintain an air temperature in the

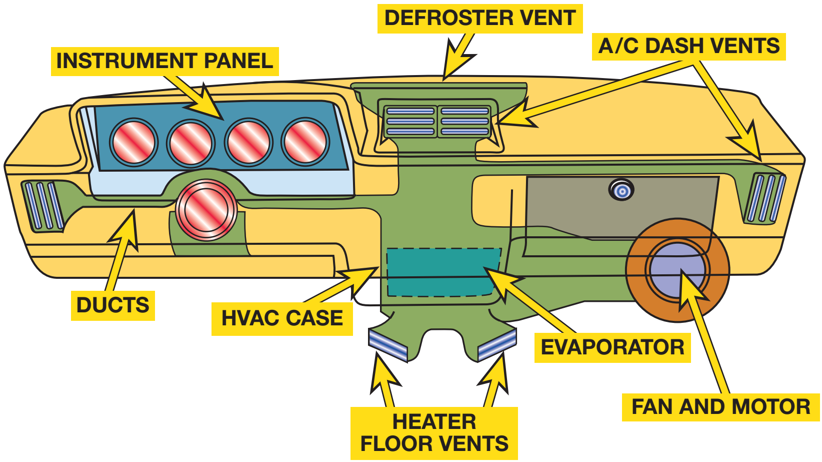

FIGURE 62–1 The HVAC airflow is directed toward the windshield, dash or floor vents, or combinations depending on the system settings.

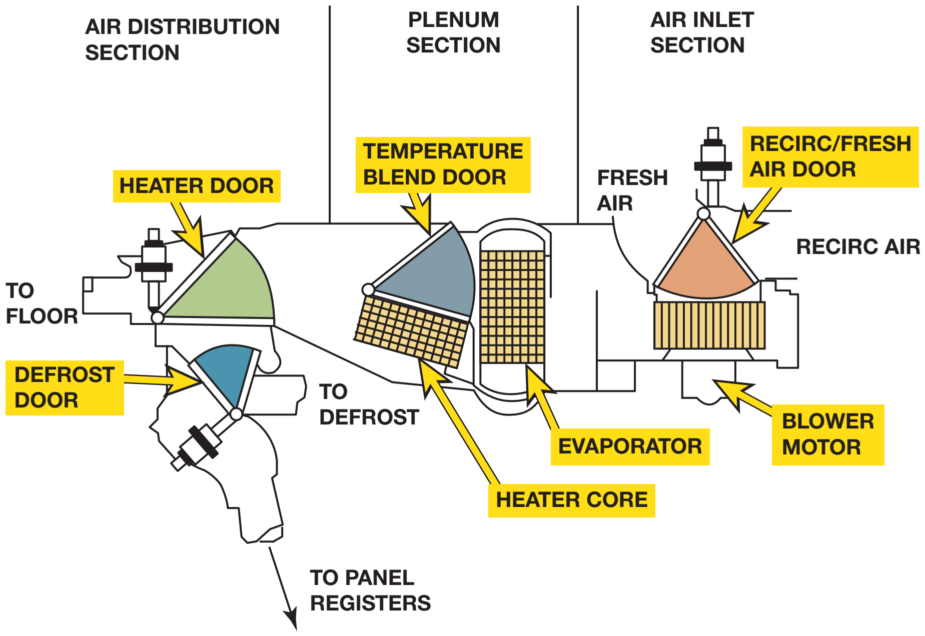

FIGURE 62–2 The three major portions of the A/C and heat system are air inlet, plenum, and air distribution. The shaded portions show the paths of the four control doors.

footwell about 7°F to 14°F (4°C to 8°C) above the temperature around the upper body. This is done by directing the heated airflow to the floor. During A/C operation, the upper body should be cooler, so the airflow is directed to the instrument panel registers. Airflow is usually controlled by three or more doors, which are called *flap doors* or valves by some manufacturers. The three doors include the following:

- **Air inlet door** is used to select outside or inside air inlet.
- **Temperature-blend door** is used to adjust air temperature.
- **Mode door** is used to select air discharge location. ● **SEE FIGURE 62–2**.

The use of these components allows the system to provide airflow under the following conditions:

1. Fresh outside air or recirculated air
2. Air conditioning
3. Defrost
4. Heat

HEAT For heat position, the following can be done:

- Temperature set to the desired setting
- Air intake—select outside air for faster heating
- Air conditioning set to off
- Set airflow to floor
- Fan speed set to desired speed

AIR CONDITIONING For air conditioning position, the following can be done:

- Temperature set to the desired setting
- Air intake—set to outside air or recirculation under high humidity conditions
- Airflow—set to dash vents (also called panel vents)
- Air conditioning set to on
- Fan speed set to desired speed

VENTILATION For ventilation position, the following can be done:

- Temperature set to desired temperature
- Air intake—select outside air
- Airflow—set to dash (panel) vents
- Air conditioning set to off
- Fan speed set to desired speed

DEFOGGING OR DEFROSTING THE INSIDE OF THE WINDSHIELD For defogging or defrosting position, the following can be done:

- Temperature set to high temperature
- Air intake set to outside air
- Airflow set to windshield (defrost)
- Fan speed set to desired speed. ● **SEE FIGURE 62–3**.

HVAC CONTROL HEAD The HVAC control head or panel is mounted in the instrument panel cluster or console. The control head includes the following controls:

- System on and off
- Outside or recirculated air
- Mode position (floor, vent, or defrost)
- Temperature desired
- Blower speed

The control head is connected to various parts through electrical connections, vacuum connections, mechanical cables, or a combination of these. ● **SEE FIGURE 62–4**.

AIRFLOW CONTROL

OPERATION The amount or volume of HVAC air is controlled by blower speed. A multispeed blower is used to force air through the ductwork when the vehicle is moving at low speeds or to increase

the airflow at any speed. At highway speeds, most systems have a natural airflow from ram air pressure created by the forward movement of the vehicle. This is the pressure generated at the base of the windshield by the speed of the vehicle. This airflow is improved in some vehicles by outlet registers placed in low-pressure areas toward the rear of the vehicle. Higher speeds move more air. The inlet and outlet directions of the airflow and the discharge air temperature are controlled by swinging, sliding, or rotating doors.

FREQUENTLY ASKED QUESTION

What Does the Snowflake Button on the Dash Do?

Some people, such as those who drive vehicles that are equipped with automatic climate control systems, sometimes find it hard to figure out how to engage the A/C compressor on a rental car or a vehicle that they have not driven before. Often the driver will turn the fan to high and the mode selector to the dash vent position, but no cool air is being delivered. For the compressor to function, the button that looks like a snowflake has to be pushed. The snowflake button is actually the air conditioning on/off button. ● **SEE FIGURE 62–5**.

TYPES OF DOORS Most systems use a flap door that swings about 45 degrees to 90 degrees. Swinging doors are very simple and require little maintenance. ● **SEE FIGURE 62–6**.

Another design uses a *rotary door*. This pan-shaped door has openings at the side and edge, and the door rotates about 100 degrees to one of four different positions. Each position directs airflow to the desired outlet(s).

The space under the instrument panel is very crowded, and some vehicles use a smaller HVAC case using a *sliding mode door* also called a *rolling door*. Some of these door designs roll up, similar to a window shade, and unroll to block a passage. ● **SEE FIGURE 62–7**.

AIR TEMPERATURE CONTROL

TEMPERATURE CONTROL USING AIRFLOW Most HVAC systems are considered *reheat* systems in that the incoming air is chilled as it passes through the evaporator. The air is then heated

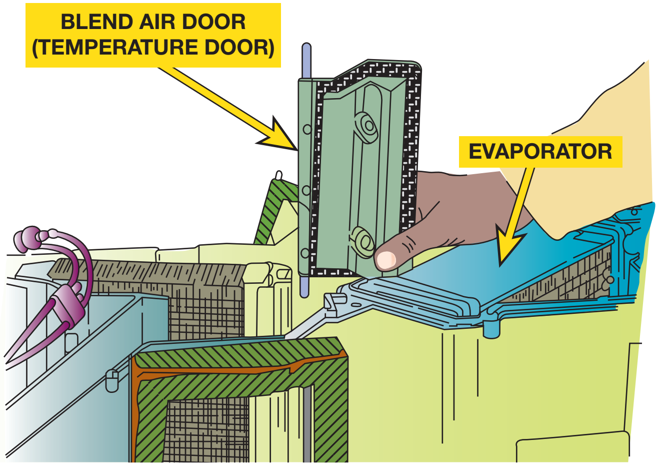

FIGURE 62–6 Many air control doors swing on their upper and lower pivots.

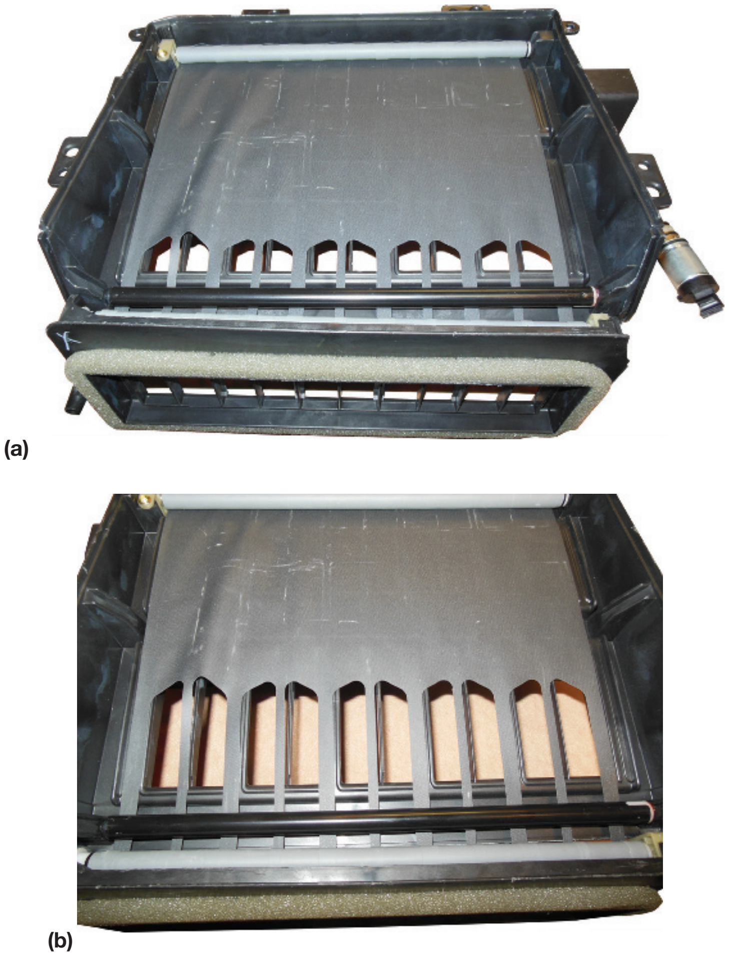

FIGURE 62–7 (a) A typical rolling-door type HVAC door that is shown almost fully closed. (b) The same door is shown about half open.

as part or all of the flow passes through the heater core so it reaches the desired in-vehicle temperature. ● **SEE FIGURE 62–8**.

TEMPERATURE CONTROL USING A VARIABLE COMPRESSOR There is an increasing trend to use an electronically controlled variable displacement compressor with an air temperature sensor after the evaporator. Compressor displacement is adjusted to cool the evaporator just enough to cool the air to the desired temperature. Cooling the incoming air no more than necessary will reduce compressor load on the engine and should improve fuel economy.

AIR FILTRATION

PURPOSE AND FUNCTION Many newer systems include an HVAC air filter, usually called a **cabin filter**, in the air distribution system. Cabin filters are located outside the air inlet and are serviced under the hood, or between blower and evaporator which are serviced from under the dash. ● **SEE FIGURE 62–9**.

This filter can also be referred to as a(n)

- interior filter
- ventilation filter
- micron filter
- particulate filter
- pollen filter

The cabin filter removes small dust or pollen particles from the incoming air stream. These filters require periodic replacement and if they are not serviced properly, they can cause an airflow reduction when they become plugged.

TYPES OF CABIN FILTERS There are two types of filter media:

1. Particle filters. Particle filters remove solid particles such as dust, soot, spores, and pollen using a special paper or nonwoven fleece material; they can trap particles that are about three microns or larger.
2. Adsorption filters. Adsorption filters remove noxious gases and odors using an activated charcoal media with the charcoal layer between layers of filter media. These two filter types can be combined into a combination or two-stage filter. The filter media can have an electrostatic charge to make it more efficient.

CASE STUDY

Cabin Filter Fault

The owner of a Ford Escape complained that the air-conditioning system was not cooling the inside of the vehicle and there seemed to be no airflow from the dash vents yet the blower motor could be heard running. A quick visual inspection of the cabin air filter with access under the hood showed that the cabin filter was almost completely blocked with paper, leaves, and debris. The vehicle had almost 80,000 miles on the odometer and the way it looked, the air filter had never been replaced. Most vehicle manufacturers recommend replacement of the cabin air filter about every three years or every 36,000 miles. Replacing the cabin air filter restored proper operation of the A/C system.

Summary:

Complaint—Customer complained of a lack of airflow from the dash vents.

Cause—A partially clogged cabin filter.

Correction—Replacement of the cabin filter restored proper airflow from the dash vents.

HOUSING AND DUCTS

CONSTRUCTION The evaporator and heater housing is molded from reinforced plastic and contains the following components:

- Evaporator
- Heater core
- Blower motor
- Most of the air control doors

The housing, called a **plenum**, is connected to the air inlets and outlets using formed plastic. These parts are required to contain and direct airflow, reduce noise, keep outside water and debris from entering, and isolate engine fumes and noises. ● **SEE FIGURE 62–10**.

HEATER HOSE CONNECTIONS
PLASTIC PLENUM HOUSING
CONDENSATE DRAIN
REFRIGERATE LINES TO EVAPORATOR

FIGURE 62–10 A typical HVAC housing that often has to be removed from the vehicle as an assembly to get access to the heater core and evaporator.

Air can enter the duct system from either the plenum chamber in front of the vehicle's windshield (outside air) or from the *recirc* (short for *recirculation*) or return register (inside air). The return register is often positioned below the right end of the instrument panel. (The right and left sides of the vehicle are always described as seen by the driver.) The outside air

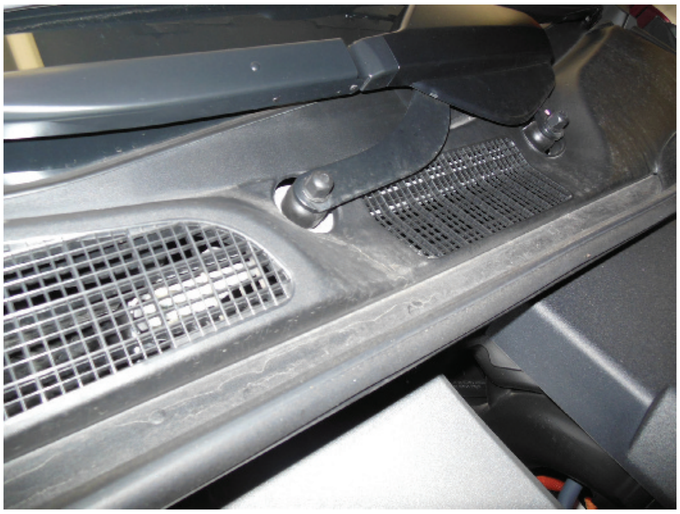

FIGURE 62–11 The air inlet to the HVAC system is usually at the base of the windshield and covered with a plastic screen (grille) to help keep debris such as leaves from entering the system.

plenum often includes a screen to keep leaves and other large debris from entering with the air. ● **SEE FIGURE 62–11**.

PLENUM AND CONTROL DOORS

AIR INLET CONTROL DOOR The air inlet control door is also called

- *Fresh air door*
- *Recirculation door*
- *Outside air door*

This door is normally positioned so it allows airflow from one source while it shuts off the other. It can be positioned to allow:

- Fresh air to enter while shutting off the recirculation opening
- Air to return or recirculate from inside the vehicle while shutting off fresh air
- A mix of fresh air and return air

In many newer vehicles, the door is set to the fresh air position in all function lever positions except off, max heat, and max A/C. Max A/C and max heat settings position the door to recirculate in-vehicle air.

TECH TIP

Keep the Air Screen Clean

The outside air inlet screen must be kept in good condition to prevent debris and small animals from entering the HVAC case. Leaves and pine needles can enter, decay, and mold. Mice have been known to enter and build nests and/or die. Any of these conditions can create a bad smell and are very difficult to clean.

NOTE: In some vehicles, the recirculation door blocks most of the outside air and allows 80% of the air to be recirculated from the passenger compartment. About 20% of the air entering the passenger compartment is outside air to help keep the air in the passenger compartment fresh and keep the CO_2 levels low.

TEMPERATURE-BLEND DOOR Most systems position the evaporator so all air must pass through it. This allows removal of moisture by the evaporator's cold temperature. Many systems operate the A/C when defrost is selected to dry the air. The heater core is placed downstream so that air can be routed either through or around it using one or two doors to control this airflow. The door used to control interior temperature is called the temperature-blend door. Some other names for this door include

- *Air-mix door*
- *Temperature door*
- *Blend door*
- *Diverter door*
- *Bypass door.* ● **SEE FIGURE 62–12**.

The temperature-blend door is connected to the temperature knob or lever at the control head using a mechanical cable or an electric actuator. When the temperature lever is set to the coldest setting, the temperature-blend door routes all air so it bypasses the heater core. This causes the air entering the passenger compartment to be the coldest, coming straight from the evaporator. When the temperature lever is set to the hottest setting, the temperature-blend door routes all air through the heater core, and heated air goes to the passenger compartment.

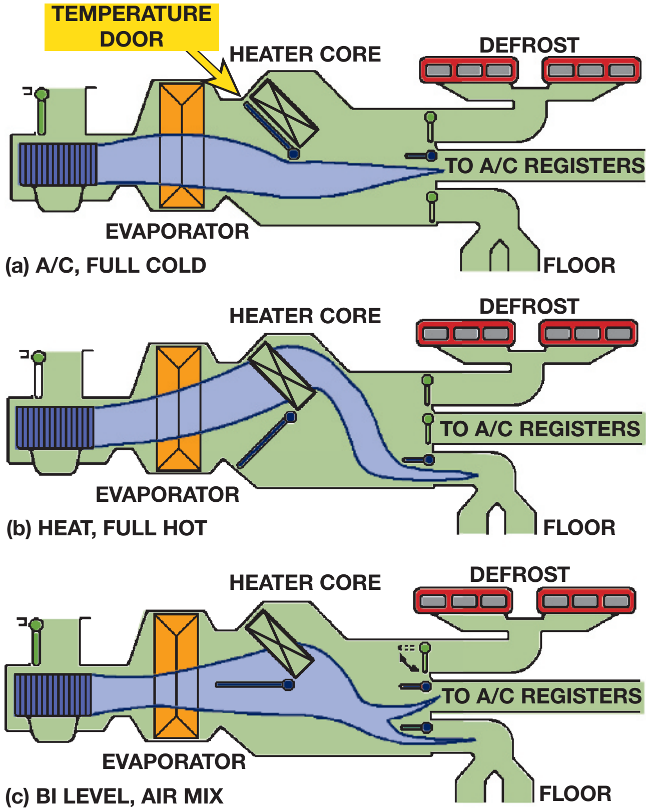

FIGURE 62–12 (a) The temperature and mode doors swing to direct all of the cool air past the heater core, (b) through the core to become hot, (c) or to blend hot and cool air.

FIGURE 62–13 (a) In a blend-air system, all of the air is cooled. Then some of it is reheated and blended with the cool air to get the right temperature. (b) In a reheat system, all of the air is cooled and then reheated to the correct temperature.

Setting the control lever to somewhere between cold and hot will mix or *temper* cold and hot air, allowing the driver to adjust the temperature to whatever is desired.

In the past in some vehicles, the evaporator was placed or stacked right next to the heater core. These systems controlled the air temperature by regulating the amount of reheat at the heater core. ● **SEE FIGURE 62–13**.

AIR DISTRIBUTION AND OUTLETS Air from the plenum can flow into one or two of three outlet paths:

1. The A/C registers (vents) in the face of the instrument panel
2. The defroster registers at the base of the windshield
3. The heater outlets at the floor under the instrument panel

Most vehicles include two ducts under the front seats or in the center console to transfer air to the rear seat area. Most vehicles also direct airflow to the side windows to defog the side windows. ● **SEE FIGURE 62–14**.

Airflow to these ducts is controlled by one or more mode doors controlled by the function lever or buttons. Mode doors are also called *function*, *floor-defrost*, and *panel-defrost* doors. Mode/function control sets the doors as follows:

- **A/C:** in-dash registers with outside air inlet
- **Max A/C:** in-dash registers with recirculation
- **Heat:** floor level with outside air inlet
- **Max Heat:** floor level with recirculation
- **Bi-level:** both in-dash and floor discharge
- **Defrost:** windshield registers

In many systems, a small amount of air is directed to the defroster ducts when in the heat mode, and while in defrost mode, a small amount of air goes to the floor level.

DUAL-ZONE AIR DISTRIBUTION **Dual-zone** air distribution allows the driver and passenger to select different temperature settings. The temperature choices can be as much as 30°F (16°C) different. Dual-zone systems split the duct and airflow past the heater core and use two air mix valves or doors with each air mix valve/temperature door controlled by a separate actuator.

HVAC CONTROLS

CABLE-OPERATED SYSTEMS Mechanical systems are the least expensive. Most early control heads used purely mechanical operation for the doors, and one or more cables connected the function lever to the air inlet and mode doors. The temperature lever was also connected to the temperature-blend door by another cable. These mechanical levers were rather simple and usually trouble free, but they had some disadvantages. They tended to bind and could require a good deal of effort to operate.

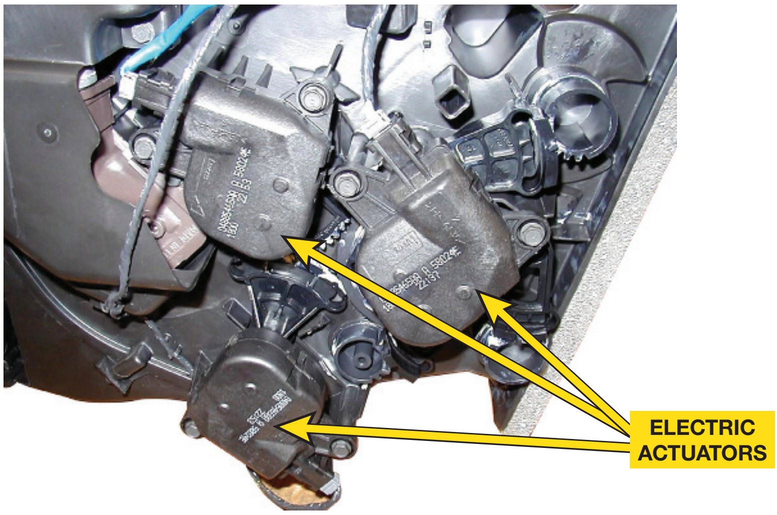

FIGURE 62–15 Three compact, electric actuators/servomotors operate the doors in this part of the HVAC case.

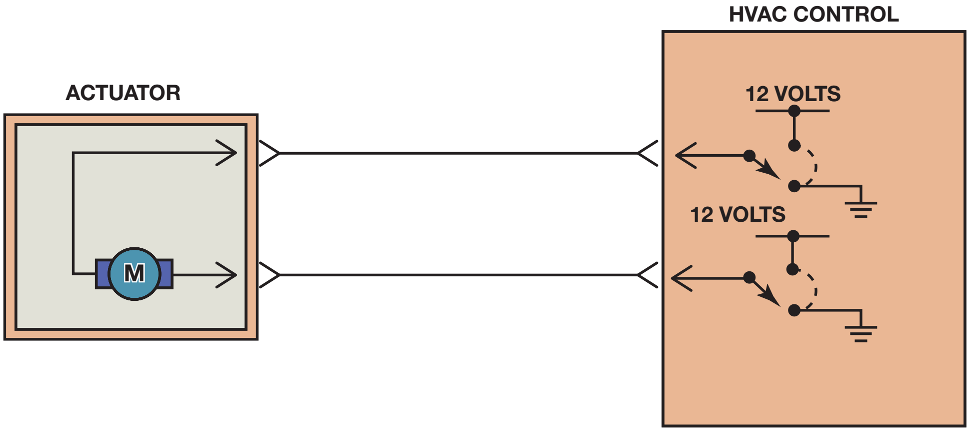

FIGURE 62–16 A two-wire HVAC electronic actuator where the direction of rotation is controlled by the HVAC control head or module, which changes the direction of rotation by changing the polarity of the power and ground connection at the motor.

ELECTRONIC HVAC CONTROLS Most recent vehicles use electrical function switches at the HVAC control head. These are often called *electromechanical controls.* These switches operate electric actuators (motors) to control the air distribution and temperature-blend doors. ● **SEE FIGURE 62–15**.

TWO-WIRE ACTUATORS A typical two-wire actuator rotates when electric impulses are sent to the brushes by the HVAC control head. The direction of rotation, and therefore the movement of the HVAC door position, is changed by changing the wire that is pulsed with power and the other brush is then connected to ground. ● **SEE FIGURE 62–16**.

THREE-WIRE ACTUATORS A typical three-wire actuator uses a power, ground, and an input signal wire from the HVAC control module. There is a module (logic chip) inside the motor assembly that receives a 0–5 volt signal from the HVAC control module. When the actuator gets a 0-volt signal from the control module, it rotates in one direction and when it receives a 5-volt signal, it rotates in the opposite direction. If the motor receives a 2.5 volt signal, the motor stops rotating. ● **SEE FIGURE 62–17**.

FIVE-WIRE ACTUATORS A five-wire actuator uses two wires to power the motor (power and ground) and three wires for a potentiometer that is used to signal the HVAC control module of the position of the motor. The potentiometer may be a separate gear-driven part attached to the motor or a part of the printed circuit board where a slider moves across resistive paint to create the potentiometer signal voltage. ● **SEE FIGURE 62–18**.

Most HVAC control modules convert the potentiometer signal voltage to a binary number ranging from 0 to 255, which is often seen on a scan tool display. The HVAC control module monitors the feedback signal to determine the actual location of the door and to determine if the door is stuck. If the motor position falls outside of the expected range, there can be two things that can occur, depending on the vehicle:

1. The controller, usually the HVAC control module, will drive the motor until it reaches its desired location. This action can result in a ticking sound being heard as the motor attempts to reach the desired position.
2. The controller will move the motor to a default position and then stop working, making the HVAC controls inoperative.

ACTUATOR CALIBRATION PROCEDURES An HVAC actuator may need to be calibrated after the actuator has been replaced. Check service information for the specified procedure to follow to perform a calibration if needed.

A typical calibration procedure to use when installing a new actuator using a scan tool includes the following steps:

STEP 1 Clear all diagnostic trouble codes (DTCs).

STEP 2 Turn the ignition switch to the off position.

STEP 3 Install the replacement actuator and reconnect all mechanical and electrical connections.

STEP 4 Start the engine and select motor recalibration program on the scan tool under the functions menu.

STEP 5 Verify that no diagnostic trouble codes have been set.

CAUTION: Do not operate an actuator prior to installation to "test it" because many actuators operate until they are stopped mechanically by the door being fully open or fully closed. If operated using a battery and jumper wires without being installed, the actuator can be moved beyond its normal range of motion and will not operate correctly, if at all, when placed into the HVAC housing.

BLOWER MOTOR

PURPOSE AND FUNCTION The same blower motor moves air inside the vehicle for:

1. Air conditioning
2. Heat
3. Defrosting
4. Defogging
5. Venting of the passenger compartment

The motor turns a squirrel cage-type fan. A squirrel cage-type fan is able to move air without creating a lot of noise. The fan switch controls the path in which the current flows to the blower motor.

PARTS AND OPERATION The motor is usually a permanent magnet, one-speed motor that operates at its maximum speed with full battery voltage. The switch gets current from the fuse panel with the ignition switch on, and then directs full battery voltage to the blower motor for high speed and to the blower motor through resistors for lower speeds.

VARIABLE SPEED CONTROL The fan switch controls the path of current through a resistor pack to obtain different fan speeds of the blower motor. The electrical path can be:

- Full battery voltage for high-speed operation
- Through one or more resistors to reduce the voltage and the current to the blower motor which then rotates at a slower speed

The resistors are located near the blower motor and mounted in the duct where the airflow from the blower can cool the resistors. The current flow through the resistor is controlled by the switch and often uses a relay to carry the heavy current (10 to 12 amperes) needed to power the fan. Normal operation includes the following:

- Low speed. Current flows through three resistors in series to drop the voltage to about 4 volts and 4 amperes.
- Medium-low speed. Current is directed through two resistors in series to lower the voltage to about 6 volts and 6 amperes.
- Medium-high speed. Current is directed through one resistor resulting in a voltage of about 9 volts and 9 amperes.
- High speed. Full battery voltage, usually through a relay, is applied to the blower motor resulting in a current of about 12 amperes.

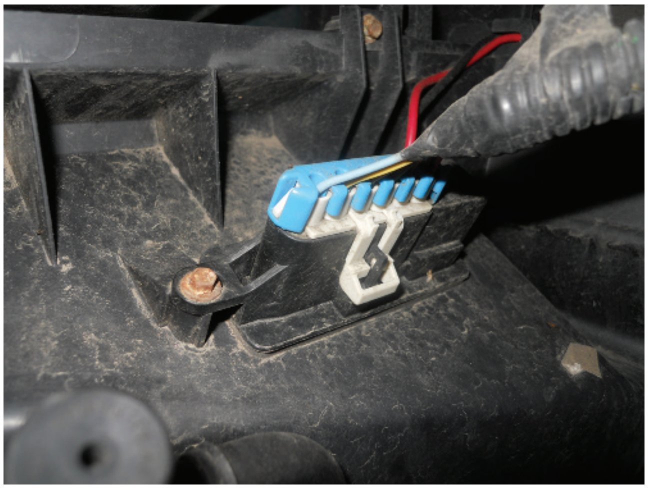
● **SEE FIGURE 62–19**.

Some blower motors are electronically controlled by the body control module and include electronic circuits to achieve variable speeds. ● **SEE FIGURE 62–20**.

BLOWER MOTOR DIAGNOSIS If the blower motor does not operate at any speed, the problem could be any of the following:

1. Defective ground wire or ground wire connection
2. Defective blower motor (not repairable; must be replaced)
3. Open circuit in the power-side circuit, including fuse, wiring, or fan switch

If the blower works on lower speeds but not on high speed, the problem is usually an in-line fuse or high-speed relay that controls the heavy current flow for high-speed operation. The high-speed fuse or relay usually fails as a result of internal blower motor bushing wear, which causes excessive resistance to motor rotation. At slow blower speeds, the resistance is not as noticeable and the blower operates normally. The blower motor is a sealed unit, and if defective, must be replaced as a unit. The squirrel cage fan usually needs to be removed from the old motor and attached to the replacement motor. If the blower motor operates normally at high speed but not at any of the lower speeds, the problem could be melted wire resistors or a defective switch. The blower motor can be tested using a clamp-on DC ammeter. ● **SEE FIGURE 62–21**.



FIGURES 62–19 A blower motor resistor pack used to control blower motor speed. The blower motor resistors are installed in the blower housing and the the wiring is the only part that is visible.

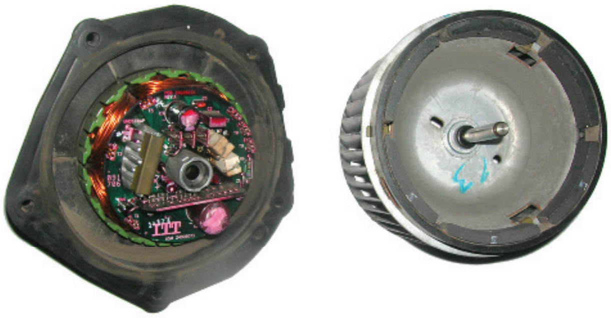


FIGURE 62–20 A brushless DC motor that uses the body computer to control the speed.

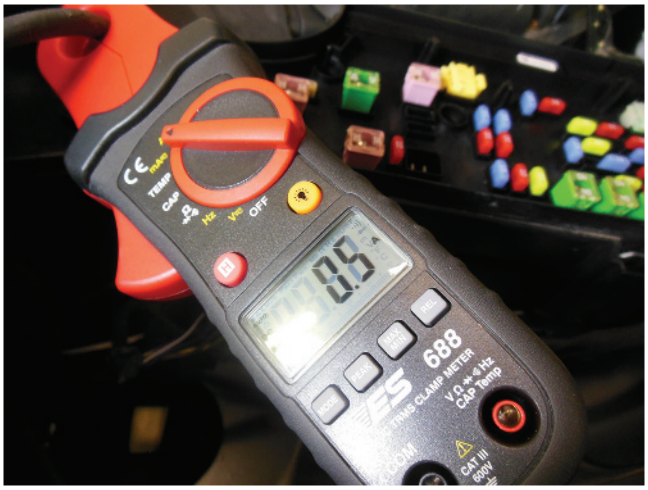

FIGURE 62–21 Using a mini AC/DC clamp-on multimeter to measure the current drawn by a blower motor.

Most blower motors do not draw more than 15 amperes on high speed. A worn or defective motor usually draws more current than normal and could damage the blower motor resistors or blow a fuse if not replaced.

REVIEW QUESTIONS

1. What do the three main HVAC doors do?
2. In the heating mode, why is heat directed toward the floor?
3. Where is the air directed when the control panel is set to defog/defrost position?
4. How does a "reheat" system work?
5. Where does the air enter the vehicle when outside air is selected?

CHAPTER QUIZ

1. "Outside air" is also called ___________ air.
   - **a.** recirculation
   - **b.** fresh
   - **c.** plenum
   - **d.** mode
2. The ___________ door is used to select air discharge location such as floor, vent, or defrost.
   - **a.** mode
   - **b.** recirculation
   - **c.** fresh air
   - **d.** Any of the above
3. What does the snowflake button on the dash do?
   - **a.** Selects defrost
   - **b.** Selects defog
   - **c.** Turns on the A/C compressor
   - **d.** Selects fresh outside air
4. The ram air that enters the vehicle from the outside enters the HVAC system from ___________.
   - **a.** beside the headlight
   - **b.** behind the grille
   - **c.** the side vents
   - **d.** the base of the windshield
5. Most systems use a flap door that swings about ___________ degrees.
   - **a.** 10 to 25
   - **b.** 25 to 40
   - **c.** 45 to 90
   - **d.** 90 to 120
6. The air inlet control door is also called ___________.
   - **a.** fresh air door
   - **b.** recirculation door
   - **c.** outside air door
   - **d.** Any of the above
7. The door used to control interior temperature is called the ___________ door.
   - **a.** temperature-blend
   - **b.** recirculation
   - **c.** outside (fresh) air
   - **d.** mode
8. A five-wire actuator uses two wires to power the motor (power and ground) and three wires for ___________.
   - **a.** direction control
   - **b.** a feedback potentiometer
   - **c.** static electricity protection
   - **d.** redundant control
9. What type of blower motor uses the body computer to control the speed?
   - **a.** An AC brush-type motor
   - **b.** Brush-type DC motor
   - **c.** Brush-less DC motor
   - **d.** Any of the above
10. The cabin filter can be accessed ___________.
    - **a.** behind the glove compartment
    - **b.** under the hood toward the front of the vehicle
    - **c.** under the hood near the windshield
    - **d.** Either a or c

AUTOMATIC AIR-CONDITIONING AND HEAT PUMP SYSTEMS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss the purpose and function of automatic temperature control (ATC) systems.
- Discuss the sensors used in ATC systems.
- Describe airflow control.
- Describe actuators.
- Discuss the purpose of automatic HVAC controls.
- Explain the automatic climatic control diagnostic procedure.
- Discuss heat pump systems.

KEY TERMS:

Ambient temperature sensor 747 • Air management system 749 • Automatic air-conditioning system 746 • Automatic climatic control system 746 • Automatic temperature control (ATC) system 746 • Compressor speed sensor 748 • Discharge air temperature (DAT) sensor 747 • Dual-position actuator 750 • Engine coolant temperature (ECT) sensor 748 • Evaporator temperature (EVT) sensor 747 • Heating ventilation and air conditioning (HVAC) 746 • Infrared (IR) sensors 748 • In-vehicle temperature sensor 747 • Negative temperature coefficient (NTC) 747 • Outside air temperature (OAT) sensor 747 • Pressure transducer 748 • Relative humidity (RH) sensor 749 • Smart motor 751 • Smart control head 751 • Sun load sensor 747 • Three-position actuator 750 • Variable-position actuator 750

AUTOMATIC TEMPERATURE CONTROL SYSTEM

PURPOSE AND FUNCTION The purpose and function of the **heating, ventilation, and air-conditioning (HVAC)** system is to provide comfortable temperature and humidity levels inside the passenger compartment. Proper temperature control to enhance passenger comfort during heating should maintain air temperature at the foot level about 7°F to 14°F (−13°C to −10°C) above the temperature around the upper body. This is accomplished by directing the heated airflow to the floor. During A/C operation, the upper body should be cooler, so the airflow is directed to the instrument panel registers. Most new HVAC systems use an electronic control head and some use electronic blower speed control, radiator fan, and control of compressor displacement.

OPERATION **Automatic temperature control (ATC) system** is also called **automatic climate control system** or **automatic air-conditioning system**. With an ATC system, the driver can turn the automatic controls on or off and select the desired temperature. The ATC will adjust the following parameters:

- Blower speed
- Temperature door
- Air inlet door
- Mode door to achieve the proper temperature
- Control the air-conditioning compressor operation. ● **SEE FIGURE 63–1**.

SENSORS

PURPOSE AND FUNCTION The purpose of using sensors is to provide information to the HVAC controller regarding the conditions outside as well as inside the vehicle. Sensors provide data about the following conditions:

- Different conditions that can affect temperature conditions within the vehicle.
- Temperature setting at the control head.
- Operation of the A/C system.
- Operation of the engine.

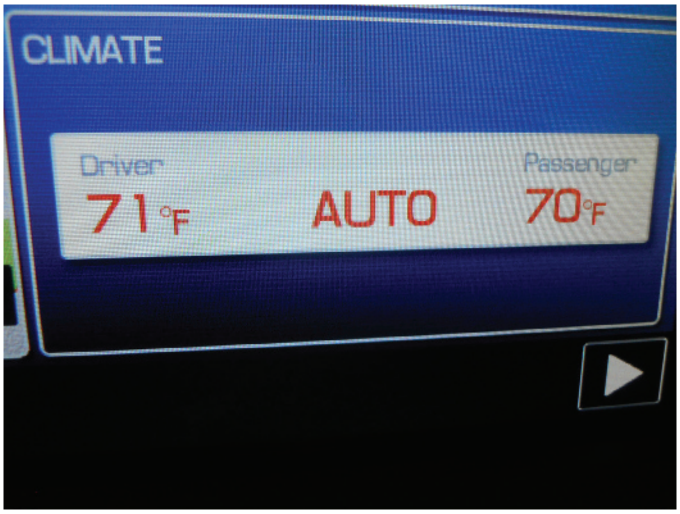

FIGURE 63–1 The automatic climate control display is part of the navigation screen on this vehicle.

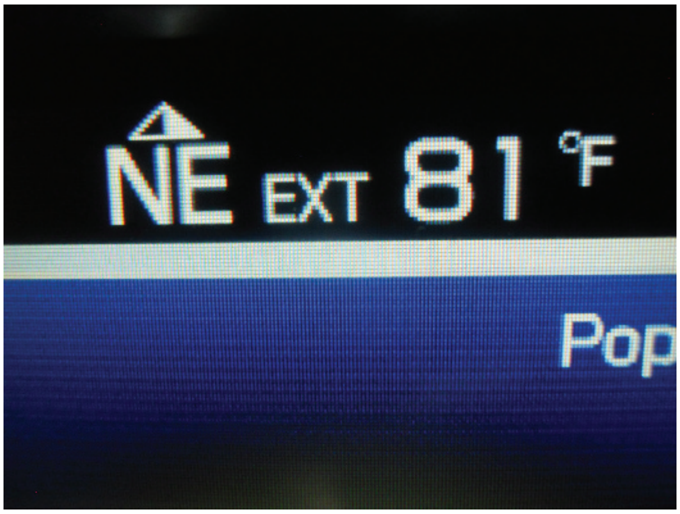

FIGURE 63–3 The outside air temperature is displayed on the navigation screen on this vehicle and uses the information from the outside air temperature sensor.

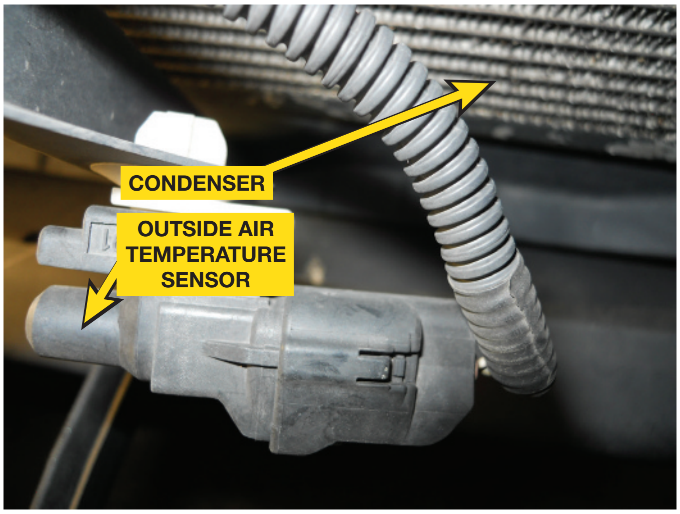

FIGURE 63–2 The outside air temperature sensor is mounted on the radiator core support in front of the A/C condenser on this vehicle.

Pressure and temperature sensors are used to determine the condition in the air-conditioning system so that the controller can do the following functions:

- Provide the most efficient use of energy.
- Provide a comfortable interior environment for the driver and passengers.
- Reduce the load on the engine and electrical system as much as possible to improve fuel economy.

OUTSIDE AIR TEMPERATURE SENSOR The **outside air temperature (OAT) sensor**, also called the **ambient temperature sensor**, measures outside air temperature and is often mounted at the radiator shroud or in the area behind the front grill. ● **SEE FIGURE 63–2**.

- Most automotive thermistors are of the **negative temperature coefficient (NTC)** type; the resistance changes in an inverse or negative relationship with temperature.
- The resistance is low when the temperature is high.
- This sensor is used to determine the outside air temperature that is displayed on the dash. ● **SEE FIGURE 63–3**.

IN-VEHICLE TEMPERATURE SENSOR The **in-vehicle temperature sensor** is often mounted behind the instrument panel, and a set of holes or a small grill allows air to pass by it. Air from the blower motor passes through the venturi of the aspirator and pulls in-vehicle air past the thermistor. This tube is called an aspirator tube and is connected to the blower housing. Blower operation produces airflow through the aspirator and past the sensor. ● **SEE FIGURE 63–4**.

DISCHARGE AIR TEMPERATURE SENSOR The **discharge air temperature (DAT)** sensor is used to measure the temperature of the air leaving the dash vents.

- This discharge air temperature can be used to determine the proper temperature position or control compressor output.
- This sensor reading is used by the controller, which compares the discharge temperature reading with the temperature set by the driver. The control module calculates the temperature difference and automatically adjusts the HVAC system to minimize this temperature difference.

EVAPORATOR TEMPERATURE SENSOR The **evaporator temperature (EVT) sensor** is used to measure the temperature of the air leaving the evaporator. Evaporator air temperature can be used to determine the proper temperature position or control compressor output. The long probe of this sensor passes between the evaporator fins. It provides an evaporator temperature input to the HVAC controller.

SUN LOAD SENSOR The **sun load sensor** (also called a *solar sensor*) is normally mounted on top of the instrument panel and is used to measure radiant heat load that might cause an increase of the in-vehicle temperature. Bright sunshine provides a signal to the electronic control module (ECM) that things are

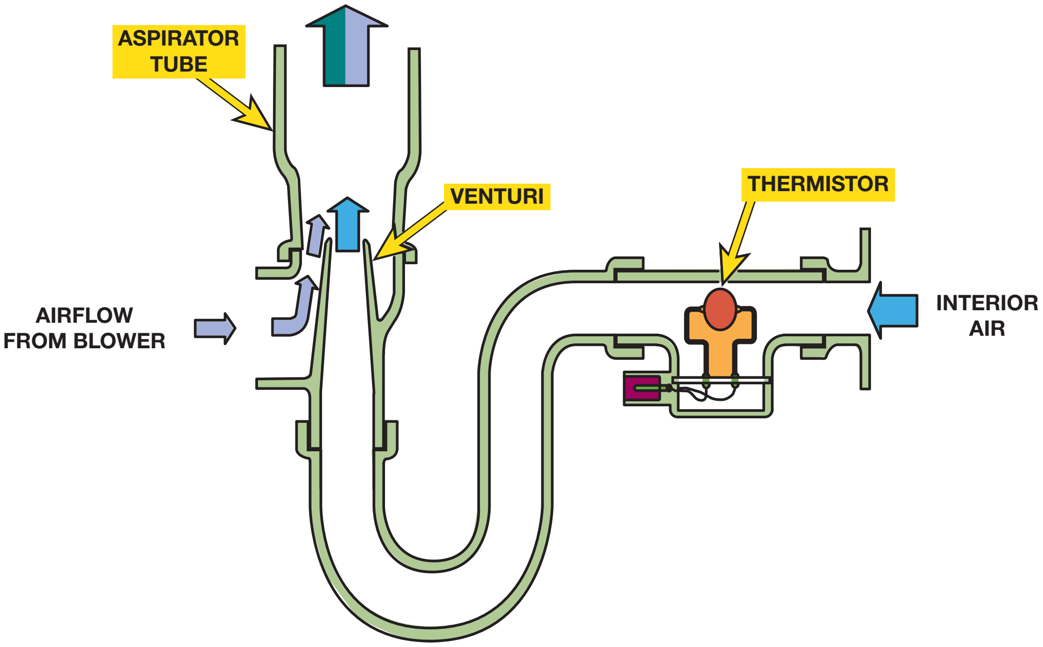

FIGURE 63–4 The airflow from the blower causes airflow to flow past the in-vehicle temperature sensor.

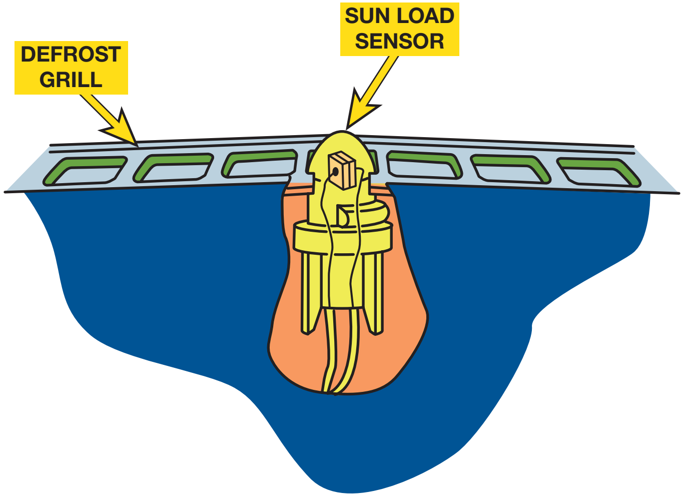

FIGURE 63–5 Sun load sensors are usually located at the top of the instrument panel.

going to get hotter. Sun load sensors are photodiodes that change their electrical conductivity based on the level of sunlight striking the sensor.

A typical sun load sensor uses a 5-volt operating voltage and produces an output signal voltage based on the intensity of the light.

- Dark = 0.3 volts
- Bright sunshine = 3.0 volts. ● **SEE FIGURE 63–5.**

INFRARED SENSORS **Infrared (IR) sensors** are mounted in the control head or overhead in the headliner. They monitor the surface temperature of the head and chest area of the driver and passenger. The system will adjust the temperature and position of the airflow depending on the temperature they measure and the settings on the control head. The detector does not emit an infrared beam but instead measures the infrared rays that are emitted from the person's body.

COMPRESSOR SPEED SENSOR The air-conditioning (A/C) **compressor speed sensor**, also called a *lock* or *belt lock* sensor, is used so the ECM will know if the compressor is running, and by comparing the compressor and engine speed signals, the ECM can determine if the compressor clutch or drive belt is slipping excessively. It prevents a locked-up compressor from destroying the engine drive belt, which, in turn, can cause engine overheating or loss of power steering. If the ECM detects an excessive speed differential for more than a few seconds, it will turn the compressor off. The sensor can be either a magnetic type or a Hall-effect sensor. Check service information for details about the sensor for the vehicle being serviced.

ENGINE COOLANT TEMPERATURE SENSOR The **engine coolant temperature (ECT) sensor** is a thermistor and measures the temperature of the engine coolant and is usually located near the engine thermostat. The ECT sensor is used to keep the system from turning on the heater before the coolant is warmed up, which is often called *cold engine lockout.* ● **SEE FIGURE 63–6.**

PRESSURE TRANSDUCERS A **pressure transducer** can be used in the low- and/or high-pressure refrigerant line. The transducer converts the system pressure into an electrical signal that allows the ECM to monitor pressure. The pressure signal can be used by the controller to

- cycle the compressor to prevent evaporator freeze-up.
- change orifice tube size.
- change the compressor displacement.
- shut off the compressor or speedup cooling fan operation because of high pressures.
- prevent compressor operation if the refrigerant level is low or empty.

The pressures of the refrigerant systems can be checked by looking at the scan tool scan data of a factory or factory-level scan tool. ● **SEE CHART 63–1** for some sample pressures and what they could indicate.

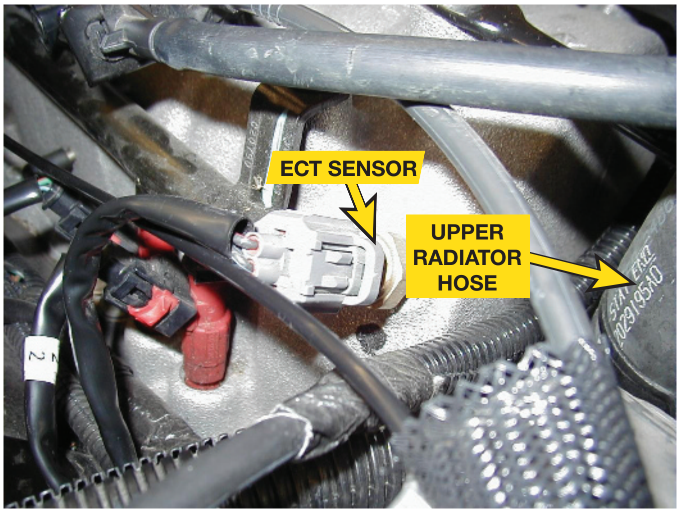

FIGURE 63–6 The engine coolant temperature (ECT) sensor is usually located near the engine thermostat so it can accurately measure the temperature of the coolant.

LOW SIDE PRESSURE	HIGH SIDE PRESSURE	CONDITION
25–35 PSI	170–200 PSI	Normal operation
Low	Low	Low refrigerant charge level
Low	High	Restriction in high-side line
High	High	System is overcharged
High	Low	Restriction in the low-side line

CHART 63–1

Sample refrigerant system pressures and possible causes as shown from the pressure sensors and displayed on a scan tool. Check service information for the exact procedures to follow if the pressures are not correct.

AIR QUALITY SENSORS Some systems use an *air quality sensor*, which detects hydrocarbons (HC) or ozone (O_3). HC can come from vehicle engine exhaust or decaying animal material and often produces offensive odors. Ozone is an irritant to the respiratory system. When the system detects an air quality issue, it automatically switches to using mostly inside air, about 80%, and reduces the amount of outside air entering the system to about 20% from the normal 80% level. This reduces the amount of outside air that is being brought into the passenger compartment until the system detects healthy outside air.

RELATIVE HUMIDITY SENSOR A few vehicles use a **relative humidity (RH) sensor** to determine the level of in-vehicle humidity. High RH increases the cooling load. The sensor responds to the full range from 0% to 100% relative humidity. The output of the sensor is sent to the HVAC controller, which uses the information to control the air inlet door and the air-conditioning compressor operation to achieve the desired level of humidity (20% to 40%) in the passenger compartment.

GPS SENSOR A few vehicles that are equipped with a global positioning system (GPS) for navigation will have a sun position strategy that tracks the angle of the sunlight entering the vehicle. Cooler in-vehicle temperatures are required if the vehicle is positioned so sunlight enters through the windshield or side windows. ● **SEE FIGURE 63–7**.

FIGURE 63–7 Some automatic HVAC system use the information from the factory navigation system to fine tune the interior temperature and airflow needs based on location and the direction of travel.

AIRFLOW CONTROL

NEED FOR AIRFLOW CONTROL The system that controls the airflow to the passenger compartment is called the **air management system** or *air distribution system.* Air flows into the housing (case) that contains the evaporator and heater core from two inlets.

The air management system is the same as a nonautomatic HVAC system. The only difference is that the HVAC controller can adjust the various doors without driver intervention. ● **SEE FIGURE 63–8**.

FREQUENTLY ASKED QUESTION

Why Is an ATC system Slow to Get Airflow?

Some vehicle owners, new to ATC system, complain that it seems to take a long time before the fan starts to move air. There are several reasons that this is done and it is to be considered normal operation: the fan speed is controlled by pulse-width modulating the voltage to the blower motor and it starts slowly, and then ramps up so very little airflow is noticed for the first few seconds.

The control doors are often set to blow first to the floor vents before moving the doors to dash vents. This is done to purge any stale air that may be in the ducts to the floor so that the driver and passengers do not notice the stale air.

As a result, most ATC systems do normally have a delay between the time the engine is started and when airflow is felt. This is perfectly normal operation and no repair or service to the system is needed.

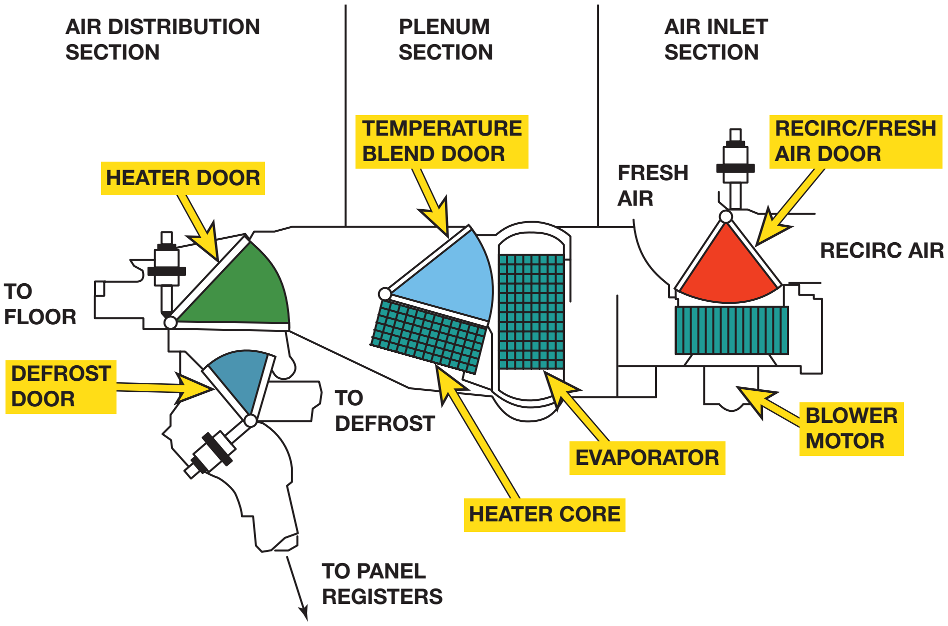

FIGURE 63–8 The three major portions of the A/C and heat system are air inlet, plenum, and air distribution. The shaded portions show the paths of the four control doors.

ACTUATORS

PURPOSE AND FUNCTION HVAC actuators are electric or mechanical devices that move doors to provide the needed airflow at the correct time and location. Actuators include

- Electric motors that operate the air/temperature doors, also called *flaps.*
- Feedback circuits that provide position information to the HVAC controller.

TYPES OF ACTUATORS An actuator is a part that moves the vanes or valves. Actuators used in air-conditioning systems are either electric or vacuum operated and include three different types:

1. **Dual-Position Actuator.** A **dual-position actuator** is able to move either open or closed. An example of this type of actuator is the recirculation door, which can be either open or closed.
2. **Three-Position Actuator.** A **three-position actuator** is able to provide three air door positions, such as the bi-level door, which could allow defrost only, floor only, or a mixture of the two.
3. **Variable-Position Actuator.** A **variable-position actuator** is capable of positioning a valve in any position. All variable position actuators use a *feedback potentiometer*, which is used by the controller to detect the actual position of the door or valve. ● **SEE FIGURE 63–9**.

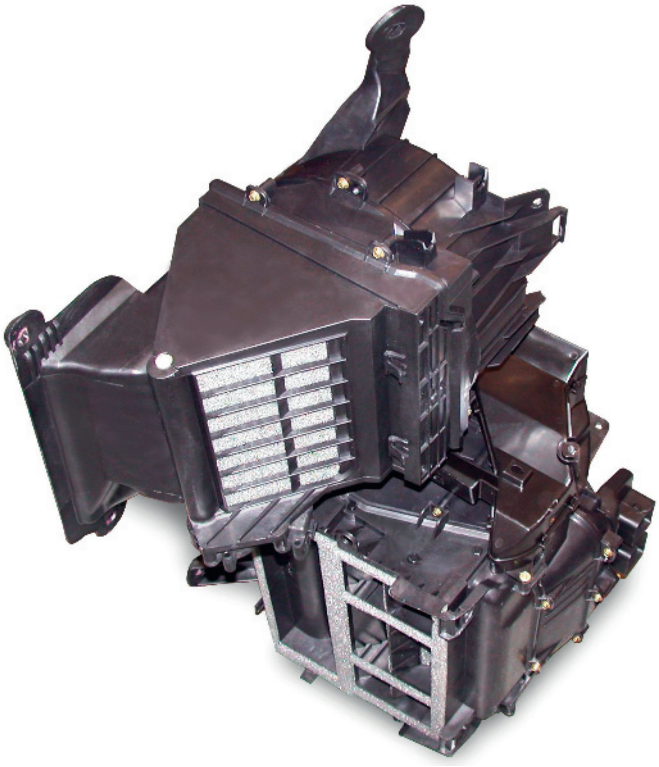

FIGURE 63–9 An entire HVAC module removed from a vehicle.

AUTOMATIC HVAC CONTROLS

OPERATION The HVAC control head or panel is mounted in the instrument cluster. The control head provides the switches and levers needed to control the different aspects of the heating and A/C system, which include the following:

- HVAC system on and off
- A/C on/off
- Outside or recirculated air
- A/C, defrost, or heating mode
- Temperature desired
- Blower speed

COMPRESSOR CONTROLS Most air-conditioning compressors use an electromagnetic clutch. Some systems may connect one or more switches in series with the compressor clutch so that all have to be functioning before the compressor clutch can be engaged. A low- and high-pressure switch or sensor may also be an input to the PCM or HVAC controller for use in controlling the compressor.

- **Low-pressure switch:** This pressure switch is electrically closed only if there is 8 PSI to 24 PSI (55 kPa to 165 kPa) of refrigerant pressure. This amount of pressure means that the system is sufficiently charged to provide lubrication for the compressor.
- **High-pressure switch:** This pressure switch is located in the high-pressure side of the A/C system. If the pressure exceeds a certain level, typically 375 PSI (2,600 kPa), the pressure switch opens, thereby preventing possible damage to the air-conditioning system due to excessively high pressure.
- **A/C relay:** The relay supplies power to the compressor.

CONTROL MODULE The control module used for automatic climatic control systems can be referred by various terms depending on the exact make and model of vehicle. Some commonly used terms include the following:

- ECM (Electronic control module)
- BCM (Body control module)
- HVAC control module (often is built into the smart control head)
- HVAC controller or programmer

The control modules are programmed to open or close circuits to the actuators based on the values of the various sensors. Although it is unable to handle the electric current for devices such as the compressor clutch or blower motor, the control module can operate relays. These relays in turn control the electric devices. Units that use small current flows, such as a light-emitting diode (LED) or digital display, can operate directly from the control module.

An ECM is programmed with various strategies to suit the requirements of the particular vehicle. For example, when A/C is requested by the driver of a vehicle with a relatively small engine, the ECM will probably increase the engine idle RPM. On this same vehicle, the ECM will probably shut off the compressor clutch during wide-open throttle (WOT).

- On other vehicles, the ECM might shut off the compressor clutch at very high speeds to prevent the compressor from spinning too fast.
- In some cases, part of the A/C and heat operating strategy is built into the control head and are called **smart control heads**. In some cases, door operating strategy is built into the door operating motors, and these are called **smart motors**.
- Many control modules are programmed to run a test sequence, called *self-diagnosis*, at start-up (when the ignition key is turned on). If improper electrical values are found, the ECM indicates a failure often by blinking the A/C indicator light at the control head. Some ECMs also monitor the system during operation and indicate a failure or stop the compressor if there is a problem. One system, for example, notes the frequency of clutch cycling that indicates a low refrigerant charge level. If there are too many clutch cycles during a certain time period, the control module will shut off the compressor and set a diagnostic trouble code (DTC). ● **SEE FIGURE 63–10**.

FREQUENTLY ASKED QUESTION

Why Is the Blower Speed So High?

This question is often asked by passengers when riding in a vehicle equipped with automatic climate control. The controller does command a high blower speed if:

- The outside temperature is low and the engine coolant temperature is hot enough to provide heat. The high blower speed is used to warm the passenger compartment as quickly as possible. When the temperature has reached the preset level, the blower speed is reduced to maintain the preset temperature.
- The outside temperature is hot and the air-conditioning compressor is working to provide cooling. The high-speed blower is used to circulate air through the evaporator in an attempt to cool the passenger compartment as quickly as possible. Once the temperature reaches close to the preset temperature, the blower speed is reduced to keep the temperature steady.

AUTOMATIC CLIMATIC CONTROL DIAGNOSIS

DIAGNOSTIC PROCEDURE If a fault occurs in the automatic climatic system, check service information for the specified procedure to follow for the vehicle being checked. Most vehicle service information includes the following steps:

STEP 1 Verify the customer concern. Check that the customer is operating the system correctly. For example, most automatic systems cannot detect when the defrosters are needed so most systems have a control that turns on the defroster(s).

STEP 2 Perform a thorough visual inspection of the heating and cooling system for any obvious faults.

STEP 3 Use a factory scan tool or a factory level aftermarket scan tool and check for diagnostic trouble codes (DTCs).

NOTE: Older systems can be accessed using the buttons on the control panel and then the DTCs and system data are displayed. Check service information for the exact procedures to follow for the vehicle being serviced.

STEP 4 If there are stored DTCs, follow service information instructions for diagnosing the system. ● **SEE CHART 63–2** for sample DTCs.

STEP 5 If there are no stored DTCs, check scan tool data for possible fault areas in the system.

SCAN TOOL BIDIRECTIONAL CONTROL Scan tools are the most important tool for any diagnostic work on all vehicles.

FREQUENTLY ASKED QUESTION

What Are the Symptoms of a Broken Blend Door?

Blend doors can fail and cause the following symptoms:

- Clicking noise from the actuator motor assembly as it tries to move a broken door.
- Outlet temperature can change from hot to cold or from cold to hot at any time especially when cornering because the broken door is being forced one way or the other due to the movement of the vehicle.
- A change in the temperature when the fan speed is changed. The air movement can move the broken blend door into another position which can change the vent temperature.

If any of these symptoms are occurring, a replacement blend door is required.

CHART 63–2

Sample automatic climate control diagnostic trouble codes.

Scan tools can be divided into two basic groups:

1. **Factory scan tools.** These are the scan tools required by all dealers that sell and service a specific brand of vehicle.

   All factory scan tools are designed to provide bidirectional capability, which allows the service technician the opportunity to operate components using the scan tool, thereby confirming that the component is able to work when commanded.

ATC components that may be able to be controlled or checked using a scan tool include

- Blower speed control (faster and slower to check operation)
- Command the position of airflow doors to check for proper operation and to check for proper airflow from the vents and ducts
- Values of all sensors
- Pressures of the refrigerant in the high and low sides of the systems

2. **Aftermarket scan tools.** These scan tools are designed to function on more than one brand of vehicle. Examples of aftermarket scan tools include
   - **Snap-on** (various models, including the Ethos, Modis, and Solus).
   - **OTC** (various models, including Pegasus, Genisys, and Task Master). ● **SEE FIGURE 63–11**.
   - **Autel** (various models).

While many aftermarket scan tools can display most if not all of the parameters of the factory scan tool, there can be a difference when trying to troubleshoot some faults.

SCAN TOOL DATA Scan data related to the automatic climatic control system can be confusing. Typical data and their meaning are shown in ● **CHART 63–3**.

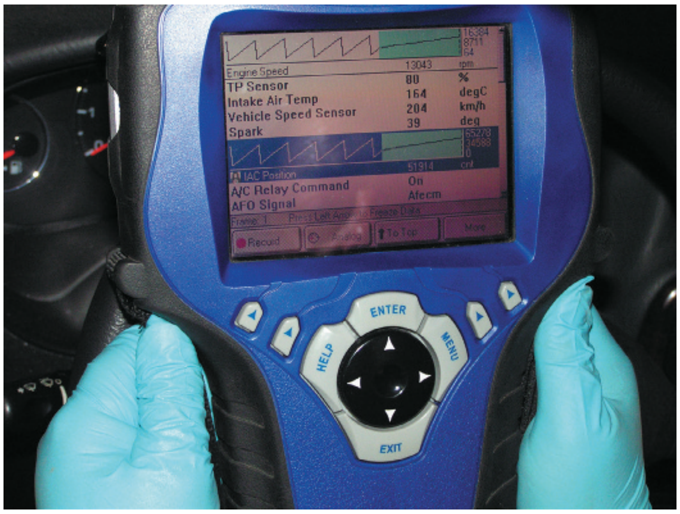

FIGURE 63–11 An OTC Genisys being used to troubleshoot a vehicle. This scan tool can be used on most makes and models of vehicles and is capable of diagnosing other computer systems in the vehicles, such as the automatic temperature control system as well as the antilock braking system (ABS) and airbag systems.

SENSOR	TYPICAL VALUE
Inside air temperature sensor	−40°F to 120°F (−40°C to 49°C)
Ambient air temperature sensor	−40°F to 120°F (−40°C to 49°C)
Engine coolant temperature (ECT) sensor	40°F to 250°F (−40°C to 121°C)
Sun load sensor	0.3 volts (dark) 3.0 volts (bright)
Evaporator temperature (EVT) sensor	Usually 34°F to 44°F (1°C to 7°C)
Relative humidity (RH) sensor	0% to 100%

CHART 63–3

Typical sensors and values that may be displayed on a scan tool. Check service information for the exact specifications for the vehicle being serviced.

HEAT PUMP SYSTEMS

PURPOSE AND FUNCTION Many automakers use a heat pump to maximize the range of an electric vehicle by scavenging waste heat to warm the cabin. A heat pump is more efficient than PTC/electric resistance heating. The 2013 Nissan Leaf was the first mass-produced vehicle in the world to offer a heat pump-based cabin heater, which helped extend driving range during the winter months. Vehicles that use a heat pump include but are not limited to the following:

- BMW i3 EV
- Jaguar I-Pace
- Audi E-tron
- Toyota Prius Prime
- Volkswagen e-Golf
- Kia Niro EV
- Tesla Model Y

NOTE: Most Tesla models don't use a heat pump as part of the climate control system but do use waste heat from the motor and power electronics to help warm the battery. Heat pumps can capture energy by recycling waste heat not only from power electrics (PE) modules, such as drive motors, on-board chargers, and inverters, but also from the battery pack. ● **SEE FIGURE 63–12.**

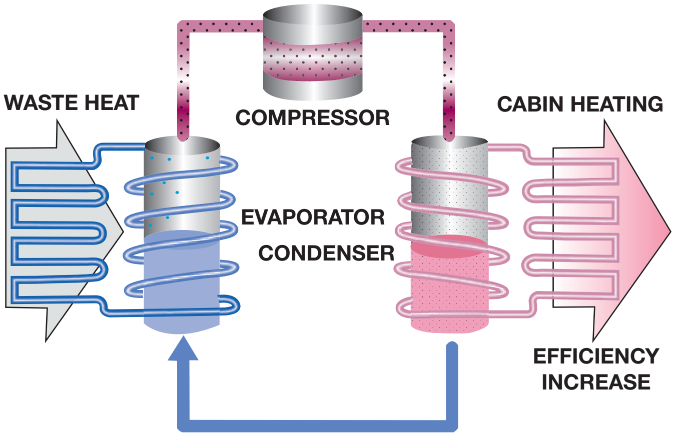

FIGURE 63–12 A heat pump is basically a reversible air-conditioning system that can provide both cabin heating and cabin cooling.

PARTS AND OPERATION A heat pump system is similar to an air-conditioning system where the operation can be reversed to provide both cabin heating and cabin cooling. A heat pump uses one refrigerant circuit that is used for both cooling and heating. ● **SEE FIGURE 63–13.**

- **Heating.** A heat pump system heats the cabin using the temperature difference between a refrigerant and the outside air making it possible to heat the vehicle cabin with less power than heating the air. When the heater is in use, the external condenser absorbs heat from the atmosphere and the compressor is used to compress it into a high-temperature gas. The cabin is heated as the hot air flows into the cabin out of the heating ducts. Heat pumps do not create heat, but instead they move heat. Heat can be moved using less electricity than it takes to heat the air in the cabin using resistive elements.
- **Cooling.** In the summer, heat is absorbed from inside the cabin and released outside by the external condenser, similar to that conventional air-conditioning works. ● **SEE FIGURE 63–14.**

NOTE: Tesla has a feature referred to as "camp mode" where the climate control system can be kept on with the doors locked. Basically, this mode would be used if sleeping in the vehicle.

FREQUENTLY ASKED QUESTION

What Is “Dog Mode”?

Dog mode (also called pet mode) is a climate control feature in Tesla and some other electric vehicles that leaves the air conditioning or heater on when owners leave their pets in their vehicle. It is accessed through the climate-control settings by selecting “Dog” under the “Keep Climate On” settings. Then, a message is displayed that reads: “My owner will be back soon. Don’t worry! The heater or A/C is on and it’s 72 degrees.” If the owner is gone for long periods of time and the battery goes below 20%, a push notification goes to the owner’s phone to prompt them to get back to their pet. ● **SEE FIGURE 63–15.**

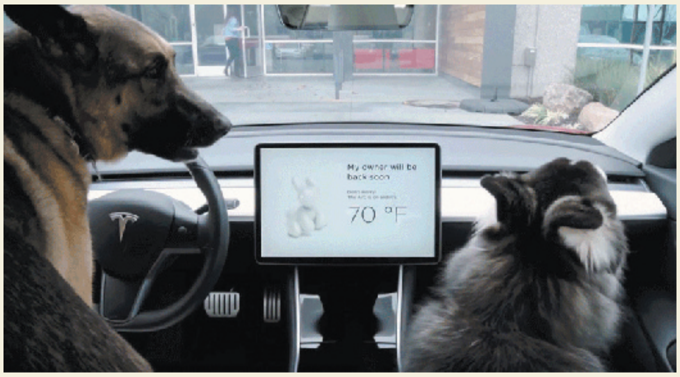

FIGURE 63–15 A message appears on the large center display when the vehicle is placed in dog mode to notify anyone near that the pets are safe being locked in the vehicle.

REVIEW QUESTIONS

1. What sensors are used in a typical automatic temperature control (ATC) system?
2. What is the difference between air conditioning and a heat pump system?
3. Why is a feedback potentiometer used on an electric actuator?
4. What is the purpose of the aspirator tube in the in-vehicle temperature sensor section?
5. What is the difference between an aftermarket scan tool and a factory scan tool?

CHAPTER QUIZ

1. What is the purpose of a compressor speed sensor?
   - **a.** To allow the ECM to control compressor speed
   - **b.** So the ECM can control high-side pressure
   - **c.** So the ECM can control low-side pressure
   - **d.** To let the ECM know if the compressor is turning
2. Which sensor is also called the ambient air temperature sensor?
   - **a.** Outside air temperature (OAT)
   - **b.** In-vehicle temperature
   - **c.** Discharge air temperature
   - **d.** Evaporator outlet temperature
3. What is the most common type of sun load sensor?
   - **a.** Potentiometer
   - **b.** Negative temperature coefficient (NTC) thermistor
   - **c.** Photodiode
   - **d.** Positive temperature coefficient (PTC) thermistor
4. An actuator can be capable of how many position(s)?
   - **a.** Two
   - **b.** Three
   - **c.** Variable
   - **d.** All of the above
5. The ATC will adjust ____________.
   - **a.** blower motor speed
   - **b.** temperature door
   - **c.** air inlet door
   - **d.** All of the above
6. Which sensor might use an aspirator tube?
   - **a.** In-vehicle temperature
   - **b.** Outside air temperature (OAT)
   - **c.** Discharge air temperature
   - **d.** Evaporator outlet temperature
7. A heat pump system is mostly used to heat and cool what type of vehicle?
   - **a.** Hybrid-electric vehicle (HEV)
   - **b.** Plug-in HEV (PHEV)
   - **c.** Electric vehicle (EV)
   - **d.** All of the above
8. Automatic temperature control (ATC) diagnosis includes ____________.
   - **a.** verifying the customer concern
   - **b.** performing a visual inspection
   - **c.** checking for stored DTCs
   - **d.** All of the above
9. The control module used for automatic climatic control systems is called ____________.
   - **a.** ECM
   - **b.** BCM
   - **c.** HVAC control module
   - **d.** Any of the above depending on the make and model of vehicle
10. A feedback potentiometer is used to ____________.
    - **a.** provide feedback to the driver as to where the controls are set
    - **b.** provide feedback to the controller as to the location of a door or valve
    - **c.** give temperature information about the outside air temperature to the dash display
    - **d.** Any of the above depending on the exact make and model of vehicle

Chapter 64

REFRIGERANTS AND REFRIGERANT OILS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- List the different types of refrigerants and refrigerant containers.
- Explain the impact of legislation related to automotive A/C systems.
- Explain the impact of environmental issues related to automotive A/C systems.
- Discuss HFO-1234yf refrigerant.
- Describe carbon dioxide as a refrigerant.
- Describe alternate refrigerants.
- Explain how to check for non-condensable gases.
- Describe refrigerant safety precautions.
- Discuss the different types and viscosities of refrigerant oils.

KEY TERMS:

Carbon dioxide (CO_2) 762 • Clean Air Act 758 • Global warming 760 • Global warming potential (GWP) 760 • Greenhouse effect 760 • Greenhouse gases (GHGs) 760 • Hygroscopic 765 • Mineral oil 765 • Non-condensable gas (NCG) 762 • Ozone depletion potential (ODP) 760 • PAG (polyalkylene glycol) 765 • POE (polyol ester) 765 • R-744 762 • Section 609 758 • Significant new alternatives policy (SNAP) 762 • Stratosphere 759 • Total Environmental Warming Impact (TEWI) 759

REFRIGERANTS

DEFINITION AND TYPES Refrigerants are colorless and odorless compounds that are human-made gases. The R number of a chemical refrigerant is assigned systematically according to molecular structure.

- **CFC-12**—Chemical name is dichlorodifluoromethane and was the first of the refrigerant used in automotive air-conditioning systems. It was commonly referred to as R-12 or by its DuPont trade name of *Freon*. R-12 was used in automotive air-conditioning systems from the early 1950s until the early 1990s.
- **HFC-134a**—Starting in the early 1990s, most vehicle manufacturers used HFC-134a (R-134a)—a refrigerant that is less harmful to the atmosphere.
- **HFO-1234yf**—Starting in the mid-2010s and required by 2021 this refrigerant used in all recent vehicles. It has a lower impact on climate change (global warming).

REFRIGERANT CONTAINERS Refrigerants are commonly available in several sizes of containers including

- Small cans of 12 oz. to 14 oz. (400 g). Small containers of R-12 can be purchased only by certified technicians. There are no national restrictions on purchase of R-134a.

FREQUENTLY ASKED QUESTION

When Was R-12 First Used in Automotive Air-Conditioning Systems?

General Motors created the refrigerant R-12 and marketed it a by the trade name Freon. Freon was first used in refrigerators manufactured by Frigidaire, a division of GM. Packard was the first vehicle manufacturer to install air conditioning in 1939 in their 120, Super-Eight 160 and Custom Super-Eight cars. In 1940, the Cadillac Division of General Motors introduced air conditioning on its 1941 models, installing it on some 300 cars. It was not until the 1953 model year that vehicle manufacturers including General Motors, Chrysler, and Packard introduced a practical system. The early system used an engine-driven compressor with the condenser located in front of the radiator as is done today. However, because the evaporator and blower motor assembly was so large, these components were placed in the trunk of the car. A clear plastic tube on each side of the package shelf directed cool air to registers located in the headliner on both sides of the interior.

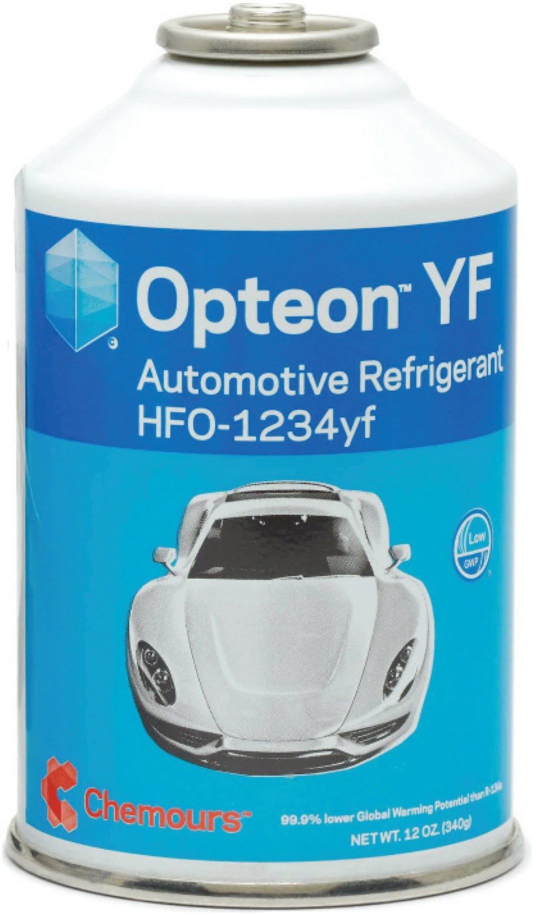

FIGURE 64–1 Because R1234yf is so expensive, many automotive shops purchase this refrigerant in small 12 oz. cans.

- Larger drums or canisters of 15 lb., 20 lb., or 30 lb. (6.8 kg, 9 kg, or 13.6 kg).
- R-1234yf is expensive, and small containers are more affordable for small shops. ● **SEE FIGURE 64–1**.

Refrigerant containers are color coded:

- R-12 containers are white
- R-22 containers are green
- R-134a containers are light blue. ● **SEE FIGURE 64–2**.
- R-1234yf are white with a red stripe

Refrigerant containers are usually disposable. These containers will be evacuated into a recovery unit, marked empty, and properly disposed of when they are emptied. The storage containers for recycled refrigerant must be approved by the DOT and carry the proper marking to show this. ● **SEE FIGURE 64–3**.

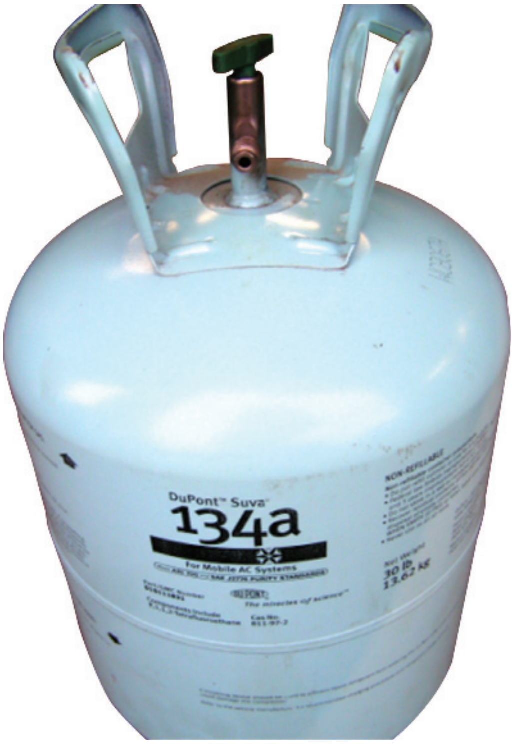

FIGURE 64–2 Large 30 pound containers of R-134a are light blue for easy identification.

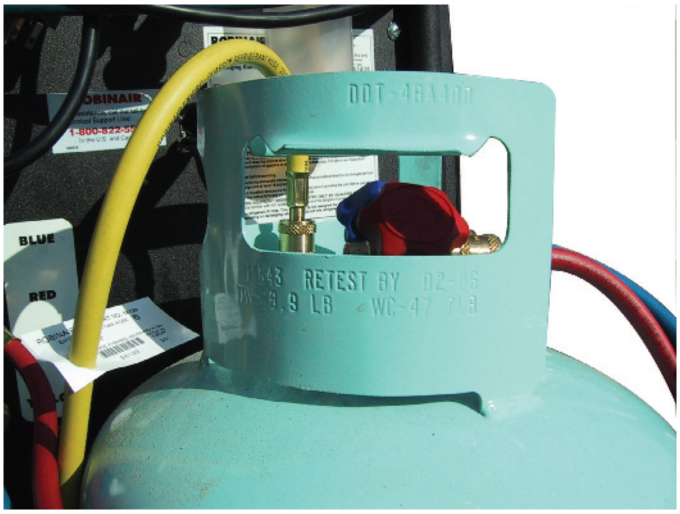

FIGURE 64–3 The stamped text at the top of this container reads "DOT-4BA400."

LEGISLATION

CLEAN AIR ACT At a conference in Montreal, Canada, in 1987, the United States, along with 22 other countries, agreed to limit the production of ozone-depleting chemicals. This agreement is referred to as the Montreal Protocol. In 1990, President Bush (senior) signed the **Clean Air Act**, which phased out the production of CFCs in the United States by the year 2000. R-12 production in the United States ceased at the end of 1995.

SECTION 609 **Section 609** is a portion of the Clean Air Act that places certain requirements on the *mobile vehicle air conditioning (MVAC)* service field. Important portions of this section require the following:

- **Sales Restriction**—Section 609 prohibits the sale of small cans (less than 20 pounds) of CFC-12 to anyone other than an EPA-certified technician.
- **Technician Training and Certification**—Technicians repairing or servicing CFC-12, HFC-134a, and CO_2, HFC-152a, or HFO-1234yf mobile vehicle air-conditioning systems must be trained and certified by an EPA-approved organization. Certification is obtained by passing an EPA-approved examination.
- **Approved Equipment**—Technicians repairing or servicing air-conditioning systems using CFC-12, HFC-134a, HFC-152a, CO_2, or HFO-1234yf must use refrigerant recovery equipment that is approved by EPA.

FREQUENTLY ASKED QUESTION

How Are Refrigerants Named?

The procedure for determining the refrigerant number is rather tedious and is of no value to the refrigerant technician. It is included in this text to reduce some misconceptions and wild stories that have passed through the industry. The system is based on the number of carbons, hydrogen, and fluorine atoms in the refrigerant molecule. Other suffix letters are added for different variations of the molecule. It is a four-character system with the letter "a" added to indicate a nonsymmetrical or asymmetrical molecule. The most common method of numbering system is: C (MINUS 1), H (PLUS 1), and F.

R-12 has 1 C $(1 - 1 = 0)$, O H $(0 + 1 = 1)$, and 2 F (2), to get 012, or 12.

- The R-12 molecule is symmetrical, which means that both sides are the same.
- The R-134a molecule is asymmetrical (the reason for the "a" in the name), which means that the left and right sides are different. The chemical name for CFC-12, dichlorodifluoromethane, indicates that the molecule has two (di) chlorine atoms and two fluorine atoms, and the suffix methane indicates there is one carbon atom. ● **SEE FIGURE 64–4**.

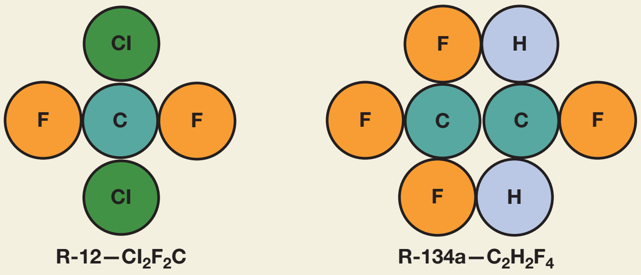

FIGURE 64–4 R-12 is a combination of one carbon, two chlorine, and two fluorine atoms. R-134a is a combination of two carbon and four fluorine atoms.

- **Recordkeeping Requirements**—MVAC service shops must maintain records of the names and addresses of facilities to which the refrigerant they recover is sent. Service shops are also required to maintain records (on-site) showing that all service technicians are properly certified and must certify to EPA that they own approved equipment.
- **Effective January 29, 1998**—Equipment used to recover or recycle R-134a must meet SAE standards. MVAC service technicians must be certified to handle non-ozone-depleting refrigerants (including R-134a).

KYOTO PROTOCOL There is still a major concern about the global warming effect from escaping refrigerants.

Representatives from many nations met in Kyoto, Japan, in 1997 and established the Kyoto Protocol to address these concerns. The **Total Environmental Warming Impact (TEWI)** index was developed, which rates the impact of various refrigerants along with the energy required to perform the cooling operation. In the future, it is hoped that each nation will reduce its negative impact on the environment to zero in order to reduce global change to zero. All factors concerning energy use and emissions will be considered. The United States has not signed the Kyoto Protocol.

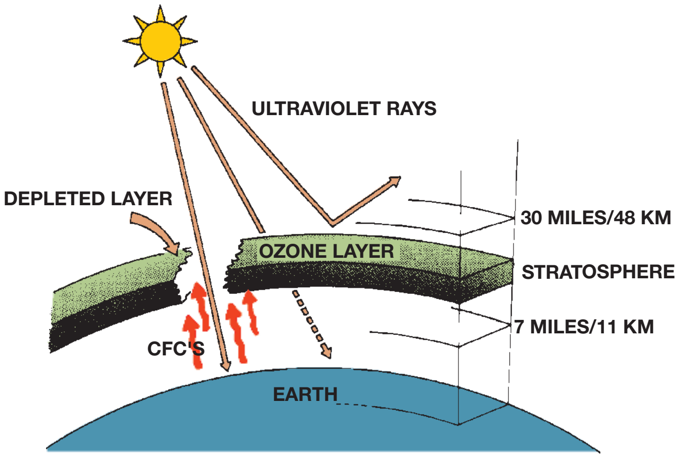

FIGURE 64–5 Depletion of the ozone layer allows more ultraviolet radiation from the sun to reach Earth's surface.

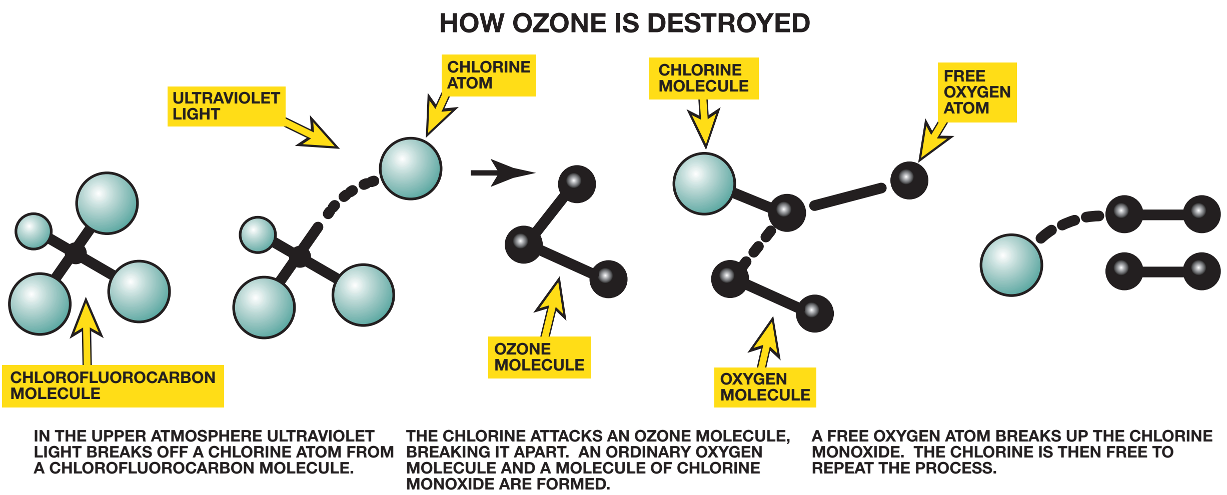
ENVIRONMENTAL ISSUES

OZONE LAYER Planet Earth is unique in many ways. It has an atmosphere that contains a percentage of oxygen high enough to allow mammals, including humans, to live in it. This atmosphere extends outward from Earth for about 31 miles (50 km). The upper layer of the atmosphere is called the **stratosphere**, and it begins about 7 miles to 10 miles (11 km to 16 km) up and extends to the outer limits. A layer of ozone (O_3) extends around the Earth in the stratosphere. ● **SEE FIGURE 64–5**.

The ozone layer is important to us because it blocks the ultraviolet wavelengths of light generated by the sun. Ultraviolet rays can be very harmful to our way of life. In humans, an excess of these rays can cause an increase in skin cancer and cataract of the eyes, as well as damage to our immune system. These same problems can affect many animals. Ultraviolet rays can also damage plants and vegetables. This damage probably also extends to plankton and larvae in the sea, the base of the food chain for sea animals. In the late 1900s, it was determined that the ozone layer is getting much thinner, and large holes are being created in it (mostly near the South Pole). The ozone layer is not providing the same protection from ultraviolet (UV) rays as it once did. It has been determined that

1. The breakup or depletion of the ozone layer is caused by human-made chemical pollution.
2. One of the major ozone-depleting chemicals is chlorine.
3. One of the major sources of chlorine in the atmosphere is R-12.

OZONE DEPLETION A chlorine atom from a *chlorinated fluorocarbon (CFC)* such as R-12 can travel into the stratosphere if it escapes or is released. There, under the effects of ice clouds and sunlight, it can combine with one of the oxygen atoms of an ozone molecule to form chlorine monoxide and an ordinary oxygen molecule, O_2. This destroys that ozone molecule. The chlorine can then break away and attack other ozone molecules.



HOW OZONE IS DESTROYED
ULTRAVIOLET LIGHT
CHLORINE ATOM
CHLORINE MOLECULE
FREE OXYGEN ATOM
CHLOROFLUOROCARBON MOLECULE
OZONE MOLECULE
OXYGEN MOLECULE
IN THE UPPER ATMOSPHERE ULTRAVIOLET LIGHT BREAKS OFF A CHLORINE ATOM FROM A CHLOROFLUOROCARBON MOLECULE.
THE CHLORINE ATTACKS AN OZONE MOLECULE, BREAKING IT APART. AN ORDINARY OXYGEN MOLECULE AND A MOLECULE OF CHLORINE MONOXIDE ARE FORMED.
A FREE OXYGEN ATOM BREAKS UP THE CHLORINE MONOXIDE. THE CHLORINE IS THEN FREE TO REPEAT THE PROCESS.

FIGURE 64–6 Chlorofluorocarbon molecules break apart in the atmosphere.

It is believed that 1 chlorine atom can destroy 10,000 to 100,000 ozone molecules. ● **SEE FIGURE 64–6**.

- CFCs do the most damage and have an **ozone depletion potential (ODP)** of 1.
- Hydrochlorofluorocarbon (HCFC), such as R-22, have an ODP around 0.01–0.1, so they have a lesser effect on the ozone layer.
- Since HFCs, such as R-134a, contain no chlorine and have an ODP of 0 (zero), they have no detrimental effect on the ozone layer.

GLOBAL WARMING AND GREENHOUSE GASES Another area of concern is a layer of gases that is causing a **greenhouse effect**. This gas layer traps heat at the Earth's surface and lower atmosphere, and it is increasing the temperature of our living area. This is called **global warming**. CFC and hydrocarbon (HC) gases such as butane and propane are considered **greenhouse gases (GHGs)**. **Global warming potential (GWP)** compares the ability of different gases to trap heat, and this is based on the heat-absorbing ability of each gas. The lower the GWP number, the lower the global warming potential. ● **SEE CHART 64–1**.

HFO-1234yf

DESCRIPTION HFO-1234yf also called R-1234yf is a hydrofluoroolefin with the formula CH2 = CFCF3 and is the refrigerant required to be used in all vehicles by the 2021 model year (MY). It was approved by US EPA in 2011 under the Significant New Alternative Policy (SNAP) for use in new model of vehicles. Since that date, some vehicle manufacturers are producing vehicles equipped with R-1234yf. Refer to the under-hood label to determine what refrigerant is used in the vehicle. ● **SEE FIGURES 64–7 AND 64–8**.

REFRIGERANT	GLOBAL WARMING POTENTIAL (GWP)	OZONE DEPLETION POTENTIAL (ODP)
CFC-12	10,900	1
HFC-134a	1,430	0.055
HFO-1234yf	4	0
R-744 (CO_2)	1	0

CHART 64–1

R-1234yf has zero ozone depletion potential and very low global warming potential compared to R-134a. R-144 is even lower but not by much.

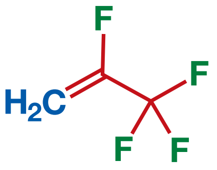


FIGURE 64–7 The chemical symbol for HFO-1234yf.

UNIQUE FITTINGS Each refrigerant is required to have unique fittings to help prevent cross contamination. ● **SEE CHART 64–2**.

MANDATED The United States EPA has banned the use of R-134a after January 1, 2021 and requires all new vehicles sold in the United States to use R-1234yf. R-134a may be used for servicing existing vehicles equipped with R-134a. R-1234yf has operating characteristics similar to R-134a. ● **SEE FIGURE 64–9**.

FLAMMABILITY R-1234yf is mildly flammable. The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) have given it an A2L classification. ● **SEE FIGURE 64–10**.

As a result of the possibility of being ignited, the following precautions need to adhered to when servicing an R-1234yf system:

- Do not smoke or have an open flame while working on or servicing a vehicle equipped with R-1234yf.
- Use tools and service equipment designed specifically for R-1234yf.
- If the evaporator is removed for any other service or replaced, it must be replaced with a new part meeting the SAE standard J2842. Using the robustly designed evaporator is one way that the occupants inside the vehicle are protected against the possibility of having the refrigerant escape into the passenger compartment in the event of a collision.

DuPont™ Opteon™ YF
refrigerant (HFO-1234yf)
For Mobile AC Systems
COMPONENTS INCLUDE 2,3,3,3-Tetrafluoropropene
CAS NO. 754-12-1
Net Weight 10 lbs. (4.54 kg)
Dispos-A-Can® Container
NON-REFILLABLE
NON-REFILLABLE CONTAINER PRECAUTIONS

FIGURE 64–8 Due to the cost of R-1234yf, most shops will purchase 10- or 20-pound containers compared to the normal 30 pound container that most shops purchased for R-134a.

REFRIGERANT	LOW SIDE FITTING	HIGH SIDE FITTING
CFC 12 (R-12)	7/16 × 20 Threads	7/16 × 20 Threads (before 1987) 3/8 × 24 (1987 – 1994)
HFC-134a (R-134a)	Quick Coupler unthreaded 13 mm O.D.	Quick Coupler unthreaded 16 mm O.D.
HFO-12343yf (R-1234yf)	Quick Coupler unthreaded 14 mm O.D.	Quick Coupler unthreaded 17 mm O.D.
R-744 (CO_2)	Quick Coupler unthreaded 16.6 mm O.D.	Quick Coupler unthreaded 18.1 mm O.D.

CHART 64–2

Refrigerant fitting sizes must be unique for each type of refrigerant to help prevent cross contamination.

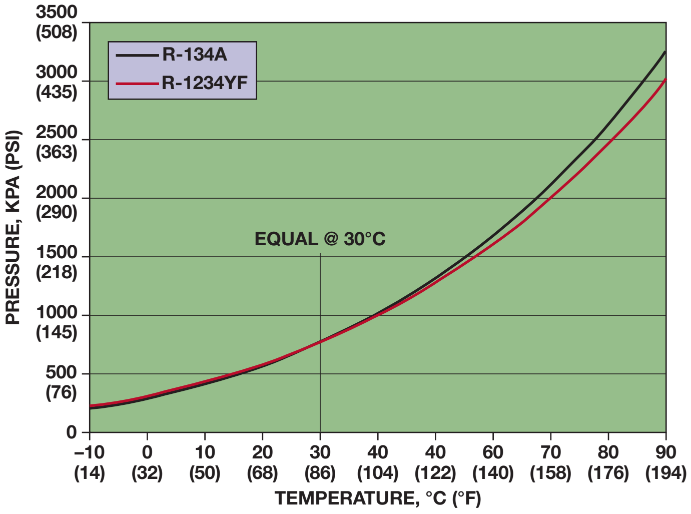

FIGURE 64–9 R-134a and R-1234yf have similar operating pressures.

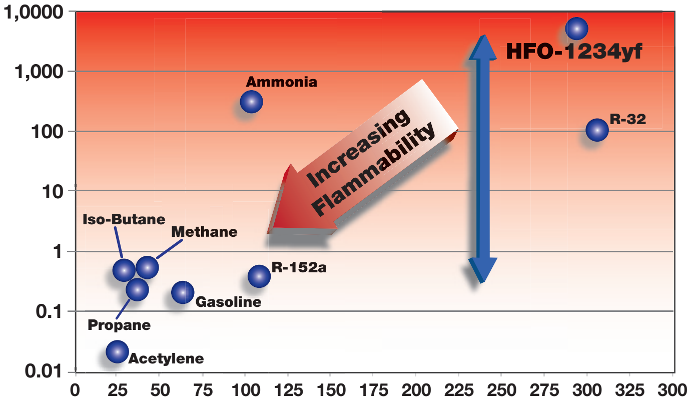

FIGURE 64–10 R-1234yf is just mildly flammable as shown at the top right of the chart.

R-1234yf CONCERNS There is concern about possible cross contamination with either R-134a or an HC:

- As little as 5% of R-134a can increase the pressure in a **recovery** cylinder high enough to cause an "air purge" and this can empty the entire cylinder in the attempt to bleed off air.
- As little as 2% HC with 2% air will increase flammability to greater-than-limits established by the refrigerant manufacturers.

FREQUENTLY ASKED QUESTION

Will R-134a Systems Be Required to Be Retrofitted to R-1234yf?

No. Currently there is no mandate to retrofit existing systems with R-1234yf. If a vehicle came from the factory with R-1234yf, then this refrigerant, of course, will be used when servicing the vehicle and will require a special machine. There is no need or legal requirement to replace it with any other refrigerant at this time.

R1234yf SAFETY PRECAUTIONS Whenever working on a vehicle equipped with R1234yf or servicing the air-conditioning system that uses R1234yf, most experts recommend that the following safety precautions be adhered to:

- Do not smoke or create an open flame in the area where R1234yf may be present.
- Be sure that the area is well ventilated.
- Use the proper torque on all threaded connections and always replace O-rings and seals with a new part and do not reuse the old seals.
- If an evaporator is removed, even if for access to another component, it must be replaced with a new part designed specifically for R1234yf and meets SAE standard J2842.

CARBON DIOXIDE AS A REFRIGERANT

DEFINITION **Carbon dioxide (CO_2)** is a colorless and odorless gas which is a naturally occurring chemical compound. Carbon dioxide is in the atmosphere as a trace gas at a concentration of about 0.04 percent or 400 parts per million (ppm) by volume. Humans breathe in oxygen and breathe out CO_2. As part of the life cycle, plants, algae, and cyanobacteria use light energy to photosynthesize carbohydrate from carbon dioxide and water, with oxygen produced as a waste product.

CO_2 AS A REFRIGERANT A carbon dioxide (CO_2), referred to as **R-744** system, is similar to the present-day systems, but operates at extremely high pressure, 7 to 10 times that of an R-134a system. This pressure puts a large added load on the compressor, heat exchanger, and refrigerant lines. The extremely high pressure requires more power from the engine to operate the compressor and this extra energy causes reduced fuel economy. At this time, a CO_2 system is up to 40% less efficient than an R-134a system and can cost about 30% more to produce. ● **SEE FIGURE 64–11**.

ALTERNATE REFRIGERANTS

SNAP PROGRAM Section 612 of the 1990 Clean Air Act established the **Significant New Alternatives Policy (SNAP)** program to determine acceptable replacements for Class I and Class II chemicals. Class I chemicals include CFCs, and Class II chemicals are HCFCs. SNAP is administered by the EPA and identifies refrigerants that are acceptable from their ozone depleting potential, global warming potential, flammability, and toxicity characteristics. Alternate refrigerants are not tested on their refrigeration quality, but only on their human health and environmental risks.

R-134a is the only alternate product for an R-12 system that has addressed the SAE retrofit documents (SAE J1657, SAE J1658, SAE J1659, and SAE J1662). These standards are designed to ensure long-term, trouble-free operation of the A/C system. An alternate refrigerant can only be used under the following conditions:

- Each refrigerant must have its own unique set of fittings, and all ports not converted must be permanently disabled.
- Each refrigerant must have a label with a unique color that specifies pertinent information.
- All original refrigerants must be removed before charging with the new refrigerant.
- With blends that contain HCFC-22, hoses must be replaced with less permeable barrier hoses.
- With systems that include a high-pressure release device, a high-pressure shutoff switch must be installed.
- Blends containing HCFC-22 will be phased out in the near future.

COUNTERFEIT AND BOOTLEG REFRIGERANTS With the high cost and limited availability of R-12, a refrigerant buyer has to be careful about where it is purchased from. Refrigerant is being illegally imported, and some of it is contaminated. There are stories of counterfeit refrigerant being sold in containers marked the same as those of a reputable, domestic manufacturer. Other stories tell of containers that contain nothing but water with air pressure. Refrigerant should be purchased only from a known source that handles reputable products.

NON-CONDENSABLE GAS

DEFINITION Any gas that does not condense (change from vapor to liquid) under the normal compression refrigeration conditions is called a **non-condensable gas (NCG)**. Any refrigerant that contains NCG, usually air, is considered contaminated.

CHECKING FOR NCG If there is non-condensable gas in a container of refrigerant, the pressure will be higher than

FREQUENTLY ASKED QUESTION

What Is a Secondary Loop System?

Systems that use potentially hazardous refrigerants will probably use a secondary loop. The CO_2 or HC portion of the system will be entirely under the hood. A heat exchanger will provide a very cold fluid to connect with a liquid-to-air heat exchanger that will replace the evaporator. These systems might also use refrigerant-leak-sensing devices and a method of venting/dumping the refrigerant into one of the fender wells to prevent a buildup of refrigerant in the passenger area. ● **SEE FIGURE 64–12**.

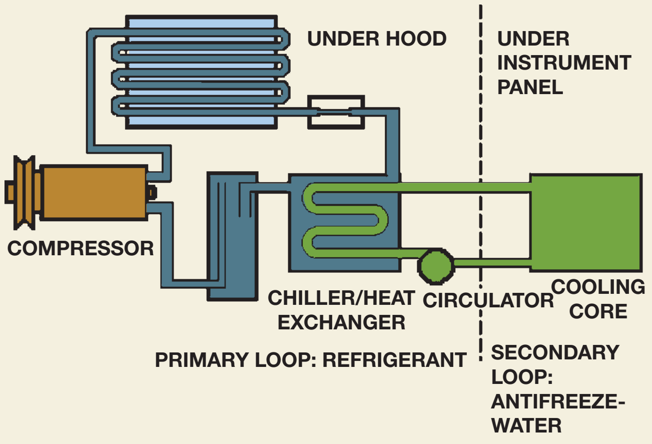

FIGURE 64–12 A secondary loop A/C system keeps the potentially dangerous or flammable refrigerant out of the passenger compartment by using a chiller/heat exchanger to cool an antifreeze and water mixture. This fluid then transfers heat from the cooling core in the air distribution section to the chiller.

normal according to a pressure/temperature chart. To check for non-condensable gas, perform the following steps:

STEP 1 Place the container of refrigerant at a location out of direct sunlight and at a temperature above 65°F (18 °C) for at least 12 hours.

STEP 2 Attach a pressure gauge to the refrigerant container and read the pressure.

STEP 3 Using an accurate infrared thermometer, measure the temperature of the container within 4 inches (10 cm) of the container. Compare the pressure of the refrigerant with the chart. ● **SEE CHART 64–3**.

REFRIGERANT SAFETY

POTENTIAL HAZARDS Refrigerants should be handled only by trained and certified technicians because of potential safety hazards:

- Physiological reaction (get physically sick)
- Asphyxiation (this means that the refrigerant does not contain oxygen, so it cannot sustain life if breathed)

TEMPERATURE F° (C°)	PRESSURE PSI (kPa)	TEMPERATURE F° (C°)	PRESSURE PSI (kPa)

87 (30.6)	103 (710)	110 (43.3)	151 (1041)

CHART 64–3

If the pressure is at or below the listed values, the refrigerant is acceptable and does not contain any non-condensable gas (air). If the pressure of the refrigerant is higher than the chart indicates, the vapor should be slowly vented from the top of the container into the recovery/recycling machine until the pressure drops to the limit in the chart.

- Frostbite and blindness
- Poisoning
- Combustion
- Explosion of storage containers

PRECAUTIONS Precautions when working with refrigerants include

- Wear safety goggles or a clear face shield and protective clothing (gloves) when working with refrigerants. If refrigerant splashes into your eyes, blindness can occur. If refrigerant splashes into your eyes or onto your skin, do not rub that body part but instead flush it with cool, clean water to restore the temperature. Place sterile gauze over the eye to keep it clean and get professional medical attention immediately.
- Always be in a well-ventilated shop area when working with refrigerants and avoid small, enclosed areas. Refrigerants do not contain oxygen and are heavier than air. If they are released into a confined area, they fill the lower space, forcing air and its oxygen upward. Any humans or animals that breathe refrigerants can be asphyxiated, and lack of oxygen can cause loss of consciousness or death. In case of accidental release of refrigerant into the atmosphere, move immediately to an area with adequate ventilation.
- If liquid refrigerant is splashed onto the skin or into the eyes of a human or animal, it immediately boils and absorbs heat from the body part it is in direct contact with. The temperature of the area is reduced to the low boiling point of the refrigerant, which is cold enough to freeze that body part.
- If a CFC such as R-12 or R-22 comes into contact with a flame or heated metal, a poisonous gas similar to phosgene is formed. This can occur while using a flame-type leak detector, if refrigerant is drawn into a running engine, or even if it is drawn through burning tobacco. An indication that a poisonous gas is forming is a bitter taste.
- Several flammable refrigerants have been marketed, and even though they have been banned and are illegal, they still show up. A mixture of more than 2% hydrocarbon (butane, isobutane, or propane) is considered flammable and about 4 oz. in a vehicle interior can become an explosive mixture. R-134a can become combustible at higher pressures if mixed with air. Air should not be used to flush an R-134a system because of the remote chance of a fire or explosion.
- When refrigerant containers are filled, room is left for expansion and the container is marked with its critical temperature, the maximum that it will be subjected to. Refrigerant containers are designed to contain the refrigerant under pressures encountered in normal working and storage conditions. Container pressure is about the same as the vapor pressure for that refrigerant up to a certain temperature point, which is where the liquid has expanded to fill the entire container. Beyond this point, any further expansion of the liquid generates very high hydraulic pressures that will rupture the container. The chance of container rupture is generally low unless the container is overfilled or overheated. ● **SEE FIGURE 64–14**.

FREQUENTLY ASKED QUESTION

What Is an HC Refrigerant?

A hydrocarbon (HC) refrigerant is butane/propane blend that is very flammable. It can be used and will function in present-day A/C systems, but it is too dangerous to use. At the present time, the EPA and 19 states have banned flammable refrigerants. A leak or rupture in the evaporator could easily result in a vehicle explosion. Some hydrocarbon refrigerants are sold to do-it-yourselfers (DIY) and while it can work in either an R-12 or an R-134a system, it would contaminate the system and make future repairs of the system much more difficult. ● **SEE FIGURE 64–13**.

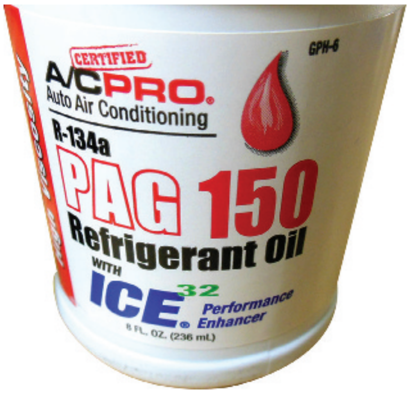

FIGURE 64–15 PAG oil is the type of refrigerant oil specified for use in most R-134a systems and the "150" is the viscosity.

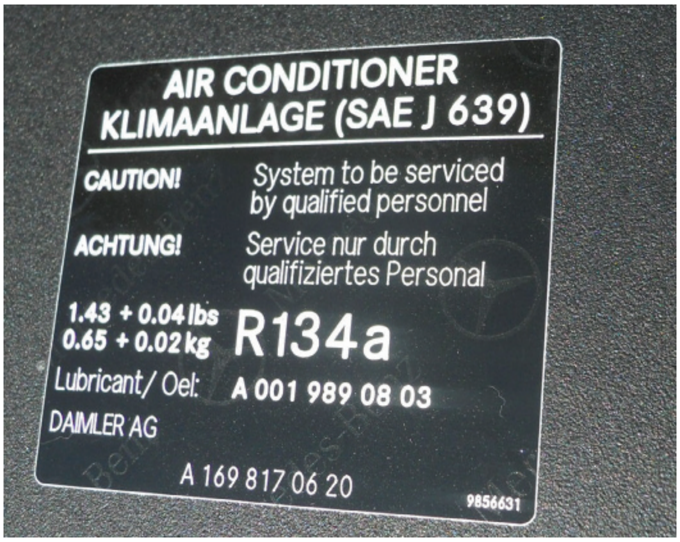

FIGURE 64–16 This under hood decal gives a Mercedes-Benz part number (A 001 989 08 03) instead of the type and viscosity of refrigerant oil. Service information was needed to determine that it was PAG 46.

oil also helps *seal* the compressor shaft seal, the insides of the hoses, and various connections between the parts to reduce refrigerant leakage. In addition, it lubricates the TXV and coats the metal parts inside the system to reduce corrosion. The oil used in a system must be completely compatible with all the materials in the system.

TYPES OF REFRIGERANT OILS

There are three types of refrigerant oils:

1. **Mineral oil** is used in R-12 systems.
2. **PAG (polyalkylene glycol)** oils are used in most R-134a systems. ● **SEE FIGURE 64–15**.
3. **POE (polyol ester)** (ester) oils are used in a few R-134a systems, and either ester or PAG oils are used in R-12 systems that have been retrofitted to R-134a.

PAG and POE are synthetic, manufactured oils. Neither PAG nor POE is soluble in R-134a, but they are easily moved by the refrigerant flow so they travel through the entire A/C system. Most compressor remanufacturers consider PAG oil a better lubricant than ester oil. There are over 30 varieties of refrigerant oil, the use of which depends on the requirements of a particular compressor or system. Piston, scroll, and vane compressors often require a different oil viscosity because of the different operating characteristics and use internal pressures to circulate the oil.

Compressors normally contain a certain amount of oil (often just 2 oz. to 8 oz.). The oil level can only be checked by removing the compressor and draining all of the oil, then measuring how much oil came out. This is normally only done when a compressor is replaced or when major service is performed on the system.

R-1234yf REFRIGERANT OIL

The refrigerant oil required for HFO-1234yf is PAG-based oil with an additive package unique to R-1234yf. The additive package is designed to provide greater chemical stability because R-1234yf breaks down in just 11 days compared to 13 years for R-134a. The oil is backward compatible with R-134a systems but R-134a oils are not compatible with R-1234yf systems.

VISCOSITY OF REFRIGERANT OILS

Viscosity is a measurement of how thick the oil is and how easily it flows. The oil must be thick enough so that moving parts float on an oil film. Oil must also be fluid enough to flow into the tiny spaces between parts. Compressor manufacturers normally specify the oil type and their viscosity for each type of compressor. The viscosity is determined by the International Standards Organization (ISO) viscosities and is measured at 40°C. Refrigerant oils are commonly available in several viscosities, including

- **46**—Called low viscosity—typically used in Ford vehicles
- **100**—Called medium to high viscosity—typically used in Chrysler vehicles
- **150**—Called ultra-high viscosity—typically used in General Motors vehicles

CAUTION: Always check the under-hood decal or service information for the exact oil and viscosity to use. ● SEE FIGURE 64–16.

HYGROSCOPIC

It is important to keep oil containers closed so that the oil does not absorb water from the atmosphere. A mineral oil can absorb about 0.005% water by weight. PAG or ester oil is very **hygroscopic**, which means that it can absorb moisture directly from the air up to about 2% to 6%. Some synthetic oils undergo hydrolysis if exposed to too much water and revert back to their original components: acid and alcohol.

OIL FLOW IN THE SYSTEM

When a system operates, oil is either absorbed or pushed by the refrigerant and moves through the system. It does not stay in any particular component, but a certain amount of oil can be expected in each component. Oil can also move while a system is shut off because of temperature changes of its various parts. Damage will occur if the compressor is operated without the refrigerant or the oil through which the refrigerant circulates. The compressor is lubricated by the oil that is mixed with and circulates with the refrigerant.

- With R-12, oil was miscible in the refrigerant and the refrigerant carried the oil.
- With R-134a, and R-1234yf, the refrigerant pushes the oil.
- A loss of refrigerant will also mean a loss of lubricating oil and possible compressor failure.
- The use of a low-pressure switch prevents the operation of the compressor if the system is low on charge.

REVIEW QUESTIONS

1. What do the colors of the containers mean?
2. How can a refrigerant cause the breakup or depletion of the ozone layer?
3. What does the Clean Air Act mandate when it comes to servicing air-conditioning systems?
4. What is a SNAP refrigerant?
5. What precautions are necessary when working with refrigerants?

CHAPTER QUIZ

1. R-134a is in what color container?
   a. Red
   b. Light blue
   c. White
   d. Green
2. Where is the ozone layer?
   a. Near ground level
   b. In the stratosphere
   c. In the clouds
   d. Between the ground and the clouds
3. The lower the GWP number, the _________.
   a. lower the global warming potential
   b. higher the global warming potential
   c. closer it is to the ground
   d. more poisonous
4. What section of the Clean Air Act concerns work on air-conditioning systems in vehicles?
   a. 847
   b. 609
   c. 777
   d. 103a
5. Which refrigerant has the lowest global warming potential (GWP)?
   a. R-744
   b. R-134a
   c. R-1234yf
   d. R-12
6. What is true about a SNAP refrigerant?
   a. Requires unique set of fittings, and all ports not converted must be permanently disabled.
   b. Each refrigerant must have a label with a unique color that specifies pertinent information.
   c. All original refrigerants must be removed before charging with the new refrigerant.
   d. All of the above
7. Checking a container of refrigerant for pressure and temperature checks for _________.
   a. moisture
   b. air
   c. dirt
   d. All of the above
8. Precautions when working with refrigerants include _________.
   a. wear safety goggles or a clear face shield and protective clothing (gloves) when working with refrigerants
   b. always be in a well-ventilated shop area when working with refrigerants and avoid small, enclosed areas
   c. when refrigerant containers are filled, reserve room is left for expansion and the container is marked with its critical temperature
   d. All of the above
9. What type of refrigerant oil is used in R-134a systems?
   a. POE
   b. PAG
   c. Mineral
   d. Either a or b depending on the vehicle
10. Why is it important to keep refrigerant oil containers closed?
    a. To keep dirt out
    b. To keep it from evaporating
    c. To keep it from absorbing moisture from the air
    d. It can leak out by traveling upward through an open container

Chapter

65

REFRIGERANT RECOVERY, RECYCLING, AND RECHARGING

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain A/C service safety practices.
- Explain SAE J standards.
- Discuss the procedure for identifying refrigerants in an A/C system.
- Describe the steps involved in A/C servicing.
- Explain the procedure for refrigerant recovery.
- Explain the procedure for recycling refrigerant.
- Discuss the purpose of flushing an A/C system.
- Describe component replacement including in-line filter and refrigerant oil.
- Explain the procedure for evacuating an A/C system.
- Explain the procedure for recharging an A/C system.
- Discuss sealants and stop leaks.

KEY TERMS:

Cubic feet per minute (cfm) 776 • Evacuation 775 • Flushing 772 • Identifier 768 • Mercury 776 • Micron 776 • Non-condensable gases (NCG) 769 • PPE 767 • Reclaimed refrigerant 771 • Recovery, recycling, and recharging (RRR) 770 • Recycled refrigerant 771 • Slugging 778

SAFETY FIRST

SUGGESTED GUIDELINES All service technicians that work on or around automotive air-conditioning systems should adhere to the following best practices for safety:

- Obtain, read, and understand the safety data sheet (SDS) information regarding the refrigerant being used.
- Work in well-ventilated area.
- Wear safety goggles or safety glasses with side shields to guard against eye exposure to refrigerant. ● **SEE FIGURE 65–1**.
- Avoid breathing refrigerant or refrigerant oil vapor.
- Avoid direct exposure to refrigerant because it can cause frostbite or difficulty breathing if exposed to vapors. Consult medical advice immediately if exposed.

FIGURE 65–1 Whenever working around refrigerant or chemicals such as dyes, always wear personal protective equipment **(PPE)**.

SAE J STANDARDS

PURPOSE Automotive service technicians are often overwhelmed with all of the various standards and specifications required for the equipment and procedure when working on the air-conditioning system. SAE (formally the Society of Automotive Engineers) has established guidelines and specifications. Each document has a "J" prefix and a number that makes searching for the details on the Internet easier. Before purchasing or using automotive air-conditioning test or service equipment, make sure that it meets the current standards for the vehicle being serviced.

COMMONLY CITED STANDARDS The most commonly referred to standards include the following:

- **J639**—Safety standards for motor vehicle refrigerant vapor compression systems. SAE J639 only addresses HFC-134a (R-134a), carbon dioxide (R-744), and HFO-1234yf (R-1234yf) refrigerants.
- **J1627**—Establishes the performance criteria for electronic refrigerant leak detectors.
- **J1628**—Establishes technician procedures for refrigerant leak detection for air-conditioning systems.
- **J1771**—This SAE standard establishes refrigerant identification equipment to be used for identifying refrigerant CFC-12 (R-12) and HFC-134a (R-134a) refrigerant when servicing a mobile A/C system. It also establishes standards for identifying refrigerant in a container to be used to charge a mobile A/C system.
- **J1991**—Establishes the standard of purity for use in mobile CFC-12 (R-12) air-conditioning systems.
- **J2099**—Sets the standard of purity for recycled R-134a (HFC-134a) and R-1234yf (HFO-1234yf).
- **J2210**—This SAE standard establishes specific minimum equipment standards for recovery/recycling equipment for HFC-134a (R-134a).
- **J2211**—This procedure provides guidelines for technicians for servicing mobile A/C systems and operating refrigerant recycling equipment designed for HFC-134a (R-134a) as described in SAE J2210.
- **J2788**—SAE Standard is to establish the specific minimum equipment performance requirements for recovery and recycling of HFC-134a (R-134a) recovery/recycling equipment. It also establishes requirements for equipment used to recharge HFC-134a to an accuracy level that meets section 9.0 of this document and SAE J2099.
- **J2791**—This SAE Standard establishes HFC-134a refrigerant electronic leak detectors, minimum performance criteria.
- **J2842**—This SAE Standard establishes design criteria and certification for mobile air-conditioning evaporator and service replacements for R-1234yf and R744.
- **J2843**—This SAE Standard establishes R-1234yf (HFO-1234yf) recovery/recycling/recharging equipment.
- **J2845**—This standard covers the technician training for service and containment of refrigerants used in mobile A/C systems for R-1234yf (HFO-1234yf).
- **J2912**—Performance requirements for R-134a and R-1234yf Refrigerant Diagnostic Identifiers (RDI) for use with mobile air-conditioning systems.
- **J2913**—This SAE Standard establishes refrigerant electronic leak detectors and minimum performance criteria for R-1234yf (HFO-1234yf).
- **J2927**—This SAE standard applies to refrigerant identification equipment to be used for identifying an acceptable level of R-1234yf purity in a refrigerant tank or vehicle system labeled as containing R-1234yf, and not misidentify other refrigerants.
- **J3030**—This SAE Standard specifies the minimum equipment requirements for recovery/recycling/recharge equipment intended for use with both R-1234yf and R-134a.

REFRIGERANT IDENTIFICATION

CROSS CONTAMINATION Cross contamination is when an unknown refrigerant is recovered and can cause the entire supply of refrigerant to become contaminated. Recovering an A/C system which is contaminated by a substance, such as R-22 or a hydrocarbon into the recovery container that is half full of R-134a will ruin the R-134a in the container. If the container is used to service another vehicle, the contaminated refrigerant will contaminate the other system(s) as well. Many compare a system with contaminated refrigerant to a virus that can sometimes spread from person to person at a very rapid rate.

At one time, contaminated refrigerant was rare, and the majority of the problems were caused by air from improper service procedures. Today, there are a variety of sealants, blends, hydrocarbons, and other refrigerants, along with recycled refrigerants available to both repair facilities and do-it-yourself (DIY) consumers that make the potential for contamination a much greater problem. The A/C industry defines the quality of refrigerant based on percentage of purity:

- 98% and better is considered pure.
- Less than 97% pure is contaminated.
- Between 97% and 98% is questionable.

REFRIGERANT IDENTIFIER Cross contamination is almost impossible to detect without the use of an electronic refrigerant **identifier**. An identifier meeting SAE standard J1771 should be used on any system using R12 or R134a. For R1234yf system, the refrigerant identifier should meet SAE standard J2843 (built into the RRR machine) or J2912 if a separate identifier is used. ● **SEE FIGURE 65–2**.

TYPES OF IDENTIFIERS To determine the correct refrigerant is for the system being serviced, inspect the service fittings and the refrigerant label. The label will list the type of refrigerant and the proper charge amount. Since each refrigerant requires

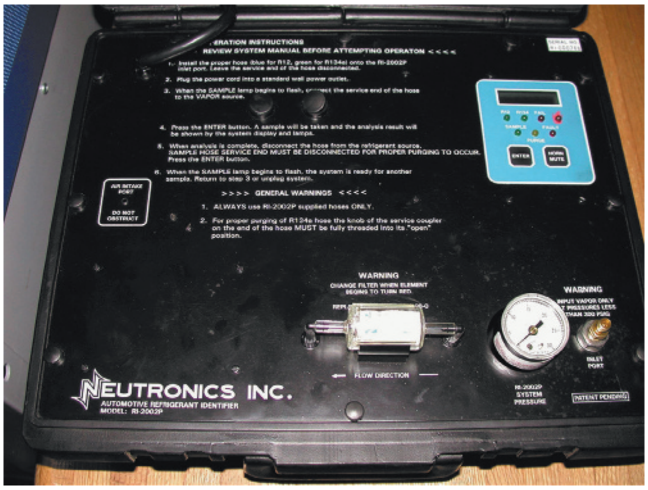

FIGURE 65–2 A typical refrigerant identification machine. The readout indicates what kind of refrigerant is in the system. If a blend or some other contaminated refrigerant is discovered, it should be recovered and stored in a separate container to keep it from contaminating fresh refrigerant.

unique fittings, the type of fittings can also help determine the proper refrigerant. There are two types of refrigerant identifiers:

1. A *go-no-go identifier* (accuracy to about 90% or better) indicates the purity of the refrigerant with lights that indicate pass or fail.
2. A *diagnostic identifier* (accuracy to 98% or better) displays the percentage by weight of R-12, R-134a, R-22, hydrocarbons, and air (displayed as NCG). If the contaminant is air, the refrigerant can be safely recovered and recycled for reuse. If the contaminant is another refrigerant or a hydrocarbon, then a special recovery procedure is required and the recovered mixture needs to be sent off for disposal or recycling.

Recycling machines cannot remove a foreign refrigerant, only air, water, oil, or particulates. Newer identifiers include a printer port, so hard-copy readouts can be printed for the customer's use.

STEPS TO IDENTIFY THE REFRIGERANT To identify the refrigerant in a system, perform the following steps:

STEP 1 The first step on all identifiers is a calibration process. Most units do not allow connection to the low-side line until the identifier shows what to do on the display.

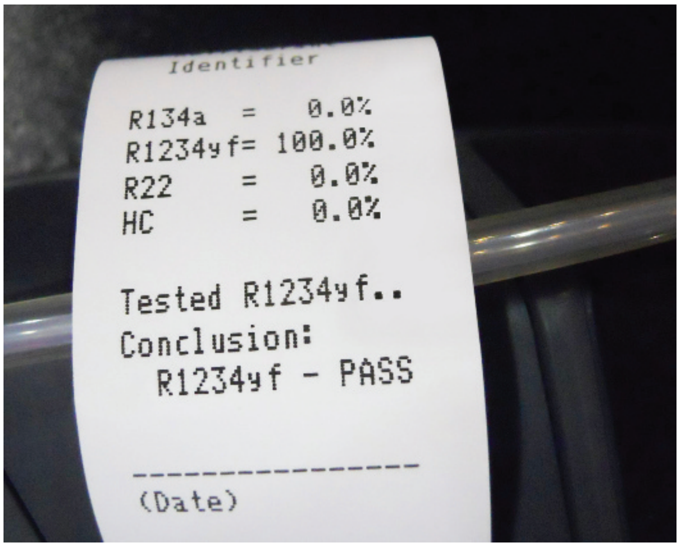
STEP 2 With the engine and the system shut off, connect the identifier to the low-side service port using the correct hose assembly for the system's refrigerant type.

STEP 3 Check the filter on the identifier for the incoming gas. It will show a color change when it needs to be changed.

STEP 4 Allow a gas sample to enter the unit. Some units include a warning device to make sure liquid refrigerant does not enter it. Many units include a warning device to indicate a flammable refrigerant.

STEP 5 Read the display to determine the nature of the refrigerant. Some units allow printing of the results at that time. If the refrigerant is good or is contaminated with air, it can be safely recovered and recycled.

STEP 6 When the analysis is complete, some units display instructions to disconnect the sampling hose and then bleed out the gas that was sampled. If the hose is not disconnected when prompted, the identifier can bleed all of the refrigerant from the system. ● **SEE FIGURE 65–3**.



```
Identifier

R134a   =   0.0%
R1234yf= 100.0%
R22     =   0.0%
HC      =   0.0%

Tested R1234yf..
Conclusion:
  R1234yf - PASS

(Date)
```

FIGURE 65–3 A typical printout showing that the system has 100% R-1234yf refrigerant in the system.

DISPOSING OF UNKNOWN REFRIGERANT If an unknown refrigerant is detected, it is considered to be the best practice to recover the refrigerant using a dedicated recovery only unit. Do not use an R-12 or R-134a recovery machine to remove a contaminated or a blend refrigerant. One alternative is to convert an older R-12 machine and gauge set to recover refrigerant blends, but this equipment should be used only for blends from that point on unless it is decontaminated after each use. If the mixture contains more than 4% hydrocarbon, it should be considered explosive, and this mixture should not be recovered using an electric-powered machine. Air-powered recovery machines are available and can be safely used for explosive mixtures. Hydrocarbon refrigerants, blends, and unknown mixtures should be recovered into containers clearly labeled CONTAMINATED REFRIGERANT. The refrigerant should then be recovered and stored in a standard DOT-approved container that is gray with a yellow top that is the standard for unknown refrigerant. Best practice standard of operation also includes the following:

- Do not fill the recovery tank over 60% of its gross weight capacity.
- Check with state and local government agencies regarding the storage of combustible or hazardous materials.
- Check with local waste-processing companies as to the proper and legal way the contaminated refrigerant can be disposed of including the possibility of it being recycled or destruction.

NON-CONDENSABLE GASES (NCG) Any refrigerant that contains **non-condensable gases (NCG)**, usually air, or with 2% or greater of another material (foreign refrigerant) is considered contaminated. If the contamination is greater than 5%, problems such as excessive high-side pressures and incorrect clutch cycling rate result. Other unseen problems of oil breakdown, seal deterioration, or compressor wear can also occur. NCG contamination can be reduced by recycling the refrigerant, purging the air out, or diluting the contaminated refrigerant with pure refrigerant. Contamination from a foreign refrigerant requires that the refrigerant be sent off for reclaiming or disposal.

FREQUENTLY ASKED QUESTION

Why Evacuate an Air-Conditioning System?

Evacuation is used to not only remove and measure the amount of refrigerant that was in the system, but to remove any air that may have been trapped in the system during a previous repair or service procedure. Air in the system can be the root cause of many air-conditioning problems including the following causes:

- Higher than normal operating pressures
- Higher than normal condenser temperatures
- Reduced air-conditioning performance (air is not a good medium for the transfer of heat)
- Noisy compressor operation

Evacuation is also a way to remove moisture from the air-conditioning system. Moisture in the refrigerant system degrades the lubricant that can lead to compressor failure. Therefore, for all of these reasons, evacuation is a needed service procedure.

MOISTURE IN THE REFRIGERANT SYSTEM Moisture in an R-134a system mixes and reacts with the refrigerant and oil in the system. It forms hydrochloric acid (HCl) that can corrode refrigerant lines, clog screens, and damage other components in the system. Any moisture in an R-134a system mixes and reacts with the refrigerant and oil in the system. The moisture blends with the hygroscopic oils used in R-134a systems, reducing its ability to lubricate components like the compressor. Moisture can be eliminated from the system by evacuating the A/C system for at least 30 minutes to boil off any moisture.

SEALANT CONTAMINATION HVAC technicians believe that contamination is caused by chemicals that are intended to seal refrigerant leaks. A simple and relatively inexpensive sealant identifier is Quick Detect made by Neutronics. Recovering refrigerant that contains a sealant might cause damage to the recovery unit. There have been cases where sealant has cured inside the machine, causing loss of the machine or expensive repairs.

A/C SERVICING

STEPS INVOLVED The service and repair of heating and A/C systems consists of the following steps:

- Identifying the refrigerant in a system using an identifier
- Recovery and disposal of contaminated refrigerant
- Repair of the system as needed, including the replacement of system components
- Maintaining proper oil level when components are serviced
- Checking the oil level in a compressor or system
- Evacuating and recharging the system

Several important facts when servicing an A/C system include the following:

- A/C systems are designed to operate using a specific amount of a particular refrigerant.
- A/C systems are designed to operate using a specific amount of particular refrigerant oil.
- Adding any other chemical into a system can create a chemical problem that can cause system damage or failure. Most original equipment manufacturers (OEM) and aftermarket suppliers consider any chemical other than the refrigerant and oil to be a foreign material.

REFRIGERANT RECOVERY

EQUIPMENT NEEDED Most refrigerant recovery units are made as part of the **recovery, recycling, and recharging (RRR)** machine and contain two service hoses (a low and high side) that are connected to the system service ports. For R-134a systems, confirm that the service connector knurled knob is turned fully counterclockwise. Then slide the quick connect collar up the hose and press the fitting onto the system service fitting and release the collar. It should "snap into place" and not be able to be removed. Slowly tighten the knurled knob until fully opened. ● **SEE FIGURE 65–4.**

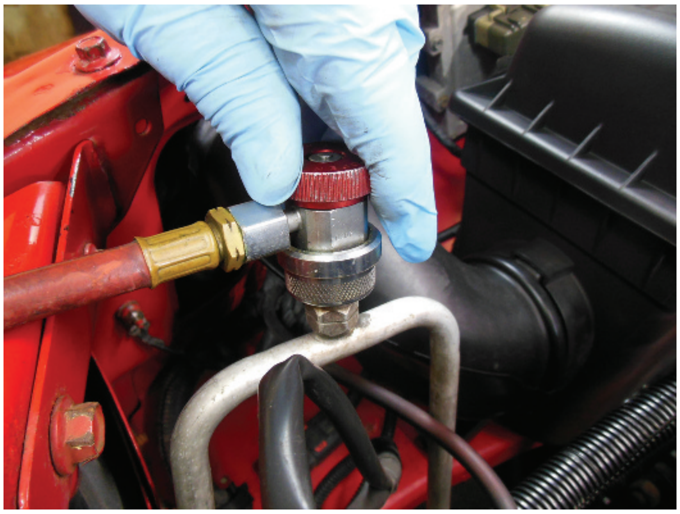

FIGURE 65–4 Installing the hoses to an RRR machine.

NOTE: Some recovery units are connected to the center hose (yellow hose) of a manifold gauge set that is used for adding refrigerant or evacuating the system.

The hoses should be equipped with shutoff valves within 12 inches of the ends and have end fittings to match the refrigerant used. Recovery units contain the following components:

- An oil separator
- A compressor-like pump
- A condenser-like heat exchanger

ENGINE PRE-HEAT PROCEDURE An engine pre-heat procedure can make the recovery process go faster and help in the complete removal of refrigerant during the recovery process if the shop area is cold. To perform pre-heat procedure, set the controls to:

- Compressor not operating
- Outside air (not MAX A/C)
- Blower on high

Operate the engine at idle for 15 minutes with the hood open so warm engine air can enter the cowl vents.

RECOVERY OPERATION Recovery units draw refrigerant vapor out of a system and convert it into liquid for storage. Recovery units weigh the amount of refrigerant that is recovered, which tells the technician if all refrigerant from a fully charged system has been recovered or whether the system was fully charged. Oil removed and separated during the recovery process is usually drained into a measuring cup and noted so that this amount of new oil can be replaced in the system as it is recharged. Oil recovery also gives an indication of the oil volume in the system. If no oil is recovered, the system was likely low on oil. If an excessive amount of oil is recovered, the system probably had too much oil. Some refrigerant in a system is absorbed in the oil and does not leave the oil immediately when a system is emptied. This trapped refrigerant *out-gases* or boils out of the oil later, after the pressure has been removed. Recovery units shut off automatically after the main refrigerant charge has been removed and the system drops into a slight vacuum. To completely remove the refrigerant, run the normal recovery procedure and recheck the pressure after a 5-minute wait. If the pressure has increased, restart the recovery process.

STORAGE CONTAINER CERTIFICATION If using older recovery equipment with a removable tank, the storage container for recovered refrigerant must be approved by the Department of Transportation (DOT) and carry the letters DOT and the certification numbers. The tank must also include the date for tank retesting. Recovery tanks must be inspected and certified to be in good condition every five years. Some rules to follow for refrigerant recovery storage tanks include

- Do not reuse disposable cylinders.
- Make sure that the recovery cylinder is labeled for the refrigerant being recovered.
- Make sure the *tank certification* is in order and the cylinder retest date has not expired.
- Inspect the cylinder for damage and do not fill if damaged.

STEPS TO RECOVER REFRIGERANT Recovering the refrigerant from a system usually includes the following steps:

STEP 1 Identify the refrigerant in the system.

STEP 2 Connect the recovery unit to the system following the instructions of the manufacturer.

STEP 3 Open the required valves and turn the machine on to start the recovery process, following the instructions of the machine's manufacturer.

STEP 4 Continue the recovery until the machine shuts off or the pressure reading has dropped into a vacuum.

STEP 5 Verify completion of recovery by shutting off all valves and watching the system pressure. If pressure rises above 0 PSI within 5 minutes, repeat steps 4 and 5 to recover the remaining refrigerant.

STEP 6 Drain, measure, and record the amount of oil removed from the system with the refrigerant and dispose of properly. This amount of new oil should be added during the recharging process. ● **SEE FIGURE 65–5**.

The system can now be repaired. Present standards and good work habits require that recovered refrigerant be recycled before reuse, even if it is to be returned to the system from which it was recovered.

FREQUENTLY ASKED QUESTION

What Is the Difference between Recycling and Reclaiming?

These terms are frequently heard and used almost interchangeability but there is a difference.

- **Recycled refrigerant**—Refrigerant that has been processed at a service facility (shop or dealership) by using recycling equipment that is SAE certified.
- **Reclaimed refrigerant**—Refrigerant that has been sent out to an EPA-certified reclamation facility where it has been processed and certified as if it were new refrigerant.

FREQUENTLY ASKED QUESTION

What Are the Concerns about Small Cans?

At one time, refrigerants were commonly sold in small cans that contained 12 oz or 15 oz of refrigerant. Refrigerant is available in larger containers, usually 10 or 30 pounds and these are commonly used by service shops. Small cans are commonly used by do-it-yourself (DIY) vehicle owners.

There are concerns that DIY service often results in the wasting or release of a substantial amount of unused refrigerant for several reasons:

- A tendency to not repair refrigerant leaks and instead just add additional refrigerant to the leaking system.
- Partially charged systems are topped off, so they probably end up over- or undercharged. A small can may not have the correct amount of refrigerant for the system, so charging is often stopped before the can is empty.
- The remaining refrigerant in the can will probably leak out over time.

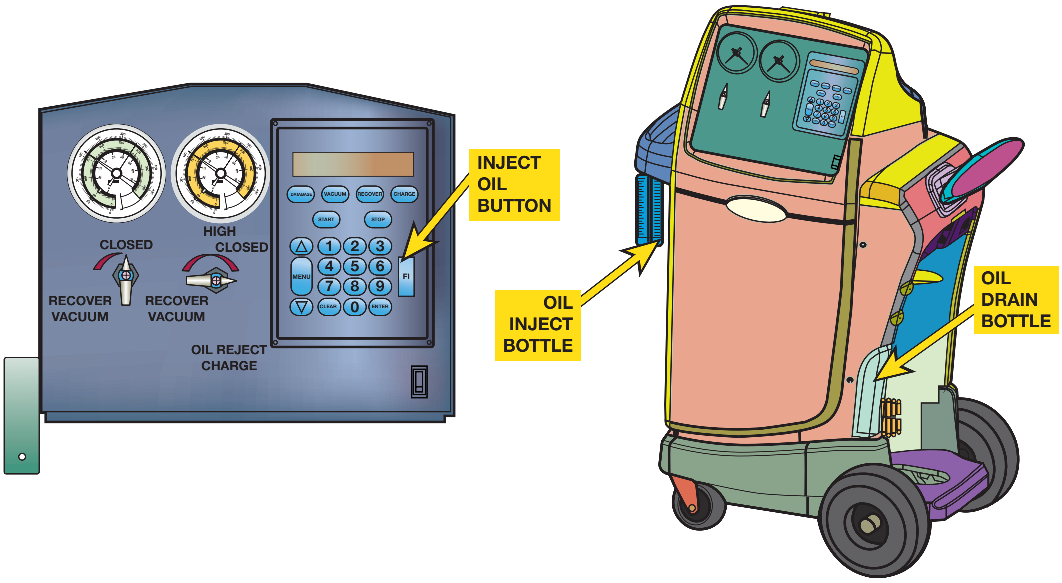

FIGURE 65–5 During the recovery process, oil from the system is separated into a container so the technician will know how much oil was removed.

RECYCLING REFRIGERANT

RECYCLING EQUIPMENT RRR equipment is used to perform the recycling process automatically, as the refrigerant is recovered from the system. There is no need for a separate recycling unit, as in the past.

During recycling the recovered refrigerant is pumped through a very fine filter to remove foreign particles, past a desiccant to remove water, and through an oil separator to remove any excess oil. Air is removed by venting it, using the non-condensable purge, from the top of the liquid refrigerant.

FILTER MAINTENANCE The filter is designed to trap acid and particulates, and to remove moisture from refrigerant. Some machines have a sight glass equipped with a moisture indicator so that the operator can tell when no more moisture can be removed. SAE 2788 recovery units are designed to stop operation if a filter or desiccant change is needed.

To meet the SAE standards for adequate moisture and contaminant removal, the filter must be replaced after 150 lb. (68 kg) of refrigerant has been filtered. The latest RRR machines give a warning when 125 lb. (57 kg) of the filter capacity has been used. When the 150 lb. (68 kg) filter capacity has been reached, the machine will lock down and cannot be used until the filter is changed. SAE 2788 recovery units are designed to stop operation if a filter or desiccant change is needed.

QUALITY STANDARDS Recycled refrigerant must meet the same purity standards as new (virgin) refrigerant including the following:

- Less than 15 ppm moisture
- Less than 4000 ppm oil
- Less than 330 ppm air

RECYCLE ONLY UNITS Some units can perform the recycling process in a single pass from the storage container through the cleaning process and back to the storage container. These machines often complete the recycling process while the system is being evacuated. Others require several passes, and the recovery process continues to circulate the refrigerant as long as necessary. ● **SEE FIGURE 65–6**.

The recycling machine is dedicated to a particular type of refrigerant, and a recycled blend can only be recharged back into the vehicle it came from or another vehicle from the same fleet.

PROCEDURE FOR RECYCLING To recycle a refrigerant, perform the following steps:

STEP 1 Open the valves or perform the programming steps required by the machine manufacturer and turn on the machine.

STEP 2 The machine operates until excess foreign particles and water have been removed or for a programmed length of time and shuts off. Check the moisture indicator to ensure that the refrigerant is dry. If the machine does not shut off in the proper amount of time, its internal filters or desiccant probably require service. ● **SEE FIGURE 65–7**.

NOTE: Sometimes all of the air will not be removed in one recycling pass. Repeat the recycling as needed to remove all of the excess air.

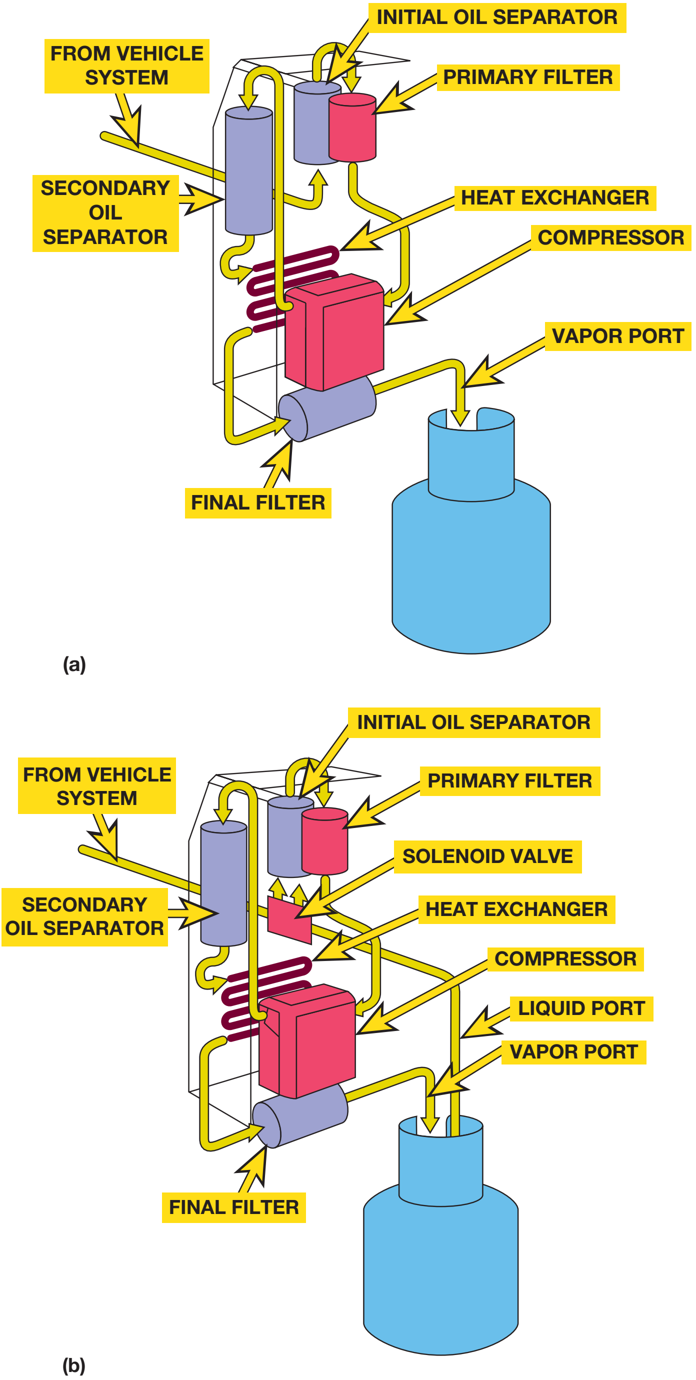

FIGURE 65–6 A single-pass recycling machine (a) cleans and filters the refrigerant as it is being recovered. A multipass machine (b) recovers the refrigerant in one operation and then cycles the refrigerant through filters and separators in another operation.

FLUSHING AN A/C SYSTEM

PURPOSE **Flushing** is using a liquid or a gas to clean the inside passages of an air-conditioning system. When a compressor fails, it usually sends solid compressor particles into the high and possibly the low sides, which can plug the condenser passages and orifice tube or TXV. It is always a good practice to check the orifice tube or TXV filter screen for debris when there is a compressor failure and to flush the system, install a filter, or both before completing the job. Flushing is done by pumping a liquid material through the passages in a reverse or normal flow direction. A gas, such as shop air or nitrogen, is not really effective in removing

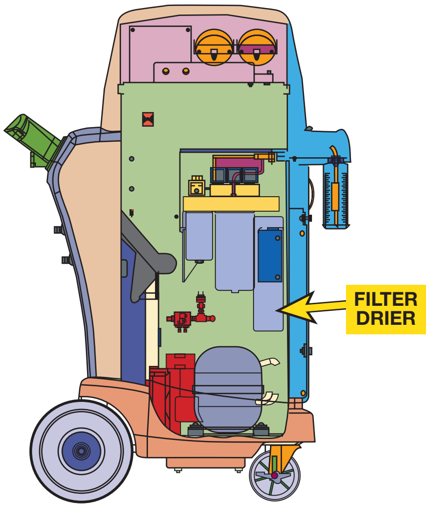

FIGURE 65–7 Recycling machines have a filter and desiccant that must be replaced after a certain amount of use.

solid material. Flushing agents can be a commercial flushing solution, liquid refrigerant, or very lightweight ester oil. However, ester oil has very little or no solvent action and remaining ester oil might be difficult to remove from the system.

NOTE: Manufacturers may not warranty a replacement compressor if the accumulator and orifice tube or receiver–drier is not also replaced.

CAUTIONS AND PRECAUTIONS No flushing operation will remove 100% of metal debris from a failed compressor. The very small metal particles can be stopped only by a filter.

- A compressor cannot be flushed.
- An accumulator or receiver–drier is not flushed and is simply replaced.
- If the evaporator is flushed, it is done to remove excessive refrigerant oil that may be trapped in the system during previous service.
- Most experts believe that the OT or TXV screen will filter out larger debris.
- Most flushing is done on the high side, from the compressor connection of the discharge line to the OT or receiver–drier fitting of the liquid line, or vice versa.

● **SEE FIGURE 65–8.**

Approved flush solvents for A/C systems are based on HFC refrigerants that have a fairly high boiling point such as Genesolv SF, which has a boiling point of 59°F (15°C). Technicians using flushing chemicals have a professional responsibility to do the following:

- Obtain, read, and understand the SDS for that chemical.
- Learn how that chemical works and how it should be used.
- Determine if that chemical will do no harm to the system and the materials like gaskets and seals.
- Determine how to remove that chemical from the system and how to properly recycle or dispose of it.

If the flush is needed only to remove oil, a low-pressure, low-flow method can be used to fill the component so the solvent can dissolve the oil. Some recovery–recycling machines can be fitted with a flushing kit that allows them to pump liquid refrigerant into one line and recover that refrigerant from the other line. If the flush is needed to remove solid debris or chemical sealants, there must be enough flow velocity to break the material loose and carry it out of the component. Better flush machines will pulsate the flow to increase the cleaning power. When the flush is completed, the chemical should be removed from the system by blowing nitrogen or clean, dry air through the system, and the chemical should be recycled or properly disposed of. The nitrogen/air should be blown through the system for 20 minutes to 30 minutes to evaporate the remaining solvent.

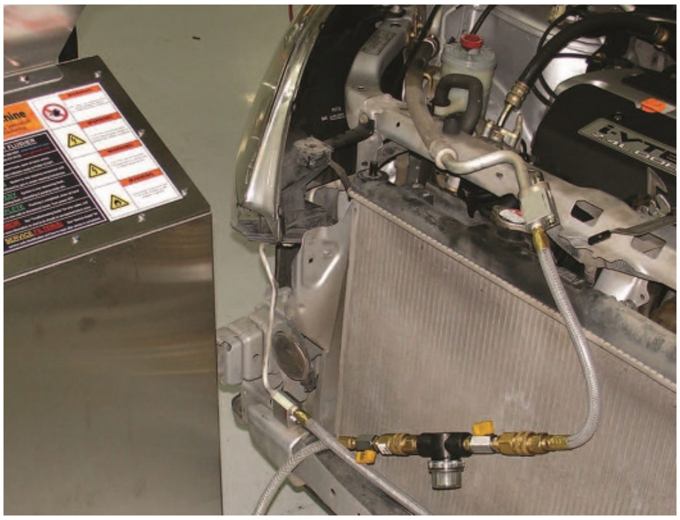

FIGURE 65–8 Portions of an A/C system can be flushed to remove debris and excess oil. Adapters are used to connect a flushing unit, which pumps the flushing material through the components. Most flushing machines are fully automated, meaning that it will vacuum, flush, recover, recycle, vacuum, and purge the cleaning solvent all automatically.

TECH TIP

The Coffee Filter Trick

Some technicians place a paper coffee filter to catch the debris in the flush material going to the catch container. This allows them to inspect the material being flushed from the system and to determine the effectiveness of the flushing process.

CAUTION: It is very difficult or impossible to flush a modern flat-tube condenser with its multiple, small passages without a flushing machine that can supply a strong, pulsating solvent flow. One or more of the small passages can be plugged so the flush material will pass through any open passages instead of clearing the plugged passages.

REPLACING COMPONENTS

GENERAL GUIDELINES After all refrigerant has been removed from the system, repairs can be accomplished. For example, the evaporator can be removed from the vehicle and replaced. Seal all openings of the system during service to prevent moisture and contaminants from entering. If the system has been opened to the atmosphere for a length of time (over 24 hours), most experts recommend replacing the drier to help prevent the possibility of damaging moisture being trapped in the system. After all repairs are completed, the system should be evacuated.

NOTE: Be sure to follow all instructions regarding the amount of oil that needs to be added to the system if components have been replaced.

O-RINGS The O-ring seal is part of a fitting that holds the ends of two refrigerant lines or hoses together inside a connector. ● **SEE FIGURE 65–9**.

The O-ring forms the seal between the lines or hoses and the connector. The O-rings usually are made of highly saturated nitriles (HSN) or neoprene rubber and remain flexible over a wide range of temperatures. The O-ring must be lubricated with clean refrigerant oil before assembly to ensure a good seal. ● **SEE FIGURES 65–10 AND 65–11**.

TIGHTENING CONNECTIONS All threaded connections should be started by hand to avoid cross-threading. Two wrenches, one on each threaded fitting, should be used to loosen or tighten O-ring fittings. Using two wrenches is often called using "double-wrenches" or a "backup wrench" and is specified to be used by most vehicle manufacturers.

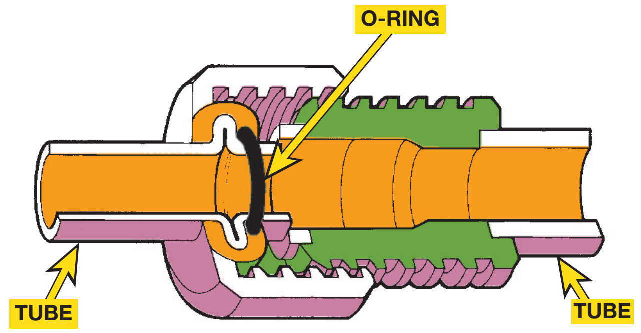

FIGURE 65–9 O-rings are usually made of neoprene rubber or highly saturated nitriles (HSN) to withstand high temperatures and flexing. O-rings should be changed during a retrofit procedure.

FIGURE 65–11 A special tool is needed to remove and install this spring-lock coupling.

SERVICE FITTINGS AND CAPS Each type of refrigerant has its own unique service fitting. This prevents accidental use of the wrong service equipment and/or the introduction of the wrong refrigerant. Service valves are found almost anywhere on the system. They may be located on the receiver–drier, accumulator, compressor, muffler, or in the lines themselves. All service valves should have plastic coverings called *service caps*.

Along with preventing dirt from entering the system, service valve caps have O-rings which become the primary seal if a valve leaks. Always reattach the caps after any service has been performed, and replace them if missing. Another built-in precaution is the refrigerant cut-off valve, which keeps the refrigerant in the service hose instead of allowing it to vent to the atmosphere.

SCHRADER VALVES A Schrader valve is similar to a tire valve. Internal pressure holds Schrader valves closed. There is also a small spring to keep the valve seated if the internal pressure becomes insufficient. When the service connection is made, the depressor in the end of the service hose or service coupling pushes on a small pin inside the valve which opens the valve. The valve opens only when the service line connection is nearly complete, preventing contamination of the system or the unnecessary release of refrigerant. Many experts recommend that the Schrader valves be replaced whenever the system is open after recovery of refrigerant. ● **SEE FIGURE 65–12**.

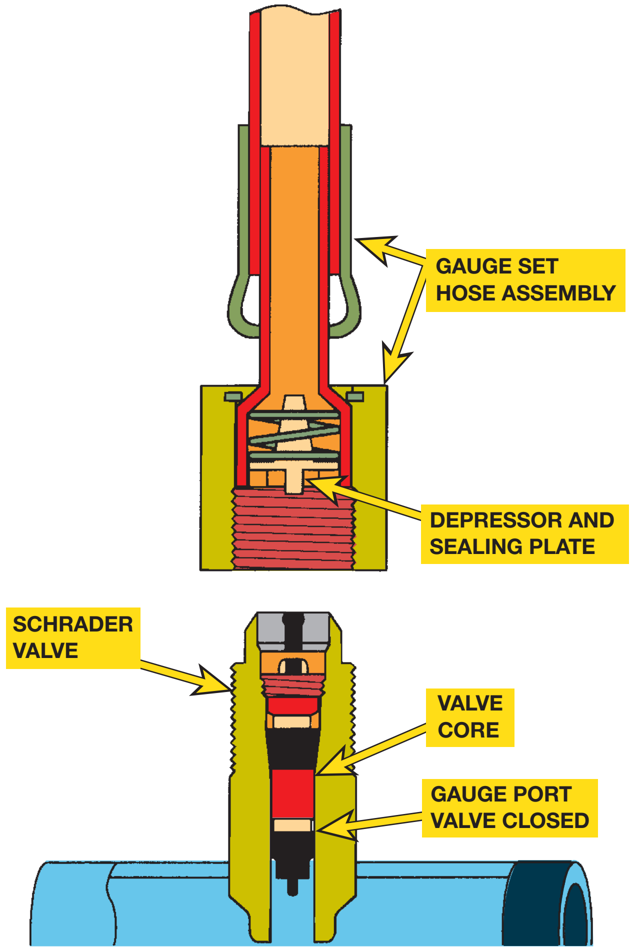

FIGURE 65–12 A depressor pin on the gauge set opens the Schrader valve when the connection is almost completely tightened. This prevents accidental refrigerant discharge.

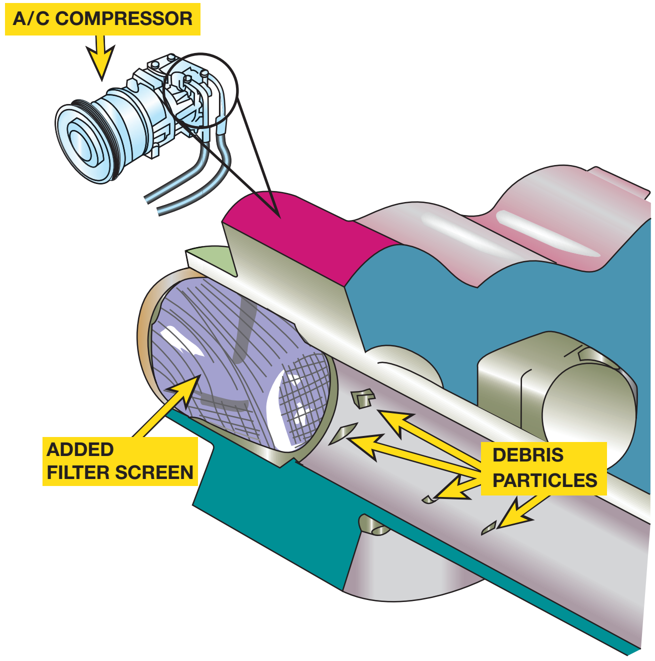

FIGURE 65–13 A typical aftermarket filter is installed in the suction line at the entrance to the compressor that is designed to catch any debris that could harm the compressor.

INLINE FILTER If a compressor fails, debris in the form of metal particles often travels downstream through the condenser and is trapped in the receiver–drier or orifice tube, where it can cause plugging. Some compressor failures send debris into the suction line. The technician can install an in-line filter in either the high side or low side to trap any debris still in the system to protect the new compressor. They are available with connections to fit different line sizes. Some filters include a new orifice tube. ● **SEE FIGURE 65–13**.

To install an in-line filter, perform the following steps:

STEP 1 Recover the refrigerant from the system.

STEP 2 Select the location for the filter. The flexibility of hose allows a great deal of freedom. With metal tubing, locate a straight section of tubing slightly longer than the filter's connections.

STEP 3 Evacuate and recharge the system after installation of the filter.

NOTE: Most aftermarket air-conditioning filters have a directional arrow that indicates refrigerant flow direction.

REFRIGERANT OIL When it is determined that additional oil must be added, several types of low-cost injectors can be used to push oil into a charged or empty system. The proper amount of oil can be kept in a system by adding oil to replace the amount of oil removed when a component is replaced. This is usually only a small amount. Compressor replacement requires a slightly larger amount. ● **SEE FIGURE 65–14**.

The amount of oil retained in a component varies with the size and design. ● **SEE CHART 65–1**.

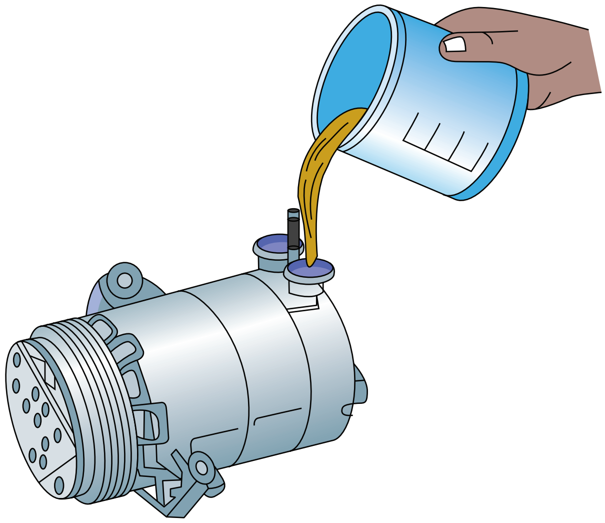

FIGURE 65–14 Always check service information and/or the instructions that accompany a new replacement compressor to determine the exact type and amount of refrigerant oil for the compressor.

COMPONENT	TYPICAL AMOUNT OF OIL IN FLUID OUNCES (FL OZ)	TYPICAL AMOUNT OF OIL IN CUBIC CENTIMETERS (CC)
Evaporator	2.0	60
Condenser	1.0	30
Receiver–Drier	0.5	15
Accumulator	2.0	60

CHART 65–1

The typical amount of refrigerant oil left in component. To convert from ounces to cubic centimeters multiply the ounces by 29.6.

EVACUATING THE SYSTEM

PURPOSE OF EVACUATING THE SYSTEM After a system has been repaired, all of the air and moisture that might have entered must be removed. **Evacuation** means that a vacuum will be applied to the system to remove the air and to vaporize any moisture that may be in the system. Although water boils at 212°F (100°C) at sea level, it can boil at much lower temperatures when the pressure is reduced. In other words, if a vacuum is applied to the air-conditioning system, the low pressure will cause any trapped moisture in the system to vaporize (boil). This water vapor is then removed from the system through the vacuum pump and released into the atmosphere. It is important to evacuate the system to at least 29-inch Hg of vacuum for at least 45 minutes to be assured that all of the moisture has been removed. For best results, the vacuum should be higher than 29.2-inch Hg. The higher the vacuum and the longer that it is allowed to evacuate, the better.

MICRON RATING Vacuum pumps are rated by both **cubic feet per minute (cfm)** and **micron** ratings:

- The cfm rating is the volume it can pump.
- The micron rating is how deep a vacuum the pump can pull.

An automotive A/C system requires about a 1.2-cfm to 1.5-cfm rating, whereas a larger system used in a bus or truck needs about a 5-cfm to 6-cfm vacuum pump. Using a vacuum pump that is too small requires a much longer evacuation time, which causes excess wear on the vacuum pump.

- A perfect vacuum is 29.92 inch Hg, or 0 microns (a micron is equal to one-millionth of a meter).
- A good vacuum pump will pull a system down to under 500 microns (29.90 inch Hg). This high vacuum drops the boiling point of water to around 0°F (–18°C). ● **SEE FIGURE 65–15**.

VACUUM PUMP SERVICE A vacuum pump must be maintained with the proper oil level and periodic oil changes to ensure proper operation. If service is neglected, it will not pump to its design capabilities. Some modern electronic units flash a warning if the oil has not been changed at the proper interval (about 10 hours).

Newer refrigerant service machines are equipped with oil-less vacuum pumps. These units eliminate the need to service the vacuum pump. To run without lubricating oil, the pump uses two high-temperature plastic pistons operating in anodized aluminum cylinders with a Teflon-type cup seal. The piston and connecting rod are one piece. The crankshaft and connecting rod bearings use a lubricated and sealed ball bearing.

EVACUATION TIME It is accepted practice to evacuate an automotive system for at least 45 minutes. Vacuum readings are affected by altitude and the drop in atmospheric pressure that occurs.

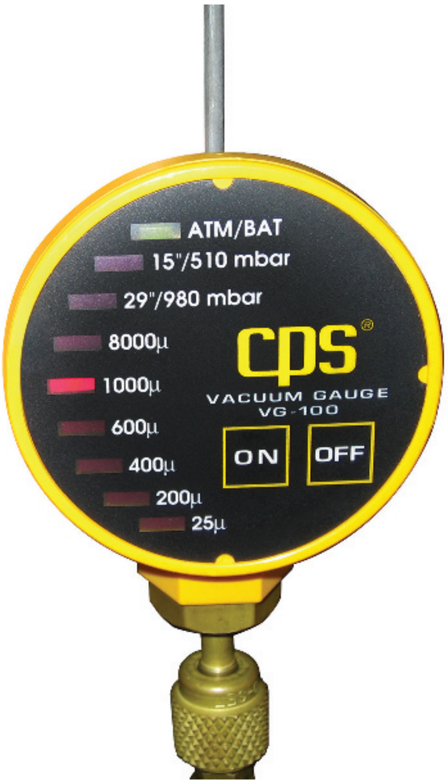

FIGURE 65–15 An air-conditioning vacuum gauge that reads in microns.

FREQUENTLY ASKED QUESTION

What Is a Micron?

A typical vacuum gauge reads in inches of **mercury** (inch Hg) and the recommended vacuum level needed to remove moisture from the system is a vacuum of 29.2 inch Hg or lower. However, many experts recommend using a vacuum gauge that measures the amount of air remaining in the system rather than just the vacuum.

- A micron is one millionth of a meter and there are about 760,000 microns of air at atmospheric pressure.
- The lower the pressure, the lower the number of microns of air.
- A vacuum reading of 29.72 inch Hg is about 5,000 microns.
- Many experts recommend that the micron level be 500 or less for best results.

This is particularly important when evacuating a dual-climate control system where two evaporators are used and there are long lengths of refrigerant lines. ● **SEE CHART 65–2**.

TEMPERATURE °F/°C	INCH HG	MICRONS*	PRESSURE (PSI)
212/100	0.00	759,068	14.7
205/96	5.00	536,000	12.3
194/90	9.81	525,526	10.2
176/80	16.0	355,092	6.9
158/70	20.8	233,680	4.5
140/60	24.1	149,352	2.9
122/50	26.4	92,456	1.8
104/40	27.9	55,118	1.1
86/30	28.8	31,750	0.6
80/27	29.0	25,400	0.5
76/24	29.1	22,860	0.4
72/22	29.2	20,320	0.4
69/21	29.3	17,780	0.3
64/18	29.4	15,240	0.3
59/15	29.5	12,700	0.2
53/12	29.6	10,160	0.2
45/7	29.7	7,620	0.1
32/0	29.8	4,572	0.1
21/–6	29.9	2,540	0.1
6/–14	29.9	1,270	0.1
–24/–31	30.0	254	0.0
–35/–37	30.0	127	0.0

** The remaining pressure in the system in microns.*

CHART 65–2

Boiling temperature of water at converted pressures.

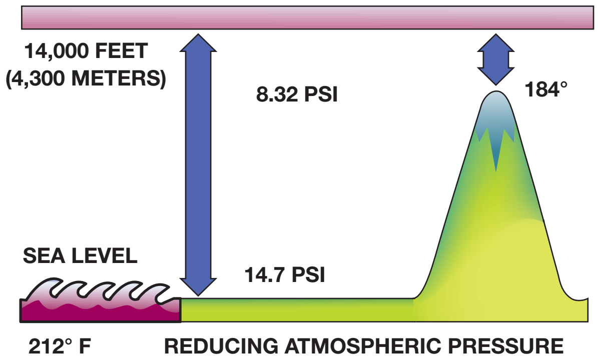

FIGURE 65–16 At sea level, water boils at 212°F (100°C), whereas at the top of Pike's Peak, at 14,000 feet, water boils at 184°F (84°C) because the atmospheric pressure is reduced from 14.7 PSI to just 8.32 PSI.

ALTITUDE ABOVE SEA LEVEL FEET (METERS)	VACUUM READING (INCH HG)
0 (0)	29.92
1000 (305)	28.86
2000 (610)	27.82
3000 (914)	26.82
4000 (1219)	25.84
5000 (1524)	24.90
6000 (1829)	23.99
7000 (2134)	23.10
8000 (2438)	22.23
9000 (2743)	21.39
10,000 (3048)	20.58

CHART 65–3

To evaporate any trapped moisture in the system, a vacuum of at least 29 inches of mercury (inch Hg) is needed. At shops located at higher elevations, the gauge reading will naturally be lower.

- At 1,000 feet (305 m) above sea level, a complete vacuum is 28.92 inch Hg, about 1 inch Hg less than at sea level.
- This pressure will decrease at a rate of about 1 inch Hg per 1,000-foot elevation increase. ● **SEE FIGURE 65–16.**

The absolute vacuum decreases as altitude increases but the gauge reading will show less. ● **SEE CHART 65–3.**

NOTE: Some vehicles with rear A/C use an electric solenoid valve to block flow through the rear unit when it is turned off. This solenoid should be activated so it will open and allow a more complete evacuation of the system.

EVACUATION PROCEDURE USING AN RRR MACHINE When using an A/C service unit (RRR machine), evacuation is often simply a matter of following instructions, assuming the service hoses are still connected from the recovery operation. Most recent machines use electric solenoids to control the flow inside the machine, and starting the evacuation process opens the solenoids needed for this process. Some also include a microprocessor that can be programmed to run the vacuum pump for the desired length of time. Some older charging stations are manually operated and, on these units, the proper valves must be opened as the vacuum pump is started.

Steps for evacuating with a typical RRR machine include the following:

STEP 1 Connect the service hoses to the air-conditioning service ports.

STEP 2 Open the service hose coupler valves by turning the collars clockwise.

STEP 3 Select VACUUM from the MAIN MENU.

STEP 4 Select VACUUM LEAK CHECK, if desired, to automatically perform a 5-minute pressure rise leak check after the vacuum.

STEP 5 Select to accept the 10-minute default evacuation time, or enter a desired vacuum time using the number keys.

NOTE: The vacuum process will halt if pressure rises above 0.35 bar (5 PSI). This means that there is still refrigerant in the system. Recover the refrigerant before proceeding.

The machine will then pull a vacuum on the A/C system for the programmed amount of time. The machine stops when the specified amount of time has elapsed.

RECHARGING THE SYSTEM

PROCEDURE After the system has been evacuated, it can be recharged with the correct amount of new or recycled refrigerant. Charge level is system specific, and as the volume of HVAC systems has been downsized, the amount of refrigerant has become critical. The charge level is normally found on a specification decal fastened to some location under the hood and includes both the type and volume of refrigerant used. The decal is attached to the compressor on some older systems. If the decal is missing or illegible, charge specifications are also given in service information from the vehicle manufacturer or aftermarket A/C component suppliers. ● **SEE FIGURE 65–17.**

UNIT CONVERSION Various vehicle manufacturers use various units for refrigerant oil capacities. When confronted with a unit of measure that is not known, use metric conversion calculator or Internet to convert from one unit to another. ● **SEE CHART 65–4.**

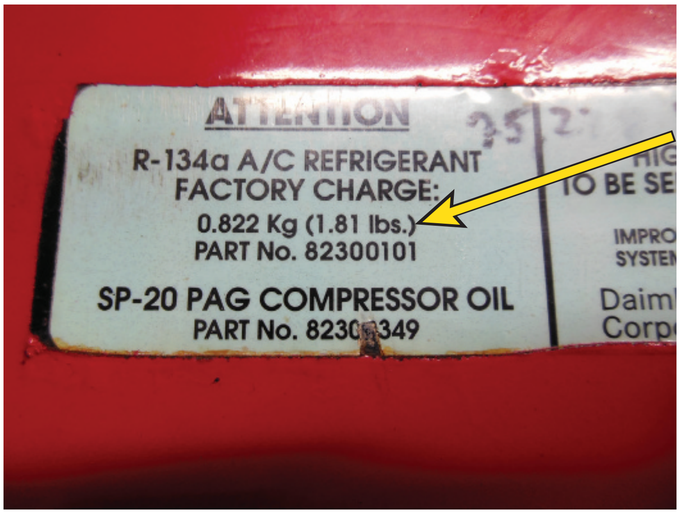

FIGURE 65–17 The underhood decal states that this vehicle requires 1.81 pounds (0.822 kg) of R-134a refrigerant.

SOURCE UNIT	DESIRED UNIT	HOW TO CONVERT
Ounces (oz)	Pounds (lb.)	Divide by 16
Pounds (lb.)	Ounces (oz)	Multiply by 16
Ounces (oz)	Grams (g)	Multiply by 28.4
Grams (g)	Ounces (oz)	Divide by 28.4
Pounds (lb.)	Kilogram (kg)	Divide by 2.2
Kilogram (kg)	Pounds (lb.)	Multiply by 2.2
Kilogram (kg)	Ounces (oz)	Multiply by 35.3
Ounces (oz)	Kilogram (kg)	Divide by 0.028

CHART 65–4

Some of the most commonly needed unit conversions.

TECH TIP

Check the Scale for Accuracy

Most charging scales can be calibrated to ensure accuracy. If a known amount of weight is placed on the scale, the weight indicator should show the correct amount of charge. If a test weight is not available use:

- 9 pennies weigh 1 ounce
- 27 pennies weigh 3 ounces

RECOMMENDED CHARGING PROCEDURE

The best method to charge a system is to start with an empty system and charge the specific amount of refrigerant as measured by accurate scales. The most commonly used A/C service machines have internal refrigerant tanks and electronic scales. ● **SEE FIGURE 65–18**.

Moving the refrigerant into the system requires that the charging container pressure be greater than the system pressure. Because the process begins with the system in a vacuum, the first portion goes rather quickly, but the first 1/2 lb. or so fills the internal volume and starts generating pressure. As refrigerant boils and leaves the container, it cools the remaining refrigerant and causes a pressure drop. Most charging stations and RRR machines include heaters that raise the internal pressure of the refrigerant container to help force refrigerant into the system. The pressure difference can be increased by starting the A/C system so the low-side pressure drops and then charging only into the low side.

With the system running, caution should be exercised if charging liquid is put into it to avoid **slugging** the compressor, which is allowing liquid refrigerant to enter a running compressor which can cause severe damage.

- If the container is upright, gas will exit.
- If the container is upside down, liquid will exit.

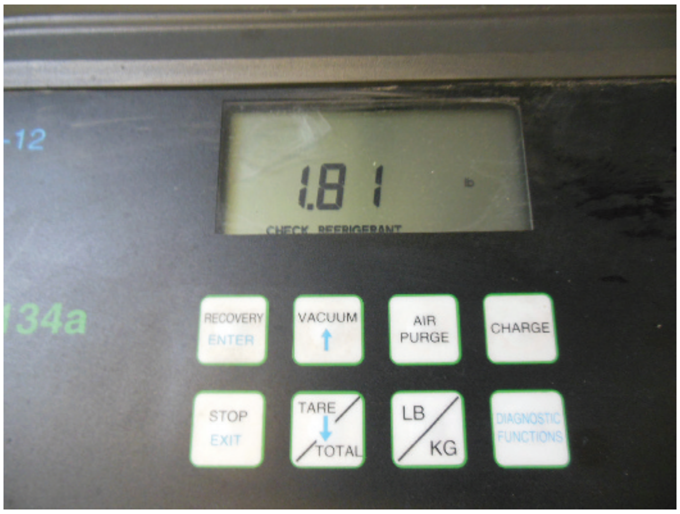

FIGURE 65–18 The calibrated scale on the RRR machine displayed the exact amount of refrigerant that was specified added to the system (1.81 lb.).

RECHARGING WITH AN RRR MACHINE

Recharging with an RRR machine usually is done as soon as the system is evacuated. During evacuation the machine will perform a vacuum leak check by holding for 5 minutes and watching for any pressure rise. Any pressure rise indicates that the system is leaking, and further repairs are needed.

NOTE: Newer RRR machines combine the evacuation, leak check, and recharge operations into a mandatory step-by-step process to prevent charging a system that is leaking. If the vacuum leak test does not pass the machine will not allow recharging.

The recharging process typically includes the following steps:

STEP 1 Connect both service hoses to the vehicle's service ports.

STEP 2 Select CHARGE from the MAIN MENU.

STEP 3 The user will be prompted to enter service data. This may include the charge amount and oil to add, if needed.

STEP 4 Select the ENTER key to start the charge process. Moving or bumping the machine at this point may result in an inaccurate charge. When the charge cycle gets close to the desired weight value, the machine slows down. It will charge, settle, charge again, settle, etc.

STEP 5 When prompted, select to perform hose equalization. Select to perform hose compensation.

NOTE: Hose equalization requires the user to start the vehicle. Hose compensation adds a preset amount of refrigerant to the charge to compensate for service hose volume.

STEP 6 When the CHARGE COMPLETE screen appears, it includes a summary of charge results.

STEP 7 The user will be prompted to close the coupler valves and disconnect the hoses from the vehicle. The machine will recover any remaining refrigerant from the hoses.

R-1234yf EVACUATE AND RECHARGE

As standards are tightened concerning refrigerants, many of the steps for evacuating and recharging systems are built into the software of the RRR machine. This helps to prevent charging refrigerant into a leaking system.

The RRR machines used to recover/recycle/recharge R-1234yf, must meet the SAE J2843 standard. The RRR machine must use either an internal or external refrigerant identifier. The identifier ensures that the refrigerant is at least 98% pure R-1234yf before the machine allows it to be recovered. The standard operating procedure when using the J2843 RRR machine to charge the system includes the following steps:

STEP 1 After the technician enters the correct charge amount, the machine first draws a vacuum on the system to 26.9 inches of mercury.

STEP 2 The machine monitors the applied vacuum to make sure that it does not degrade lower than 25.9 inches mercury in 5 minutes. If the vacuum drops more than allowed, the leak has to be repaired before the machine will allow refrigerant to be added to the system.

STEP 3 If the systems passed the vacuum test, the RRR machine will automatically add a small refrigerant charge to the system equal to about 10% of the capacity of the system and then monitors the system pressure for 5 minutes. If the pressure decreases by 10% or more, this indicates a leak is present and the machine will not add more refrigerant.

STEP 4 If the system is leak-free, the machine will proceed and fully charge the system.

SEALANTS AND STOP LEAKS

PURPOSE Sealants and stop leaks are included in many do-it-yourself (DIY) automotive air-conditioning charging products and are designed to plug or stop small refrigerant leaks. Most HVAC technicians dislike stop leaks as they are considered an inadequate or temporary repair method, and the best repair is to actually fix the leak.

SEALANT CONCERNS Sealants and stop leaks will not always be successful in stopping leaks and may damage the A/C system. Stop leaks also have a reputation of plugging up small orifices that might reduce the proper flow of refrigerant or oil. There is also a question of whether the stop leak material will contaminate the rather delicate chemical balance within an A/C system. In spite of these misgivings, sealants have become popular with do-it-yourselfers.

TYPES There are two types of sealants:

1. *Type I* is a rubber "conditioner," often called a "seal swell." It contains a hydrocarbon or alcohol that softens rubber that has hardened and causes it to swell. Type I sealants are generally low cost and will cause little harm and are often available combined in a small can of refrigerant. Other sealants are single- or two-part chemicals that are moisture-activated and remain fluid until in contact with moisture.
2. *Type II* is a stop-leak chemical that hardens when it contacts moisture as it escapes, which results in sealing the leak. Type II sealants have hardened and caused plugging inside a system and service machines. The sealant is purchased as a kit that includes the sealant with a valve and short adapter hose. The absence of moisture inside the A/C system along with the heat and pressure prevent the sealant from hardening inside the system. ● **SEE FIGURE 65–19**.

CAUTION: Refrigerant service machines have experienced problems of lines plugging up and solenoids sticking after recovering refrigerant from systems containing sealants. One compressor manufacturer will not warranty compressors if sealant residue is found in them.

REVIEW QUESTIONS

1. What safety precautions should be followed when working on air-conditioning systems?
2. What is considered to be a non-condensable gas (NCG)?
3. What are the steps to recover refrigerant?
4. What are the criteria for recycled refrigerant?
5. Why do A/C experts recommend using a micron meter to measure the vacuum in the system?

CHAPTER QUIZ

1. All of the following are SAE J standards for air-conditioning systems EXCEPT __________.
   - **a.** J639
   - **b.** J1630
   - **c.** J2099
   - **d.** J2211
2. What is the SAE specification number of an RRR machine that meets the 2006 and newer standards?
   - **a.** J-2788
   - **b.** J-2210
   - **c.** J-1930
   - **d.** J-0560
3. The storage container for recovered refrigerant must be approved by __________.
   - **a.** EPA
   - **b.** OSHA
   - **c.** DOT
   - **d.** MSDS
4. Why should service technicians check a system for the presence of sealant before recovering the refrigerant?
   - **a.** It can harm the recovery machine.
   - **b.** It can contaminate the refrigerant that is stored in the recovery container.
   - **c.** It can damage a refrigerant identifier.
   - **d.** All of the above
5. Present standards and good work habits require that recovered refrigerant be __________.
   - **a.** sent out to be discarded at an EPA-certified facility
   - **b.** recycled
   - **c.** sent back to the manufacturer
   - **d.** kept for 90 days
6. When is it acceptable to use a stop leak in an A/C system?
   - **a.** If the refrigerant leak is small
   - **b.** If the refrigerant leak is medium size
   - **c.** If the refrigerant leak is large
   - **d.** None of the above.
7. What component(s) cannot be flushed?
   - **a.** Compressor
   - **b.** Receiver–drier
   - **c.** Orifice tube
   - **d.** Any of the above
8. What is the primary seal in the service fitting?
   - **a.** Schrader valve
   - **b.** Valve cap O-ring
   - **c.** Cut-off valve
   - **d.** Valve spring
9. When charging, caution should be exercised if charging liquid into the system to avoid __________ the compressor.
   - **a.** vaporizing
   - **b.** slugging
   - **c.** condensing
   - **d.** Any of the above
10. Most experts recommend that the system be drawn down to how many microns?
    - **a.** 500 or lower
    - **b.** 10,000 or higher
    - **c.** 243
    - **d.** 127

AIR-CONDITIONING SYSTEM DIAGNOSIS AND SERVICE

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe the eight-step diagnostic procedure for an A/C system.
- Discuss the importance of verifying the customer concern.
- Describe the visual inspection.
- Explain how to check DTCs.
- Explain how to check TSBs.
- Discuss how to perform an A/C performance test.
- Describe how to find the root cause of a customer concern.
- Describe how to address system odor issues.
- Describe how to address noise issues.
- Describe how to repair a problem in an A/C system.
- Explain how to locate refrigerant leaks.

KEY TERMS:

After-blow module 789 • Body control module (BCM) 784 • Diagnostic trouble codes (DTCs) 784 • Electronic evaporator dryer (EED) 789 • Electronic leak detector 791 • Groundout 790 • Oil trap 791 • Technical service bulletin (TSB) 784 • Strategy-based diagnosis 781 • Visual inspection 782

DIAGNOSTIC PROCEDURE

STRATEGY-BASED DIAGNOSTICS

When diagnosing a heating and air-conditioning system problem, most vehicle manufacturers recommend that the following steps be performed. **Strategy-based diagnosis** is to follow the same steps given below each time an air-conditioning issue is found.

STEP 1 Verify the Customer Complaint (concern). ● **SEE FIGURE 66–1**.

STEP 2 Perform a Thorough Visual Inspection.

STEP 3 Check for Diagnostic Trouble Codes (DTCs).

STEP 4 Check for Related Technical Service Bulletins (TSBs).

STEP 5 Perform an A/C Performance Test.

STEP 6 Determine the Root Cause.

STEP 7 Repair the System.

STEP 8 Verify the Repair.

COMMON ISSUES WITH A/C SYSTEMS

Commonly found issues that cause a lack of cooling and how to find the root cause include the following conditions:

- **Undercharged**—This condition can be detected by using pressure gauges and looking at both the low-side and high-side pressure.
- **Overcharged**—This condition can be detected by using pressure gauges and looking at both the low-side and high-side pressure.
- **Non-condensable gas (air) in the refrigerant**—This condition can be detected by using pressure gauges and looking at both the low-side and high-side pressure and/or differential temperature measurements across components.
- **Restricted expansion device (TXV or OT)**—This condition can be detected by using pressure gauges and looking at both the low-side and high-side pressure and/or differential temperature measurements across components.

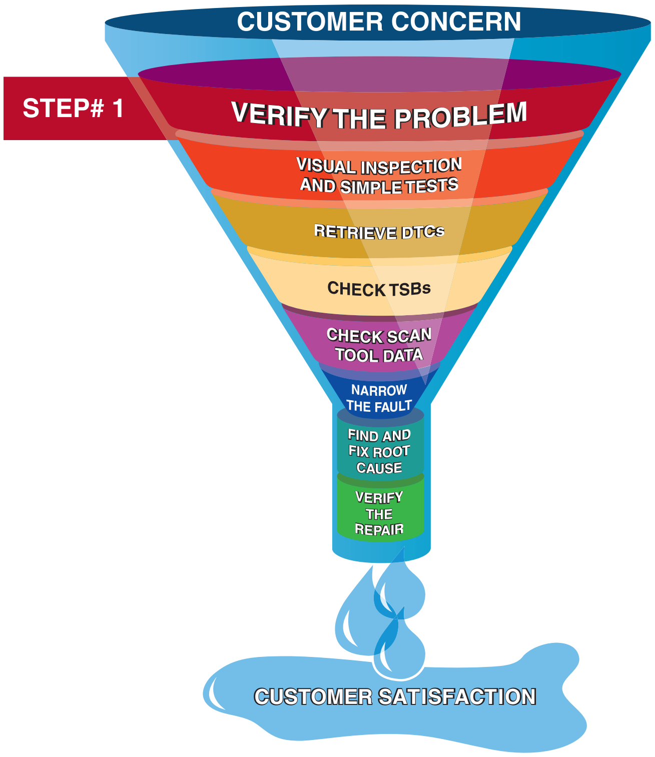

FIGURE 66–1 Step #1 is to verify the customer concern or problem. If the problem cannot be verified, then the repair cannot be verified.

- **Restricted or dirty condenser**—This condition can be detected by using pressure gauges and/or differential temperature measurements across components.
- **Restricted airflow thorough the evaporator**—This condition can be detected by using pressure gauges and/or differential temperature measurements across components.

VERIFY CUSTOMER CONCERN

UNDERSTAND THE EXACT FAULT The first step in the strategy-based diagnosis process is to verify the customer concern. The customer concern needs to be addressed. If a problem occurs and if it is intermittent, identify when it occurs. Sometimes an A/C system functions normally for the conditions that could include any of the following:

- Higher than normal outside air (ambient) temperature.
- High humidity level.
- A new vehicle that is larger or has more glass area than the customer's previous vehicle.
- A new vehicle that is black or dark in color compared with their previous vehicle that was a lighter color such as white or silver. A light-colored vehicle reflects light and the heat from the sun instead of being absorbed as with a dark-colored vehicle.

Other needed information includes the following:

1. What recent service work was performed on the vehicle? (Previous repairs could have somehow affected the HVAC system.)
2. Has the vehicle been in storage? (Animals like to build nests in HVAC ducts, which would affect A/C operation and airflow.)
3. Has the vehicle been involved in a collision? (Hidden damage could cause faults in the HVAC system, yet may not be visible from the outside.)
4. Has the A/C system been serviced before? (This may indicate that the system has sealant or other impurities in the system.)

The service adviser or shop owner should ask the customer to state their concern in their own words such as

- "Does not seem to cool as fast as last year."
- "Airflow through the driver's side vent appears to be blocked."
- "The fan noise is high but I can't feel much cool air coming from the vents."

FREQUENTLY ASKED QUESTION

What Does "Short Cycling" Mean?

If the system is low on refrigerant, it will short cycle, or rapidly cycle on and off. This is the result of the compressor pulling the refrigerant out of the low side quickly to open either the cycling switch or the low-pressure switch. With the compressor off, the flow into the evaporator raises the pressure enough to reclose the switch and restart the compressor. With a normal charge, the low-side pressure should be 15 PSI to 35 PSI and the clutch should be on for 45 seconds to 90 seconds and be off for only about 15 seconds to 30 seconds.

VISUAL INSPECTION

UNDERHOOD CHECKS The second step in the strategy-based diagnosis process is to perform a thorough visual inspection. A **visual inspection** of the underhood items includes the following checks:

1. Check the condition of the A/C compressor drive belt.
2. Check the tension of the A/C compressor drive belt and the automatic tensioner.
3. Inspect the refrigerant hoses and lines for signs of oily residue and damage. Oil residue with caked-on dirt indicates a probable leak. Check that each of the A/C service ports is capped.
4. While checking the hoses and lines, determine if the system uses a thermal expansion valve system (TXV) or an orifice tube (OT) system and if a variable displacement compressor is used. The compressor shape and model number are used for identification.
5. Check that the compressor mounting bolts are tight.
6. Check to make sure that the air gap of the A/C compressor clutch is correct.
7. Check the electrical wires to the clutch, blower motor, and any A/C switches for good, tight connections, and possible damage. ● **SEE FIGURE 66–2.**

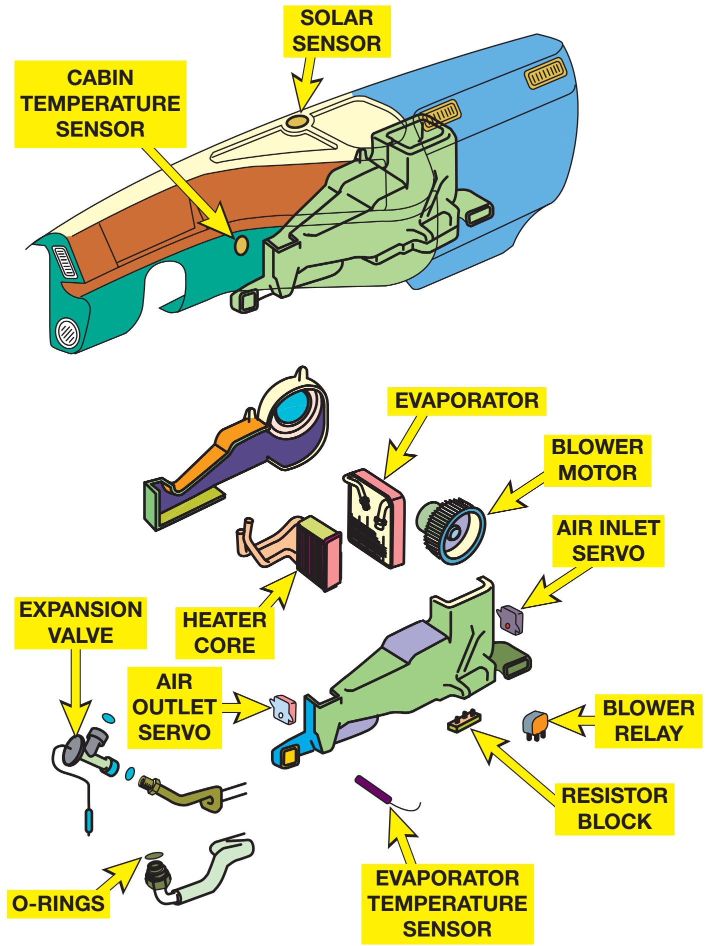

FIGURE 66–2 A visual inspection checks all of the visible, underhood components for possible wear or damage. The under-dash components are checked for noise and proper airflow.

8. Check the condition of any vacuum hoses between the intake manifold and bulkhead, if equipped.
9. Check the faces of the condenser and radiator core for restriction to airflow caused by debris and clean as needed.

IN-VEHICLE CHECKS With the engine off, the in-vehicle checks include the following:

1. Operate the blower switch through its various speeds while listening to the fan and motor for unusual noises. Note that some systems do not have blower operation unless the heat or A/C controls are on or unless the engine is running.
2. Move the temperature lever of mechanically operated doors to both ends of its travel. It should move smoothly and stop before making contact at the ends. An early or late stop indicates that adjustment is needed.

ENGINE RUNNING CHECKS With the engine running, the underhood checks include the following:

1. Make sure the compressor clutch is engaged and the compressor is running. Listen for any signs of improper compressor operation.
2. Turn off the A/C clutch to make sure it releases smoothly. With the clutch released, listen for proper clutch bearing operation.

TECH TIP

Broken Condenser Line?—Check the Engine Mounts!

Most air-conditioning systems use aluminum and flexible rubber lines between the compressor and the condenser. Because the compressor is mounted on and driven by the engine and the condenser is mounted to the body, these lines can break if the engine mounts are defective. The rubber hoses attached between the aluminum fittings of the compressor and condenser are designed to absorb normal engine movement. Worn engine mounts would allow the engine to move too much. Aluminum lines cannot be flexed without crushing and breaking.

Therefore, the wise technician will carefully inspect and replace any and all worn engine mounts if a broken aluminum condenser line is discovered to prevent a premature failure of a replacement condenser.

3. Feel the temperature of the A/C lines and hoses. Be cautious on the high side because the lines should be warm to hot, with the temperature increasing. All the lines on the low side should be cool to cold, with the temperature getting colder. ● **SEE FIGURE 66–3**.
4. Feel the temperature of the heater hoses. If the engine is at operating temperature, both hoses should feel hot. Expect a temperature difference on heater systems with a coolant flow control valve.
5. Check the engine cooling fan operation (if running). The fan should be turning smoothly, with good airflow.

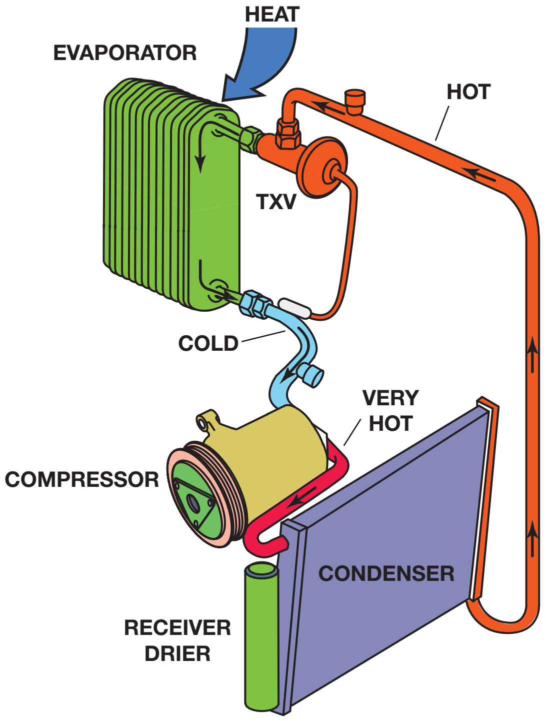

FIGURE 66–3 When a system is operating properly, the suction line to the compressor should be cool, and the discharge line should be hot to very hot. The liquid lines should also be hot.

6. Check the evaporator drain. After a few minutes of operation on a humid day, there should be a small puddle of water under the evaporator area and drops of water coming from the drain. With some vehicles, the drain is routed through a frame member. Check the service information for the location of the drain.

NOTE: In areas with very low humidity, water may not drain out.

7. With the engine still running, check inside the vehicle for overall operation. By now the A/C system should be delivering cool to cold air from the instrument panel registers. Refer to performance check for actual expected temperatures. Moving the temperature control should cause a temperature change. Changing the function control to heat should move the air discharge to floor level.

CHECK DTCS

CHECK UNDER BODY OR CHASSIS The third step in the strategy-based diagnosis process is to check for **diagnostic trouble codes (DTCs)** under chassis and body systems and do not just look under engines. Therefore, a global or generic scan tool that can read only "P" codes is not suitable for diagnosing an HVAC system. Engine or emission control-type codes are "P" codes, whereas module communications are "U" codes. These are most often found when looking for DTCs under chassis or body systems. Chassis-related codes are labeled "C" and body system-related codes are labeled "B" codes, and these can cause an HVAC issue if they affect a sensor that is used by the system. ● **SEE FIGURE 66–5**.

TECH TIP

Water on the Carpet? Check the Evaporator Water Drain

If the evaporator water drip tube becomes clogged with mud, leaves, or debris, water will build up inside the evaporator housing and spill out onto the carpet on the passenger side. Customers often think that the windshield or door seals are leaking. Most evaporator water drains are not visible unless the vehicle is hoisted. ● **SEE FIGURE 66–4**.

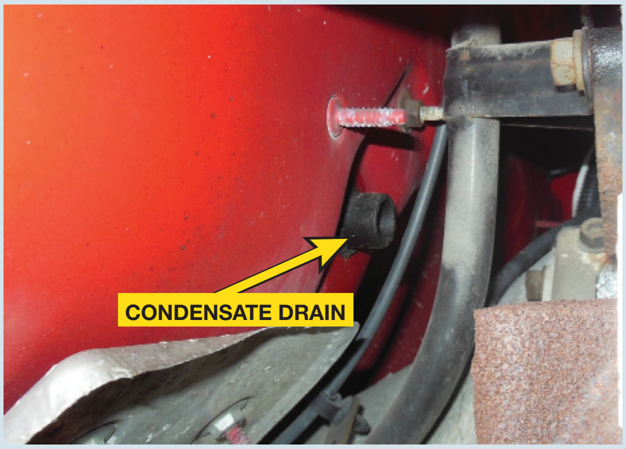

FIGURE 66–4 Check the condensate drain to be sure it is open if there is water on the carpet on the passenger side.

Check for any stored DTCs. While most HVAC-related trouble codes will be "B," "C," or "U" codes, there are some that are Powertrain-related P codes, including the following:

- P0645 A/C Clutch Relay Control Circuit
- P0646 A/C Clutch Relay Control Circuit Low
- P0647 A/C Clutch Relay Control Circuit High
- P0691 Fan 1 Control Circuit Low
- P0692 Fan 1 Control Circuit High
- P0693 Fan 2 Control Circuit Low
- P0694 Fan 2 Control Circuit High

These P codes can be read using global (generic) scan tools that are available at low cost. However, to get access to the codes set for most of the HVAC-related faults requires the use of a factory scan tool or an enhanced factory-level aftermarket scan tool. Many HVAC systems are controlled by the **body control module (BCM)**. The air-conditioning–related diagnostic trouble codes are usually found under "Body" or "Chassis," and if set, will NOT light the "check engine" warning light. The check engine light is called the *malfunction indicator light (MIL)* and is commanded on if there is a fault that can affect emissions. Because HVAC-related faults often do not affect emissions, a DTC will be stored and may light another warning lamp or a message on the dash, such as the "A/C on" lamp will flash to indicate that a fault has been detected with the HVAC system.

CHECK TSBs

FOURTH STEP The fourth step in the strategy-based diagnosis process is to check **technical service bulletins (TSBs)**. These are issued by vehicle and aftermarket manufacturers to inform technicians of a situation or technical problem and give the corrective steps and a list of parts needed to solve the problem. Any diagnostic trouble codes should be retrieved before looking at the technical service bulletins because many bulletins include what DTCs may or may not be present. TSBs are often released

Service Bulletin

FIGURE 66–6 After checking for stored DTCs, the wise technician checks service information for any technical service bulletins that may relate to the vehicle being serviced.

by new vehicle manufacturers to dealership service departments. ● **SEE FIGURE 66–6**.

While some of these TSBs concern minor problems covering few vehicles, many contain very helpful solutions to hard-to-find problems that cover many vehicles. TSBs can also be purchased through aftermarket companies that are licensed and available on a Web site. Visit the National Automotive Service Task Force (NASTF) Web site (www.NASTF.org) for a list of the Web addresses for all vehicle manufacturers' sites where the full text of TSBs can be purchased directly. Factory TSBs can often save the technician many hours of troubleshooting.

PERFORM A/C PERFORMANCE TEST

PROCEDURE The fifth step in the strategy-based diagnosis process is to perform an A/C performance test, which is used to determine if the system is capable of performing as designed. Most A/C performance tests include the following steps:

STEP 1 Install pressure gauges to the service ports.

STEP 2 Start the engine, set the parking brake, and raise the idle to 2000 RPM.

STEP 3 Measure ambient temperature 3 inches (80 mm) in front of the condenser and measure the humidity.

STEP 4 Place a thermometer in the air conditioner center vent. ● **SEE FIGURE 66–7**.

STEP 5 Set the air conditioner for maximum cooling.

STEP 6 Open the doors and set the blower speed to high, which applies the maximum load on the system.

STEP 7 Allow the system to operate for another five minutes before recording the gauge readings.

- Check the sight glass (if equipped). Clear? Bubbles? Foam?
- Check the A/C lines for frosting:
  - Low-Side Lines: Frosted (indicates low refrigerant level and should be corrected before continuing the test).
  - High-Side Lines: Frosted (indicates a restriction where the frost begins and should be corrected before continuing the test).

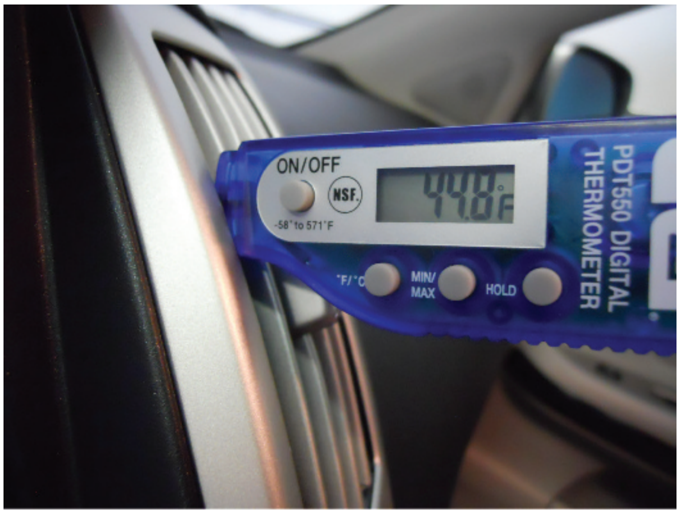

FIGURE 66–7 A digital thermometer checking the duct (vent) temperature.

LOW SIDE	HIGH SIDE	CONDITION (POSSIBLE CAUSE)
25–35 PSI	170–200 PSI	Normal
Low	Low	Low refrigerant charge level
Low	High	Restriction in high-side line
High	High	System is overcharged Expansion valve stuck open
High	Low	Restriction in the low-side line

CHART 66–1

Pressure gauge readings and possible causes.

SYSTEM TEST RESULTS Wait several minutes to allow the system to reach maximum output and observe the thermometer.

- If 35°F to 45°F (2°C to 7°C) or 30°F (15°C) cooler than the outside air temperature, the system is functioning normally.
- If over 45°F (7°C) or over 30°F (15°C) warmer than the outside air temperature, continue with pressure gauge testing.

If pressures are okay and the sight glass is clear, but vent temperature is high, check for a blend door or heater control valve problem, or look for a possible system oil overcharge. If pressures vary from specifications, perform further tests to locate the problem. ● **SEE CHART 66–1**.

ROOT CAUSE

TEMPERATURE AND PRESSURE MEASUREMENTS The sixth step in the strategy-based diagnosis process is to find the root cause of the customer concern. Temperature and pressure are directly related in A/C systems. As the ambient temperature

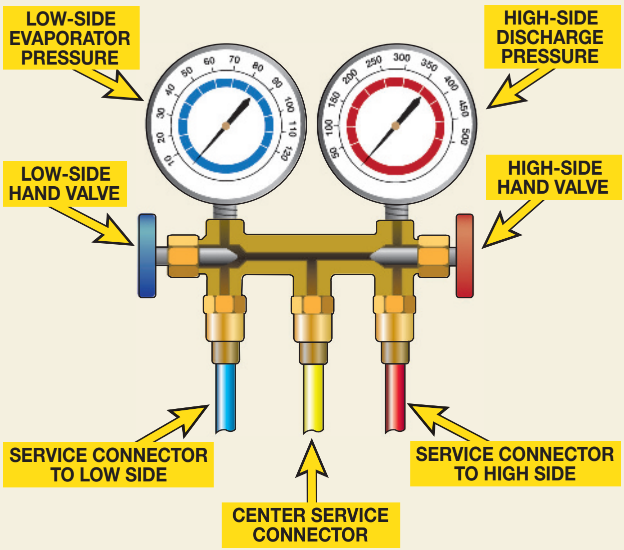
FREQUENTLY ASKED QUESTION

What Is the Center Yellow Hose Used For on a Gauge Set?

The center (yellow hose) port to the utility chamber (hose) is to

- add or remove refrigerant
- pull a vacuum on the system
- transfer refrigerant to cylinder.

The utility hose is where these accessories are connected. ● **SEE FIGURE 66–8**.



LOW-SIDE EVAPORATOR PRESSURE
HIGH-SIDE DISCHARGE PRESSURE

HIGH-SIDE HAND VALVE
SERVICE CONNECTOR TO LOW SIDE
SERVICE CONNECTOR TO HIGH SIDE
CENTER SERVICE CONNECTOR

FIGURE 66–8 The center, yellow hose is used to connect the air-conditioning system to a vacuum pump or refrigerant cans. When the hose is not being used, it should be attached to the blanks fitting to seal the system.

AMBIENT AIR TEMPERATURE	HUMIDITY	LOW-SIDE PRESSURE (PSI)	HIGH-SIDE PRESSURE (PSI)
70°F/21°C	Low	25–30	140–190
	High	28–35	165–220
80°F/27°C	Low	26–33	150–200
	High	30–36	190–260
90°F/32°C	Low	31–37	170–220
	High	37–45	210–290
100°F/38°C	Low	35–44	195–245
	High	38–48	230–320
110°F/43°C	Low	40–50	235–285
	High	42–52	260–350

CHART 66–2

The average R-134a pressure–temperature readings during a performance test. The pressures for R-1234yy will be similar.

LOW SIDE	HIGH SIDE	DUCT (VENT) TEMPERATURE	POSSIBLE CAUSE
Normal	Normal	Cold/normal	Operating as designed
Low	Low	Warm	Low refrigerant charge
High	High	Warm	Overcharged
High	High	Slightly cool	Overcharged or air in the system
Normal	Normal	Warm	Moisture in the system
Low	Low	Warm	High side restriction
Low	Low	Warm	Expansion valve stuck closed or orifice tube clogged
High	Low	Warm	Compressor or control valve failure

CHART 66–3

Diagnostic chart that can help determine the root cause of a lack-of-cooling customer concern.

increases, the high-side pressure must also increase to have a heat transfer at the condenser.

The temperature of the vapor must be higher than the ambient temperature to allow enough heat to be removed for condensation. Also, higher ambient temperatures, and high humidity, usually mean a higher heat load on the evaporator. This means a larger quantity of heat has to be removed at the condenser.

- The high-side pressure is directly related to the amount of heat that needs to be removed, and the heat transfer at the condenser.
- Low-side pressure indicates the boiling point of the temperature of the evaporator. If the pressure is too high, the boiling point of the refrigerant and temperature of the evaporator are too high. Low-side pressure that is too low indicates the evaporator is too cold and may ice, or that there is not enough boiling refrigerant in the evaporator to remove an adequate amount of heat. ● **SEE CHARTS 66–2 AND 66–3**.

Insufficient heat transfer at the condenser is usually the cause of high-side pressure that is too high. The number 1 cause of poor heat transfer is lack of airflow across the condenser.

The vehicle is dependent upon portable fans to move enough air when testing in the shop. It may be necessary to drive the vehicle at 30 MPH (48 km/h) to get the ram air necessary to determine if lack of airflow is the reason for the poor heat transfer.

Another cause of excessive high-side pressure is contamination with a different refrigerant. Mixing R-12 and R-134a raises the condensing pressure of the mixture. If the system is contaminated with R22, the pressures can become extremely high. At 150°F, the pressure of R-12 is 235 PSI (1,620 kPa), R-134a is 263 PSI (1,813 kPa), and R-22 is 381 PSI (2,627 kPa).

This is an important reason to use a refrigerant identifier. ● **SEE FIGURES 66–9 THROUGH 66–15**.

TEMPERATURE DIFFERENCES ACROSS COMPONENTS Test for heat transfer at the evaporator and the condenser.

- Temperature change across the evaporator—The temperature difference between the inlet and outlet of the evaporator should be the same or within 5° (−5° to +5°). If the temperature at the evaporator outlet is more than 6° different than the inlet temperature, the system is overcharged.

- Temperature change across the condenser—The temperature difference between the inlet and outlet of the condenser should be 20°F to 50°F (10°C to 30°C).
- If the temperature difference is higher than 50°, the system is undercharged or has a restriction.
- If the temperature difference is less than 19°, the system is overcharged.

ADDRESSING SYSTEM ODORS

SOURCE OF ODORS Some systems develop a musty, moldy smell, which is not really a fault of the system.

Some sources classify these odors into two types:

- "Dirty socks/gym locker" odor, which has an organic cause
- "Refrigerator, cement, or dusty room" odor, which is caused by chemicals

The organic odor problem is most common in areas with high relative humidity, and it is caused by mildew-type fungus growth on the evaporator and in the evaporator plenum. Modern evaporators have more fins that are closer together, and they tend to trap more moisture and bacterial growth.

The cool surface of the evaporator collects moisture as it dehumidifies the air, and most of this moisture runs out the bottom of the case. After a vehicle is shut off, the moist surface of the evaporator warms up, and this warm, wet area becomes an ideal environment for fungus and bacteria growth. A coating is applied to many evaporators to speed up water runoff, which helps dry the evaporator and reduce bacterial growth. Airborne bacteria also collect on this surface, and if the surface stays moist, these bacteria will live and grow, creating the unpleasant smell. Then when the air-conditioning or blower motor is turned on, that smell blows through the vehicle.

Several companies market chemicals, essentially fungicides, to kill the bacterial growth, or detergents to clean the evaporator

TECH TIP

The Clogged Orifice Tube Test

A clogged orifice tube is a common air-conditioning system failure. When the orifice tube becomes clogged, it blocks the flow of refrigerant through the evaporator, which causes a reduced cooling of the passenger compartment. To check for a possible restriction in the system, follow these easy steps:

STEP 1 Connect the A/C pressure gauge to both low- and high-side pressure fittings.

STEP 2 Operate the A/C system for 5 minutes to 10 minutes.

STEP 3 Shut off the A/C system and watch the pressure gauges. If the pressures do not equalize quickly, there is a restriction in the system. Normal time needed to equalize is often 15 seconds to 30 seconds, depending on the amount of refrigerant. ● **SEE FIGURE 66–16.**

NOTE: To locate a restriction anywhere in the system, feel along the system lines. The restriction exists at the point of greatest temperature difference. "Frosting" is a good indication of a restriction.

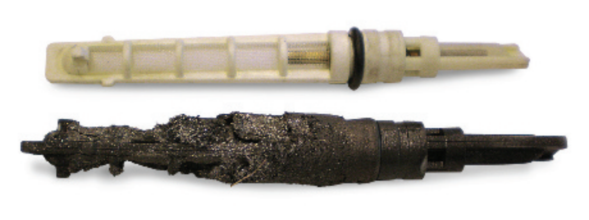

FIGURE 66–16 A new orifice tube (top) compared to a clogged orifice tube (bottom).

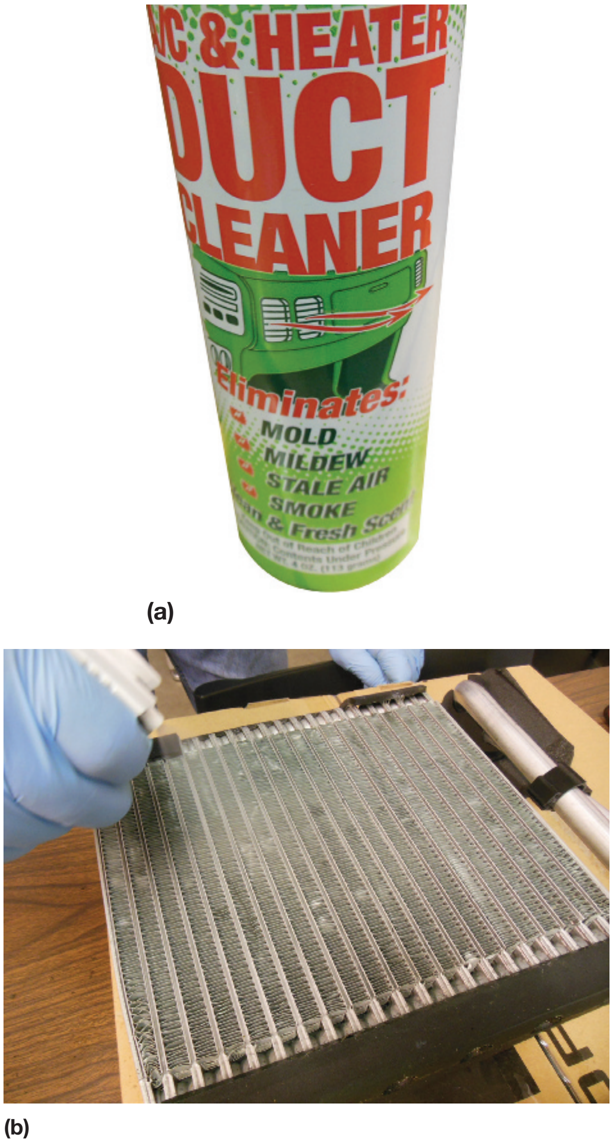

(a)

(b)

FIGURE 66–17 (a) A spray can of mold and mildew eliminator available at local parts stores and used on the evaporator before installing it into the vehicle is good insurance against HVAC-related odors. (b) Spraying the clear liquid mold and mildew eliminator onto the surface of the replacement evaporator prior to installation.

core. Some of these chemicals and a procedure to use them have been approved by vehicle manufacturers. These chemicals are sprayed into the ductwork or onto the evaporator fins. ● **SEE FIGURE 66–17.**

Some manufacturers install an **electronic evaporator dryer (EED)**, also called an **after-blow module**. In some vehicles, the A/C control module is programmed to operate the blower for a drying cycle after the car is shut off. This device turns on the blower (with the ignition switched off for 30 minutes to 50 minutes) and lets it run long enough to dry off the evaporator after the vehicle has been shut off. One system waits 10 minutes, runs the blower on high for 10 seconds, shuts down for another 10 minutes, and then repeats the 10-second operation and 10-minute pause for 10 cycles. The objective is to blow the moist air out of the evaporator without discharging the battery. EED modules are available for vehicles with either ground or B+ side blower switch systems.

NOISE ISSUES

COMMON CAUSES The A/C system is the potential source for several noise problems, and the compressor and clutch are the main culprits.

- A moaning or growling noise is a relatively low-frequency noise caused by something moving slowly.
- A whine or squeal is a high-pitch and high-frequency noise produced by something moving rapidly.

Another problem can be **groundout**, in which a vibrating metal A/C line contacts another surface (flat surfaces produce the most noise). Groundout problems also occur when the exhaust pipes make metal-to-metal contact with the vehicle body.

REPAIR THE SYSTEM

PURPOSE The purpose of any repair is to restore the system to like-new condition. Typical repairs include the replacement of components, such as the accumulator, compressor, evaporator, condenser, and refrigerant lines/hoses.

TYPICAL REPAIRS Many repairs require the proper identification, recovery, evacuation, and charging of the refrigerant. After the repairs, the system should function and operate as designed and the repair should be performed according to established industry and vehicle manufacturer's recommendations. All safety precautions should be adhered to and the refrigerant handled according to federal and local laws.

VERIFY THE REPAIR After the repairs or service procedures have been performed, verify that the system is working as designed. If needed, drive the vehicle under the same conditions as when the customer concern was corrected to verify the repair. Document the work order and return the vehicle to the customer in clean condition.

LEAK DETECTION

PURPOSE If the A/C system is low on a charge of refrigerant, the sources of the leak should be found and corrected. Look for oily areas that are formed when refrigerant leaks and some refrigerant oil is lost. It is this oil that indicates a refrigerant leak. ● **SEE FIGURE 66–18**.

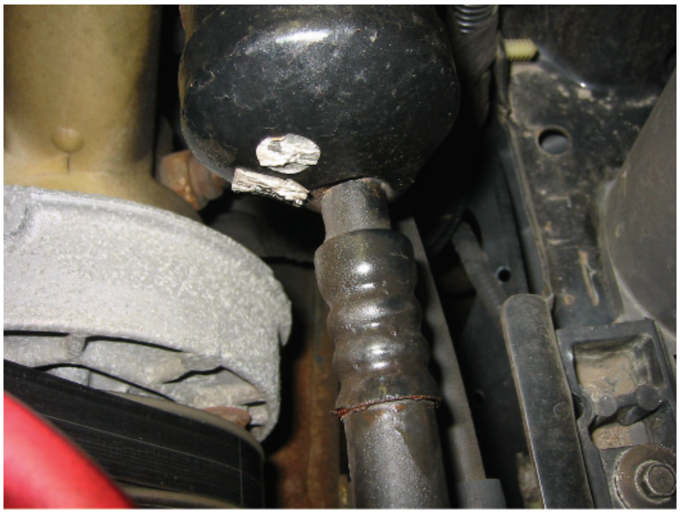

FIGURE 66–18 A through visual inspection is used to locate refrigerant leaks by looking for oily areas usually near fittings.

FREQUENTLY ASKED QUESTION

What Is the Procedure to Retrofit an Air-Conditioning System from R-12 to R-134a?

To retrofit a system, perform the following steps:

STEP 1 Visually inspect the system to ensure good condition, install a gauge set, and operate the system to bring it up to operating temperatures. Check for proper operation and note any needed repairs. Record the high-side pressure for later comparison.

STEP 2 Recover the R-12 from the system and remove as much oil-dissolved R-12 as possible.

STEP 3 Make any repairs to the system to cure problems that were found in step 1.

STEP 4 If the compressor failed, remove the failed compressor, flush the system and/or install a high-side filter, and install the replacement compressor along with a new accumulator or receiver–drier.

STEP 5 Check the system to determine whether a high-pressure relief valve is used. If it has one, a high-pressure cutoff switch must be installed to stop the compressor before pressure relief valve release pressures occur. The switch is installed so it senses high-side pressure and is wired into the clutch circuit or relay so it can interrupt clutch operation.

STEP 6 If directed, replace the receiver–drier or accumulator.

STEP 7 Replace any line-fitting O-rings on connections that were disturbed, or as directed.

STEP 8 Replace any switches and valves as directed.

STEP 9 Add the proper type and amount of oil—ester or PAG—into the compressor oil fill port or suction port. If the accumulator or receiver–driver is replaced, pour part of the oil into the inlet port.

STEP 10 Install the R-134a service fittings. Old Schrader valves that remain in service should be replaced with new R-134a valves.

STEP 11 Fill out and install the identifying decal to properly identify the system. The old label must be rendered unreadable.

STEP 12 Connect a vacuum pump to the system and pull a minimum vacuum of 29 inch Hg (500 microns) for at least 30 minutes to evacuate the system.

STEP 13 Recharge the system using R-134a. Charge the system with 80% to 90% of the specified amount of R-12.

STEP 14 Operate the system and check for proper operation, paying careful attention to the high-side pressure.

STEP 15 Test for leaks.

ELECTRONIC LEAK DETECTION

The use of an **electronic leak detector** meeting SAE J1628 is the most used method that experts and vehicle manufacturers recommend to find refrigerant leaks. Detector devices that are the most sensitive are capable of finding smaller leaks. SAE standards and their use and sensitivity include the following:

- **J1627**—Detectors certified under this standard are capable of detecting leaks that result in a loss of refrigerant of 0.5 oz per year at a distance of 0.25 inch (6 mm).
- **J2791**—Detectors certified under this standard are for use with R134a systems and are capable of detecting leaks as small as 0.15 oz at a distance of 0.375 inch (10 mm).
- **J2913**—Detectors certified under this standard are for use with R1234yf systems and are capable of detecting leaks as small as 0.15 oz at a distance of 0.375 inch (10 mm).

Before using an electronic leak detector, perform a visual inspection and check the entire refrigerant system for traces of oil, which usually indicates the location of a refrigerant leak.

According to the SAE J1628 service procedure, the system does not need to be fully charged. The system just needs a few ounces of refrigerant to achieve a pressure of at least 50 PSIG for most detectors to find leaks.

Perform leak detection by pointing the sensor above, below, and around each hose, component, and refrigerant line. ● **SEE FIGURE 66–19**.

CAUTION: If less than a full refrigerant charge, do not start the engine and operate to the A/C compressor to avoid possible compressor damage due to a lack of refrigerant oil being circulated through the system.

DYE LEAK DETECTION

Ultraviolet (UV) fluorescent trace dye is added to some refrigerant to help the technician visually spot a leak in the refrigerant system. A typical UV dye leak kit contains the following components:

- Dye formulated for use in an air-conditioning refrigerant
- Dye injector usually a hand-operated injector used to introduce the dye into the system
- UV flashlight used to light the area so that the dye is easily seen
- Special yellow-colored goggles to protect the eyes from the UV and also helps the user to see the dye's fluorescence.

Always follow the instructions that came with the dye kit. To successfully use dye, the system should be fully charged with refrigerant.

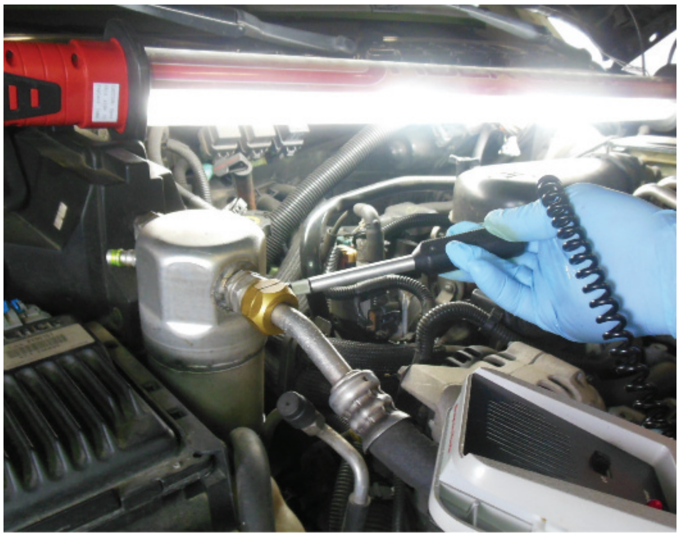

FIGURE 66–19 An electronic leak detector being used to locate a possible leak in a system. For best results, move the detector probe completely around each fitting and connection.

USING DYE

Dye is very corrosive so most dye kit instructions state to only use ¼ ounce (7 grams). The dye is added to the low side using the supplied installation device. The air-conditioning system should be operated to allow the dye to circulate through the system. The refrigerant leaks out as a gas and escapes into the atmosphere, but the dye circulates throughout the system with the refrigerant oil. Leaks can be viewed by the technician using the light supplied with the dye kit. It may take just a few minutes for the dye to be seen from a leak if a large leak is present or it can take several days for a smaller leak to be seen. Many A/C compressors use an **oil trap** to help the oil in the compressor. This method is not as efficient as it has been in the past when used with older systems. Dye works well except for leaks in the evaporator, which are usually not visible unless the UV light is used at the evaporator drain. ● **SEE FIGURE 66– 20**.

SOAPY WATER

Mix a few drops of liquid soap or detergent into a small glass of water. Using a small brush or a small spray bottle, apply the soapy solution to all fittings and other areas such as the condenser and compressor, which often are sources of leaks. Using soapy water is a safe and low-cost method but it is not very accurate at finding refrigerant leaks, especially small leaks.

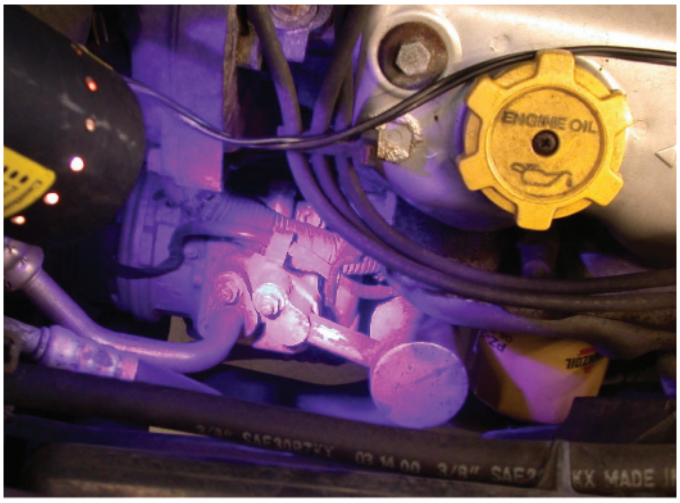

FIGURE 66–20 An ultraviolet (UV) light being used to look for refrigerant leakage after a fluorescent dye was installed in the system.

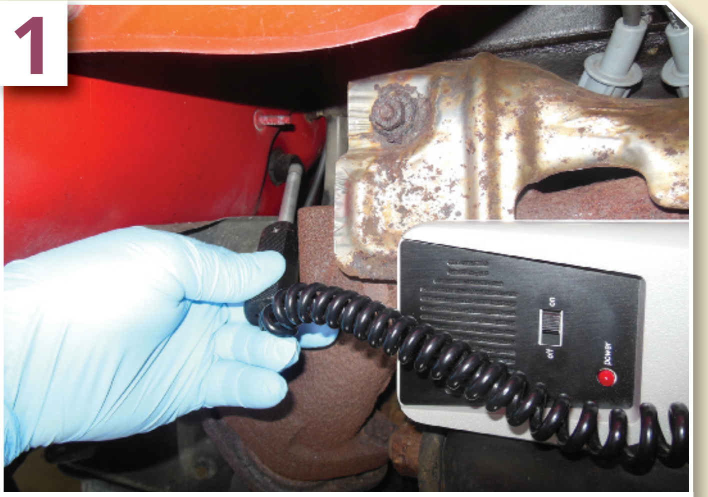
LACK OF COOLING DIAGNOSIS AND REPAIR

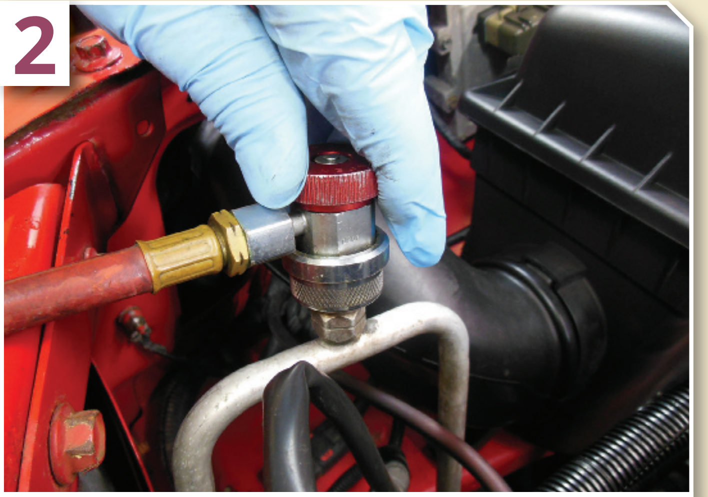
1



on
off
power

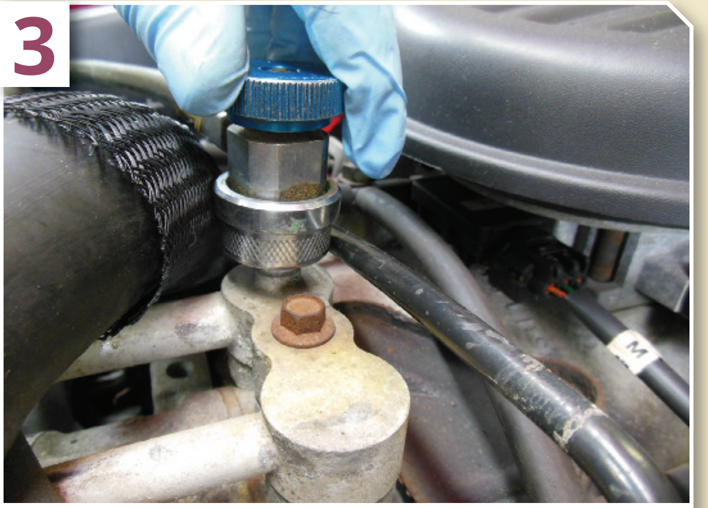
The lack of cooling was diagnosed using a leak detector, which showed the evaporator was leaking when tested at the condensate drain.

2



The recovery process was started by connecting an RRR machine to the high-side fitting.

3



The low-side fitting was connected and the recovery was begun.

4

0.1

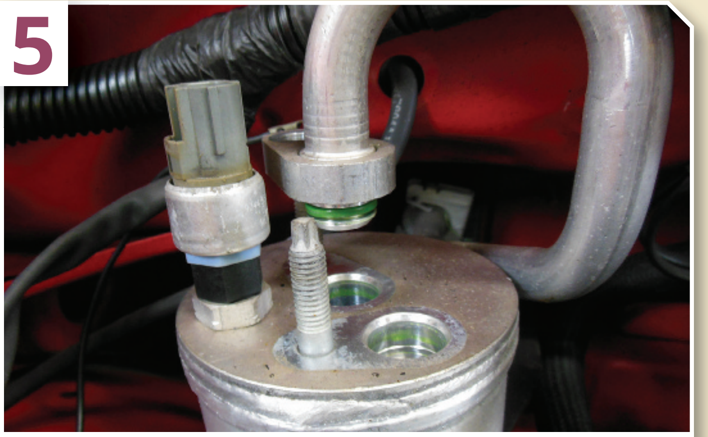
34a

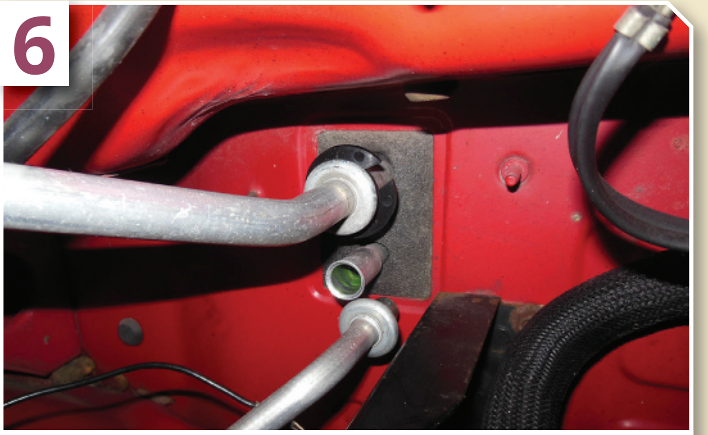
Very little refrigerant was left in the system (0.1 pound) but it was recovered.

5



The lines to the accumulator were removed.

6



The lines to the evaporator were disconnected using a quick connect tool to release the fitting.

7

The retaining nuts were removed that held the HVAC case to the bulkhead from under the hood. In one case, the entire stud came out instead of just the nut.

8

Before going into the passenger compartment, the negative battery cable was disconnected from the battery.

9

The dash assembly is being removed, and this process includes disconnecting the airbag wiring connectors.

10

The driver/passenger side of the dash is removed to gain access to the additional fasteners.

11

The two retaining fasteners that hold the steering column to the dash are removed and the steering column lowered into the seat, which is protected using a fender cover.

12

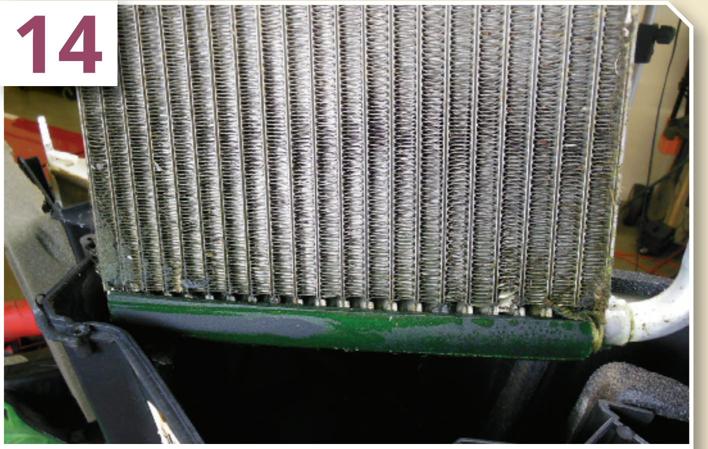
The entire dash assembly is being gently removed.

LACK OF COOLING DIAGNOSIS AND REPAIR

13

The HVAC case is being disassembled after being removed from the vehicle.

14

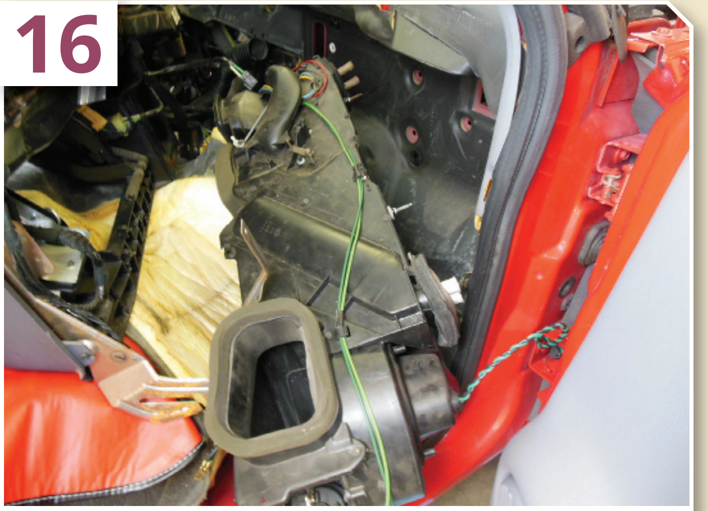


The evaporator is removed, and it shows signs of leaking. The root cause of the lack of cooling has been found.

15

The heater core was also removed and replaced at the same time as insurance against possible future leaks from this unit.

16



The reassembled HVAC case is now being installed back into the vehicle.

17

A new accumulator is installed.

The system was evacuated and charged to the specified amount, and the pressure gauge and temperature reading indicated that the system was restored to like-new performance.

REVIEW QUESTIONS

1. What are the steps that a technician should follow when diagnosing and repairing an air-conditioning–related problem?
2. What should be checked as part of a visual inspection?
3. Why should the diagnostic trouble codes be checked before checking for technical service bulletins?
4. What does the temperature difference across the condenser and evaporator tell the technician?
5. What is required if retrofitting an air-conditioning system from R-12 to R-134a?

CHAPTER QUIZ

1. When should the service technician check for technical service bulletins?
   - **a.** As soon as the work order is received with the customer complaint shown
   - **b.** Before performing a visual inspection
   - **c.** After checking for any stored diagnostic trouble codes
   - **d.** After making the repair
2. Clear water is seen dripping from beneath the vehicle on the passenger side. This means __________.
   - **a.** normal operation
   - **b.** possible clogged evaporator
   - **c.** possible restricted condenser
   - **d.** receiver–drier is at the end of its normal life
3. What should the technician use when checking for diagnostic trouble codes?
   - **a.** Any global (generic) scan tool that can read body and/or chassis codes
   - **b.** Any enhanced scan tool that can read body and/or chassis codes
   - **c.** Only a factory scan tool can be used
   - **d.** A paper clip because it is needed to read codes
4. What could be wrong if the A/C compressor clutch cycles on and off rapidly?
   - **a.** Defective A/C compressor
   - **b.** Defective A/C compressor clutch
   - **c.** Low refrigerant charge
   - **d.** Shorted compressor clutch diode
5. The low-side pressure is low and the high-side pressure is higher than normal. What is the most likely cause?
   - **a.** Low refrigerant charge level
   - **b.** System is overcharged; expansion valve stuck open
   - **c.** Restriction in the low-side line
   - **d.** Restriction in high-side line
6. The temperature difference between the inlet and outlet of the condenser should be __________.
   - **a.** equal
   - **b.** 10°F to 30°F
   - **c.** 20°F to 50°F
   - **d.** greater than 60°
7. Most A/C performance tests include __________.
   - **a.** start the engine, set the parking brake, and raise the idle to 2000 RPM
   - **b.** measure ambient temperature 3 inches (80 mm) in front of the condenser and measure the humidity
   - **c.** open the doors and set the blower speed to high, which applies the maximum load on the system
   - **d.** All of the above
8. Where should a leak detector be used when checking for refrigerant leaks?
   - **a.** Around hoses and fittings
   - **b.** At the condensate drain
   - **c.** Around the compressor and lines
   - **d.** All of the above
9. The temperature outside is 90°F (32°C) and the humidity is high. With the A/C operating, what should the high side gauge read?
   - **a.** 31–37 PSI
   - **b.** 210–290 PSI
   - **c.** Less than 150 PSI
   - **d.** 170–210 PSI
10. A musty, moldy smell in the air-conditioning system is usually due to __________.
    - **a.** mildew-type fungus growth
    - **b.** a restricted evaporator
    - **c.** a clogged condenser
    - **d.** a weak or defective AC compressor

Chapter 67

GASOLINE, ALTERNATIVE FUELS, AND DIESEL FUELS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss the characteristics of gasoline and refining of gasoline.
- Discuss the volatility of gasoline.
- Explain air–fuel ratios.
- Explain normal and abnormal combustion.
- Explain octane rating.
- Discuss gasoline additives.
- Discuss testing gasoline for alcohol content.
- Discuss general gasoline recommendations.
- Discuss E85.
- Discuss alternative fuel vehicles.
- Discuss propane.
- Discuss compressed natural gas fuels.
- Discuss diesel fuel.
- Discuss biodiesel.

KEY TERMS:

GASOLINE

REFINING **Gasoline** is a term used to describe a complex mixture of various hydrocarbons refined from crude petroleum oil for use as a fuel in engines. Gasoline and air burns in the cylinder of the engine and produces heat and pressure, which is transferred to rotary motion inside the engine and eventually powers the drive wheels of a vehicle. When the combustion process in the engine is perfect, all of the fuel and air are consumed and only carbon dioxide and water are produced.

DISTILLATION In the late 1800s, crude was separated into different products by boiling in a process called **distillation**. Distillation works because crude oil is composed of hydrocarbons with a broad range of boiling points.

In a distillation column, the vapor of the lowest boiling hydrocarbons, propane and butane, rises to the top. The straight-run gasoline (also called naphtha), kerosene, and diesel fuel cuts are drawn off at successively lower positions in the column.

CRACKING **Cracking** is the process during which hydrocarbons with higher boiling points can be broken down (cracked) into lower boiling hydrocarbons by treating them to very high temperatures. This process, called *thermal cracking,* was used to increase gasoline production starting in 1913.

Today, instead of high heat, cracking is performed using a catalyst and is called **catalytic cracking**. A catalyst is a material that speeds up or otherwise facilitates a chemical reaction without undergoing a permanent chemical change itself. Catalytic cracking produces gasoline of higher quality than thermal cracking.

Hydrocracking is similar to catalytic cracking in that it uses a catalyst, but the catalyst is in a hydrogen atmosphere. Hydrocracking can break down hydrocarbons that are resistant to catalytic cracking alone and it is used to produce diesel fuel rather than gasoline.

Other types of refining processes include the following:

- Reforming
- Alkylation
- Isomerization
- Hydrotreating
- Desulfurization

● **SEE FIGURE 67–1**.

SHIPPING The gasoline is transported to regional storage facilities by tank railway car or by pipeline. In the pipeline method, all gasoline from many refiners is often sent through the same pipeline and can become mixed. All gasoline is said to be **fungible**, meaning that it is capable of being interchanged because each

grade is created to specification so there is no reason to keep the different gasoline brands separated except for grade. Regular grade, midgrade, and premium grades are separated by using a device, called a *pig*, in the pipeline and sent to regional storage facilities. ● **SEE FIGURE 67–2**.

It is at these regional or local storage facilities where the additives and dye (if any) are added and then shipped by truck to individual gas stations.

VOLATILITY

DEFINITION **Volatility** describes how easily the gasoline evaporates (forms a vapor). The definition of volatility assumes that the vapors will remain in the fuel tank or fuel line and will cause a certain pressure based on the temperature of the fuel.

REID VAPOR PRESSURE **Reid vapor pressure (RVP)** is the pressure of the vapor above the fuel when the fuel is at 100°F (38°C). Increased vapor pressure permits the engine to start in cold weather. Gasoline without air will not burn. Gasoline must be vaporized (mixed with air) to burn in an engine. ● **SEE FIGURE 67–3**.

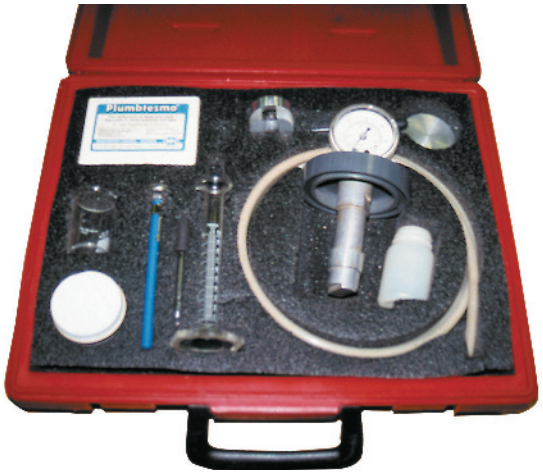

FIGURE 67–3 A gasoline testing kit, including an insulated container where water at 100°F is used to heat a container holding a small sample of gasoline. The reading on the pressure gauge is the Reid vapor pressure (RVP).

FREQUENTLY ASKED QUESTION

Why Do I Get Lower Gas Mileage in the Winter?

Several factors cause the engine to use more fuel in the winter than in the summer:

- Gasoline that is blended for use in cold climates is designed for ease of starting and contains fewer heavy molecules, which contribute to fuel economy. The heat content of winter gasoline is lower than summer-blend gasoline.
- In cold temperatures, all lubricants are stiff, causing more resistance. These lubricants include the engine oil, as well as the transmission and differential gear lubricants.
- Heat from the engine is radiated into the outside air more rapidly when the temperature is cold, resulting in longer run time until the engine has reached normal operating temperature.
- Road conditions, such as ice and snow, can cause tire slippage or additional drag on the vehicle.

SEASONAL BLENDING Cold temperatures reduce the normal vaporization of gasoline; therefore, winter-blended gasoline is specially formulated to vaporize at lower temperatures for proper starting and driveability at low ambient temperatures.

- **Winter blend.** The **American Society for Testing and Materials (ASTM)** standards for winter-blend gasoline allow volatility of up to 15 pounds per square inch (PSI) RVP.
- **Summer blend.** At warm ambient temperatures, gasoline vaporizes easily. However, the fuel system (fuel pump, fuel-injector nozzles, etc.) is designed to operate with liquid gasoline. The volatility of summer-grade gasoline should be about 7 PSI RVP. According to ASTM standards, the maximum RVP should be 10.5 PSI for summer-blend gasoline.

VOLATILITY-RELATED PROBLEMS If using winter-grade fuel during warm weather, the following may occur:

- Heat causes some fuel to evaporate, thereby causing bubbles.
- When the fuel is full of bubbles (sometimes called *vapor lock*), the engine is not being supplied with enough fuel and the engine runs lean. A lean engine will lead to the following:
  1. Rough idle
  2. Stalling
  3. Hesitation on acceleration
  4. Surging

If using summer-grade fuel in cold temperatures, the engine will be hard to start (long cranking before starting) due to the lack of volatility to allow the engine to start easily.

AIR–FUEL RATIOS

DEFINITION The **air–fuel ratio** is the proportion by weight of air and gasoline that the injection system mixes as needed for engine combustion. Air–fuel ratios in which a gasoline engine can operate without stalling range from 8:1 to 18.5:1. ● **SEE FIGURE 67–4**.

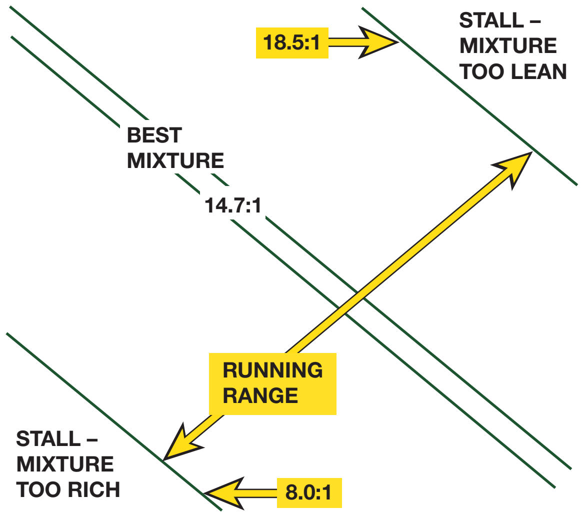

FIGURE 67–4 An engine will not run if the air–fuel mixture is either too rich or too lean.

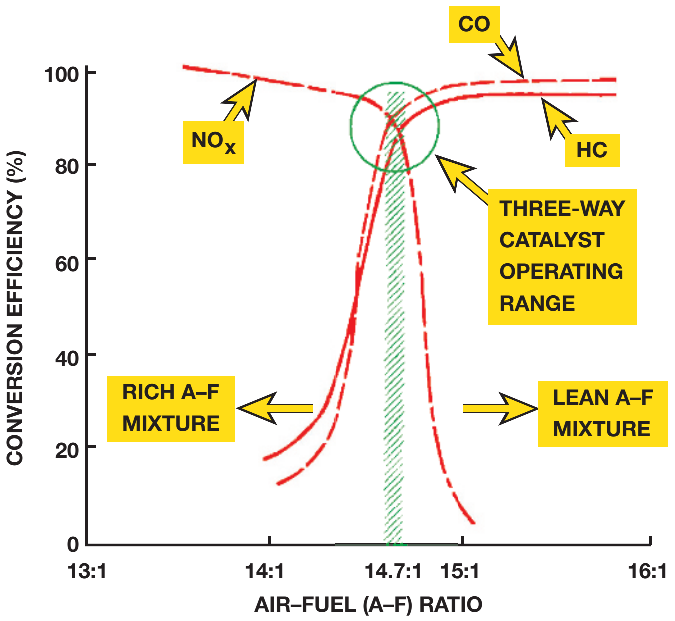

FIGURE 67–5 With a three-way catalytic converter, emission control is most efficient with an air–fuel ratio between 14.65:1 and 14.75:1.

These ratios are usually stated by weight, as follows:

- 8 parts of air by weight combined with 1 part of gasoline by weight (8:1), which is the richest mixture that an engine can tolerate and still fire reliably
- 18.5 parts of air mixed with 1 part of gasoline (18.5:1), which is the leanest practical ratio

Richer or leaner air–fuel ratios cause the engine to misfire badly or not run at all.

STOICHIOMETRIC AIR–FUEL RATIO The ideal mixture or ratio at which all of the fuel combines with all of the oxygen in the air and burns completely is called the **stoichiometric** ratio, a chemically perfect combination. In theory, this ratio for gasoline is an air–fuel mixture of 14.7:1. The stoichiometric ratio is a compromise between maximum power and maximum economy. ● **SEE FIGURE 67–5**.

NORMAL AND ABNORMAL COMBUSTION

TERMINOLOGY The **octane rating** of gasoline is the measure of its antiknock properties. **Spark knock** (also called **detonation** or **ping**) is a metallic noise an engine makes, usually during acceleration, resulting from abnormal or uncontrolled combustion inside the cylinder. Normal combustion occurs smoothly and progresses across the combustion chamber from the point of ignition. ● **SEE FIGURE 67–6**.

Normal flame-front combustion travels between 45 and 90 mph (72 and 145 km/h). The speed of the flame front depends on air–fuel ratio, combustion chamber design (determining amount of turbulence), and temperature.

ABNORMAL COMBUSTION During periods of abnormal combustion, called spark knock or detonation, the combustion speed increases by up to 10 times to near the speed of sound. The increased combustion speed also causes increased temperatures and pressures, which can damage pistons, gaskets, and cylinder heads. ● **SEE FIGURE 67–7**.

CONTROLLING SPARK KNOCK Spark knock was commonly heard in older engines, especially when under load and in warm weather temperatures. Most engines built since the 1990s are equipped with a knock sensor that is used to signal the powertrain control module (PCM) to retard the ignition timing if knock is detected. Using the proper octane fuel helps to ensure that spark knock does not occur.

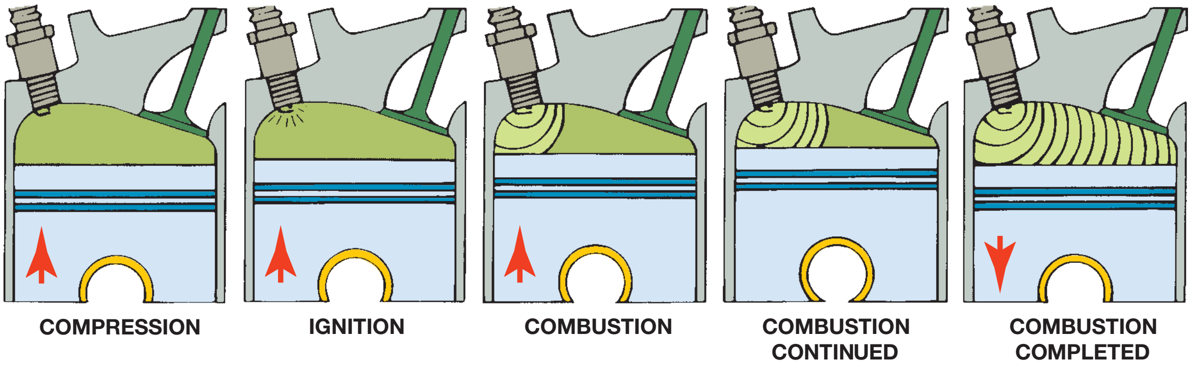

FIGURE 67–6 Normal combustion is a smooth, controlled burning of the air–fuel mixture.

FIGURE 67–7 Detonation is a secondary ignition of the air–fuel mixture. It is also called spark knock or pinging.

OCTANE RATING

RATING METHODS The two basic methods used to rate gasoline for antiknock properties (octane rating) include the *Research method* and the *Motor method.*

Each uses a model of the special *cooperative fuel research* (CFR) single-cylinder engine to test the octane of a fuel sample, and the two methods use different engine settings. The research method typically results in readings that are 6 to 10 points higher than those of the motor method. For example, a fuel with a research octane number (RON) of 93 might have a motor octane number (MON) of 85.

GASOLINE GRADES The octane rating posted on pumps in the United States is the average of the two methods and is referred to as R + M ÷ 2, meaning that, for the fuel used in the previous example, the rating posted on the pumps would be the following:

$$\frac{\text{RON} + \text{MON}}{2} = \frac{93 + 85}{2} = 89$$

This pump octane rating is often called the **antiknock index (AKI)**.

● **SEE FIGURE 67–8.**

Except in high-altitude areas, the grades and octane ratings are shown in ● **CHART 67–1**.

FREQUENTLY ASKED QUESTION

What Grade of Gasoline Does the EPA Use When Testing Engines?

Due to the various grades and additives used in commercial fuel, the government (EPA) uses a liquid called indolene, which has a research method octane number of 96.5 and a motor method octane rating of 88, resulting in a (R + M) ÷ 2 rating of 92.25.

TECH TIP

Horsepower and Fuel Flow

To produce 1 hp, the engine must be supplied with 0.50 lb of fuel per hour (lb/hr). Fuel injectors are rated in pounds per hour. For example, a V-8 engine equipped with 25 lb/hr fuel injectors could produce 50 hp per cylinder (per injector) or 400 hp. Even if the cylinder head or block is modified to produce more horsepower, the limiting factor may be the injector flow rate.

The following are flow rates and resulting horsepower for a V-8 engine:

- 30 lb/hr: 60 hp per cylinder, or 480 hp
- 35 lb/hr: 70 hp per cylinder, or 560 hp
- 40 lb/hr: 80 hp per cylinder, or 640 hp

Of course, injector flow rate is only one of many variables that affect power output. Installing larger injectors without other major engine modifications could decrease engine output and drastically increase exhaust emissions.

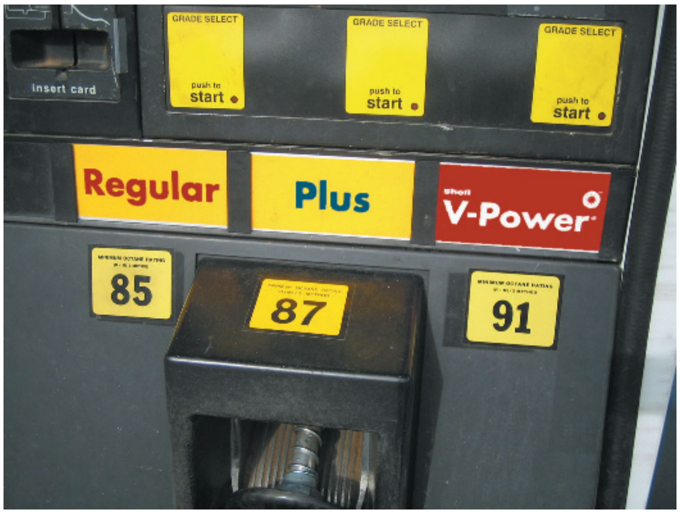

FIGURE 67–9 The posted octane rating in most high-altitude areas shows regular at 85 instead of the usual 87.

OCTANE EFFECTS OF ALTITUDE As the altitude increases, atmospheric pressure drops. The air is less dense because a pound of air takes more volume. The octane rating of fuel does not need to be as high because the engine cannot take in as much air. This process will reduce the combustion (compression) pressures inside the engine. In mountainous areas, gasoline (R + M) ÷ 2 octane ratings are two or more numbers lower than normal (according to the SAE, about one octane number lower per 1,000 ft (300 m) in altitude). ● **SEE FIGURE 67–9**.

A second reason for the lowered octane requirement of engines running at higher altitudes is the normal enrichment of the air–fuel ratio and lower engine vacuum with the decreased air density. Some problems, therefore, may occur when driving out of high-altitude areas into lower areas where the octane rating must be higher. Most electronic fuel injection systems can compensate for changes in altitude and modify air–fuel ratio and ignition timing for best operation.

VOLATILITY EFFECTS OF ALTITUDE High altitude also allows fuel to evaporate more easily. The volatility of fuel should be reduced at higher altitudes to prevent vapor from forming in sections of the fuel system, which can cause driveability and stalling problems. The extra heat generated in climbing to higher altitudes plus the lower atmospheric pressure at higher altitudes combine to cause possible driveability problems as the vehicle goes to higher altitudes.

GASOLINE ADDITIVES

DYE Dye is usually added to gasoline at the distributor to help identify the grade and/or brand of fuel. Fuels are required to be colored using a fuel soluble dye in many countries. In the United States and Canada, diesel fuel used for off-road use and not taxed is required to be dyed red for identification. Gasoline sold for off-road use in Canada is dyed purple.

OXYGENATED FUEL ADDITIVES **Oxygenated fuels** contain oxygen in the molecule of the fuel itself. Examples of oxygenated fuels include the following:

- **Methyl tertiary butyl ether (MTBE).** This fuel is manufactured by means of the chemical reaction of methanol and isobutylene. Unlike methanol, MTBE does not increase the volatility of the fuel, and is not as sensitive to water as are other alcohols. The maximum allowable volume level, according to the EPA, is 15% but is currently being phased out due to health concerns, as well as MTBE contamination of drinking water if spilled from storage tanks.

FIGURE 67–10 This fuel pump indicates that the gasoline is blended with 10% ethanol (ethyl alcohol) and can be used in any gasoline vehicle. E85 contains 85% ethanol and can only be used in vehicles specifically designed to use it.

- **Tertiary-amyl methyl ether (TAME).** This fuel contains an oxygen atom bonded to two carbon atoms, and is added to gasoline to provide oxygen to the fuel. It is slightly soluble in water, very soluble in ethers and alcohol, and soluble in most organic solvents including hydrocarbons.
- **Ethyl tertiary butyl ether (ETBE).** This fuel is derived from ethanol. The maximum allowable volume level is 17.2%. The use of ETBE is the cause of much of the odor from the exhaust of vehicles if using reformulated gasoline, as mandated for use in some parts of the country.
- **Ethanol.** Also called *ethyl alcohol,* **ethanol** is drinkable alcohol and is usually made from grain. Adding 10% ethanol (ethyl alcohol or grain alcohol) increases the (R + M) ÷ 2 octane rating by three points.

The alcohol added to the base gasoline, however, also raises the volatility of the fuel about 0.5 PSI. Most automobile manufacturers permit up to 10% ethanol if driveability problems are not experienced.

The oxygen content of a 10% blend of ethanol in gasoline, called **E10**, is 3.5% oxygen by weight. ● **SEE FIGURE 67–10**.

TESTING GASOLINE FOR ALCOHOL CONTENT

Take the following steps when testing gasoline for alcohol content:

STEP 1 Pour suspect gasoline into a graduated cylinder.

STEP 2 Carefully fill the graduated cylinder to the 90 mL mark.

STEP 3 Add 10 mL of water to the graduated cylinder by counting the number of drops from an eyedropper.

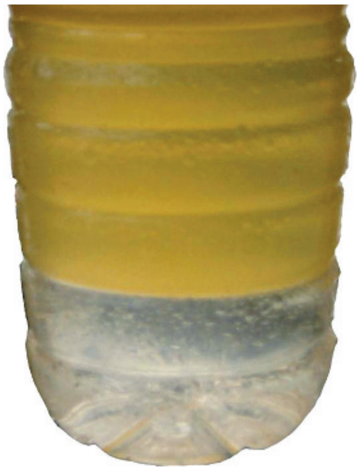

FIGURE 67–11 A container with gasoline containing water and alcohol. Notice the separation line where the alcohol–water mixture separated from the gasoline and sank to the bottom.

FREQUENTLY ASKED QUESTION

What Is Meant by “Phase Separation”?

All alcohols absorb water, and the alcohol–water mixture can separate from the gasoline and sink to the bottom of the fuel tank. This process is called phase separation. To help avoid engine performance problems, try to keep at least a quarter tank of fuel at all times, especially during seasons when there is a wide temperature span between daytime highs and nighttime lows. These conditions can cause moisture to accumulate in the fuel tank as a result of condensation of the moisture in the air. Keeping the fuel tank full reduces the amount of air and moisture in the tank. ● **SEE FIGURE 67–11**.

FREQUENTLY ASKED QUESTION

Is Water Heavier than Gasoline?

Yes. Water weighs about 8 lb per gallon, whereas gasoline weighs about 6 lb per gallon. The density as measured by specific gravity includes the following:

Water = 1.000 (the baseline for specific gravity)

Gasoline = 0.730 to 0.760

This means that any water that gets into the fuel tank will sink to the bottom.

WARNING

Do not smoke or run the test around sources of ignition!

STEP 4 Put the stopper in the cylinder and shake vigorously for one minute. Relieve built-up pressure by occasionally removing the stopper. Alcohol dissolves in water and will drop to the bottom of the cylinder.

STEP 5 Place the cylinder on a flat surface and let it stand for two minutes.

STEP 6 Take a reading near the bottom of the cylinder at the boundary between the two liquids.

STEP 7 For percentage of alcohol in gasoline, subtract 10 to get the percentage.

For example,

The reading is 20 mL: 20 − 10 = 10% alcohol

If the increase in volume is 0.2% or less, it may be assumed that the test gasoline contains no alcohol. ● **SEE FIGURE 67–12**.

Alcohol content can also be checked using an electronic tester. See the photo sequence at the end of the chapter.

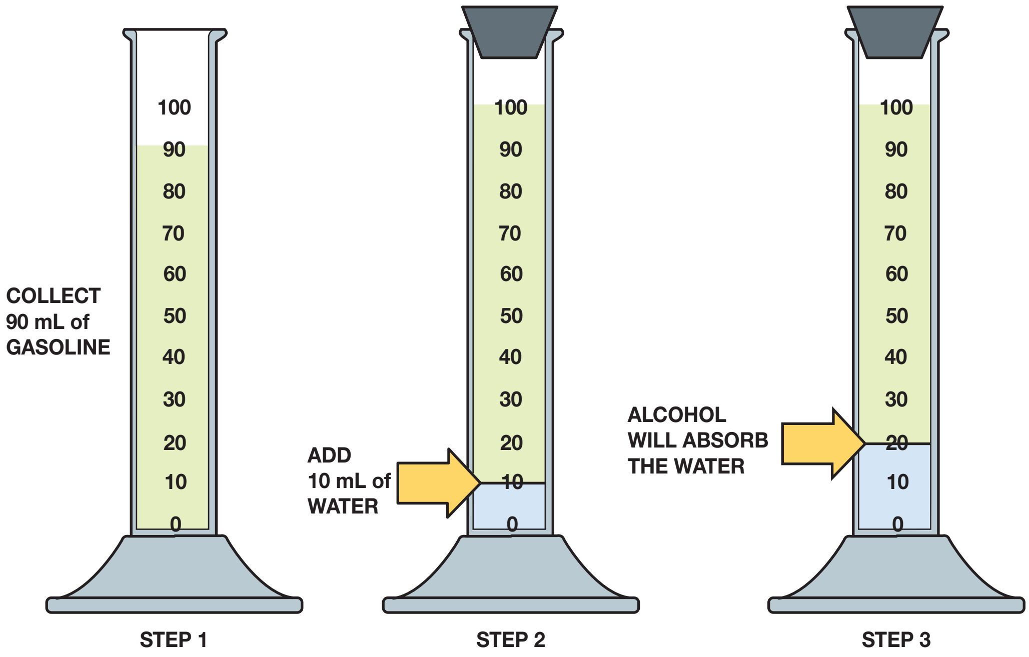

FIGURE 67–12 Checking gasoline for alcohol involves using a graduated cylinder and adding water to check if the alcohol absorbs the water.

GENERAL GASOLINE RECOMMENDATIONS

The fuel used by an engine is a major expense in the operation cost of the vehicle. The proper operation of the engine depends on clean fuel of the proper octane rating and vapor pressure for the atmospheric conditions.

To help ensure proper engine operation and keep fuel costs to a minimum, follow these guidelines:

1. Purchase fuel from a busy station to help ensure that it is fresh and less likely to be contaminated with water or moisture.
2. Keep the fuel tank above one-quarter full, especially during seasons in which the temperature rises and falls by more than 20°F between daytime highs and nighttime lows. This helps to reduce condensed moisture in the fuel tank and could prevent gas line freeze-up in cold weather.

NOTE: Gas line freeze-up occurs when the water in the gasoline freezes and forms an ice blockage in the fuel line.

3. Do not purchase fuel with a higher octane rating than is necessary. Try using premium high-octane fuel to check for operating differences. Most newer engines are equipped with a detonation (knock) sensor that signals the vehicle computer to retard the ignition timing when spark knock occurs. Therefore, an operating difference may not be noticeable to the driver when using a low-octane fuel, except for a decrease in power and fuel economy. In other words, the engine with a knock sensor will tend to operate knock free on regular fuel, even if premium, higher octane fuel is specified. Using premium fuel may result in more power and greater fuel economy. The increase in fuel economy, however, would have to be substantial to justify the increased cost of high-octane premium fuel. Some drivers find a good compromise by using midgrade (plus) fuel to benefit from the engine power and fuel economy gains without the cost of using premium fuel all the time.
4. Try to avoid using gasoline with alcohol in warm weather, even though many alcohol blends do not affect engine driveability. If warm-engine stumble, stalling, or rough idle occurs, change brands of gasoline.
5. Do not purchase fuel from a retail outlet when a tanker truck is filling the underground tanks. During the refilling procedure, dirt, rust, and water may be stirred up in the underground tanks. This undesirable material may be pumped into your vehicle's fuel tank.
6. Do not overfill the gas tank. After the nozzle clicks off, add just enough fuel to round up to the next dime. Adding additional gasoline will cause the excess to be drawn into the charcoal canister. This can lead to engine flooding and excessive exhaust emissions.
7. Be careful when filling gasoline containers. Always fill a gas can on the ground to help prevent the possibility of static electricity buildup during the refueling process. ● **SEE FIGURE 67–14**.

76
TOP TIER® Detergent Gasoline

FIGURE 67–13 Not all top-tier gas stations mention that they are top-tier like this station. For more information and the list of top-tier gasoline stations, visit www.toptiergas.com.

FREQUENTLY ASKED QUESTION

What Is "Top-Tier" Gasoline?

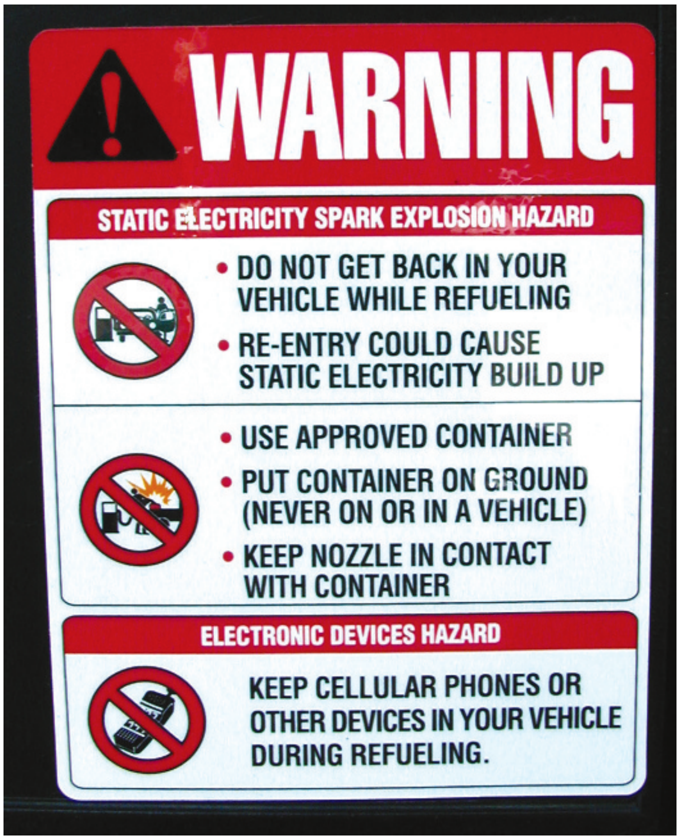
Top-tier gasoline has specific standards for quality, including enough detergent to keep all intake valves clean. Four automobile manufacturers (BMW, General Motors, Honda, and Toyota) developed the standards. Top-tier gasoline exceeds the quality standards developed by the **World Wide Fuel Charter (WWFC)** in 2002 by vehicle and engine manufacturers. The gasoline companies that agreed to make fuel that matches or exceeds the standards as a top-tier fuel include ChevronTexaco, Shell, and ConocoPhillips. ● **SEE FIGURE 67–13**.

TECH TIP

The Sniff Test

Problems can occur with stale gasoline from which the lighter parts of the gasoline have evaporated. Stale gasoline usually results in a no-start situation. If stale gasoline is suspected, sniff it. If it smells rancid, replace it with fresh gasoline.

NOTE: If storing a vehicle, boat, or lawnmower over the winter, put some gasoline stabilizer into the gasoline to reduce the evaporation and separation that can occur during storage. Gasoline stabilizer is frequently available at most automotive parts stores.



WARNING
STATIC ELECTRICITY SPARK EXPLOSION HAZARD
• DO NOT GET BACK IN YOUR VEHICLE WHILE REFUELING
• RE-ENTRY COULD CAUSE STATIC ELECTRICITY BUILD UP
• USE APPROVED CONTAINER
• PUT CONTAINER ON GROUND (NEVER ON OR IN A VEHICLE)
• KEEP NOZZLE IN CONTACT WITH CONTAINER
ELECTRONIC DEVICES HAZARD
KEEP CELLULAR PHONES OR OTHER DEVICES IN YOUR VEHICLE DURING REFUELING.

FIGURE 67–14 Many service stations have signs posted warning customers to place plastic fuel containers on the ground while filling. If placed in a trunk or pickup truck bed equipped with a plastic liner, static electricity could buildup during fueling and discharge from the container to the metal nozzle, creating a spark and possible explosion. Some service stations have warning signs not to use cell phones while fueling to help avoid the possibility of an accidental spark creating a fire hazard.

FREQUENTLY ASKED QUESTION

Why Should I Keep the Fuel Gauge above One-Quarter Tank?

The fuel pickup inside the fuel tank can help keep water from being drawn into the fuel system unless water is all that is left at the bottom of the tank. Over time, moisture in the air inside the fuel tank can condense, causing liquid water to drop to the bottom of the fuel tank. (Recall that water is heavier than gasoline—about 8 pound per gallon for water and about 6 pound per gallon for gasoline.) If alcohol-blended gasoline is used, the alcohol can absorb the water and the alcohol–water combination can be burned inside the engine. However, when water combines with alcohol, a separation layer occurs between the gasoline at the top of the tank and the alcohol–water combination at the bottom. When the fuel level is low, the fuel pump will draw from this concentrated level of alcohol and water. Because alcohol and water do not burn as well as pure gasoline, severe driveability problems can occur such as stalling, rough idle, hard starting, and missing.

TECH TIP

Do Not Overfill the Fuel Tank

Gasoline fuel tanks have an expansion volume area at the top. The volume of this expansion area is equal to 10% to 15% of the volume of the tank. This area is normally not filled with gasoline, but rather is designed to provide a place for the gasoline to expand into, if the vehicle is parked in the hot sun and the gasoline expands. This prevents raw gasoline from escaping from the fuel system. Valves in the evaporative system control how much vapor is sent to the charcoal cannister.

This volume area could be filled with gasoline if the fuel is slowly pumped into the tank. Since it can hold an extra 10% (2 gallons in a 20 gallon tank), some people deliberately try to fill the tank completely. When this expansion volume is filled, liquid fuel (rather than vapors) can be drawn into the charcoal canister. When the purge valve opens, liquid fuel can be drawn into the engine, causing an excessively rich air–fuel mixture. Not only can this liquid fuel harm vapor recovery parts, but overfilling the gas tank could also cause the vehicle to fail an exhaust emission test, particularly during an enhanced test when the tank could be purged while on the rollers.

E85

WHAT IS E85? Vehicle manufacturers have available vehicles that are capable of operating on gasoline plus ethanol or a combination of gasoline and ethanol called **E85**, composed of 85% ethanol and 15% gasoline. Ethanol is also called **ethyl alcohol** or **grain alcohol** because it is usually made from grain and is the type of alcohol found in alcoholic drinks such as beer, wine, and distilled spirits like whiskey. Ethanol is composed of two carbon atoms and six hydrogen atoms with one added oxygen atom. ● **SEE FIGURE 67–15**.

Pure ethanol has an octane rating of about 113. E85, which contains 35% oxygen by weight, has an octane rating of 100 to 105. This compares to a regular unleaded gasoline which has a rating of 87. ● **SEE FIGURE 67–16**.

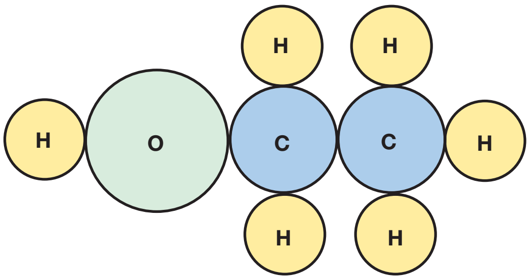


FIGURE 67–15 The ethanol molecule showing two carbon atoms, six hydrogen atoms, and one oxygen atom.

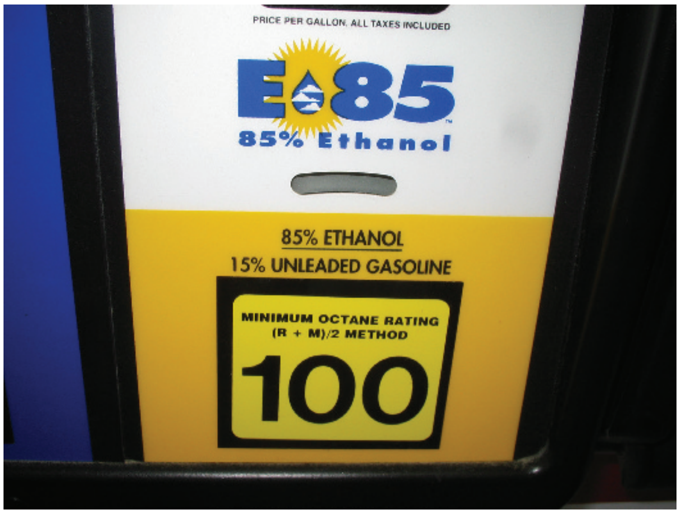

FIGURE 67–16 E85 has 85% ethanol mixed with 15% gasoline.

TECH TIP

Purchase a Flex Fuel Vehicle

If purchasing a new or used vehicle, try to find a flex fuel vehicle. Even though you may not want to use E85, a flex fuel vehicle has a more robust fuel system than a conventional fuel system designed for gasoline or E10. The enhanced fuel system components and materials usually include

- Stainless steel fuel rail
- Graphite commutator bars instead of copper in the fuel pump motor (ethanol can oxidize into acetic acid, which can corrode copper)
- Diamondlike carbon (DLC) corrosion-resistant fuel injectors
- Alcohol resistant O-rings and hoses

The cost of a flex fuel vehicle compared with the same vehicle designed to operate on gasoline is a no-cost or a low-cost option.

NOTE: The octane rating of E85 depends on the exact percentage of ethanol used, which can vary from 81% to 85%. It also depends on the octane rating of the gasoline used to make E85.

HEAT ENERGY OF E85 E85 has less heat energy than gasoline.

Gasoline: 114,000 BTUs per gallon

E85: 87,000 BTUs per gallon

This means that the fuel economy is reduced by 20% to 30% if E85 is used instead of gasoline.

Example: A Chevrolet Tahoe 5.3-liter V-8 with an automatic transmission has an EPA rating using gasoline of 15 mpg in the city and 20 mpg on the highway. If this same vehicle is fueled with E85, the EPA fuel economy rating drops to 11 mpg in the city and 15 mpg on the highway.

ALTERNATIVE FUEL VEHICLES

The 15% gasoline in the E85 blend helps the engine start, especially in cold weather. Vehicles equipped with this capability are commonly referred to as the following:

- **Alternative fuel vehicles (AFVs)**
- **Flex fuels**
- **Flexible fuel vehicles (FFVs)**

Using E85 in a flex fuel vehicle can result in a power increase of about 5%. For example, an engine rated at 200 hp using gasoline or E10 could produce 210 hp if using E85.

NOTE: E85 may test as containing less than 85% ethanol if tested because it is often blended according to outside temperature. A lower percentage of ethanol with a slightly higher percentage of gasoline helps engines start in cold climates.

These vehicles are equipped with an electronic sensor in the fuel supply line that detects the presence and percentage of ethanol. The PCM then adjusts the fuel injector on-time and ignition timing to match the needs of the fuel being used.

E85 contains less heat energy, and therefore will use more fuel, but the benefits include a lower cost of the fuel and less environmental impact associated with using an oxygenated fuel.

E85 vehicles use fuel system parts designed to withstand the additional alcohol content, modified driveability programs that adjust fuel delivery and timing to compensate for the various percentages of ethanol fuel, and a **fuel compensation sensor** that measures both the percentage of ethanol blend and the temperature of the fuel. This sensor is also called a **variable fuel sensor**. ● **SEE FIGURES 67–17 AND 67–18**.

E85 FUEL SYSTEM REQUIREMENTS Most E85 vehicles are very similar to non-E85 vehicles. Fuel system components may be redesigned to withstand the effects of higher concentrations of ethanol. In addition, since the stoichiometric point for ethanol is 9:1 instead of 14.7:1 as for gasoline, the air–fuel mixture has to be adjusted for the percentage of ethanol present in the fuel tank.

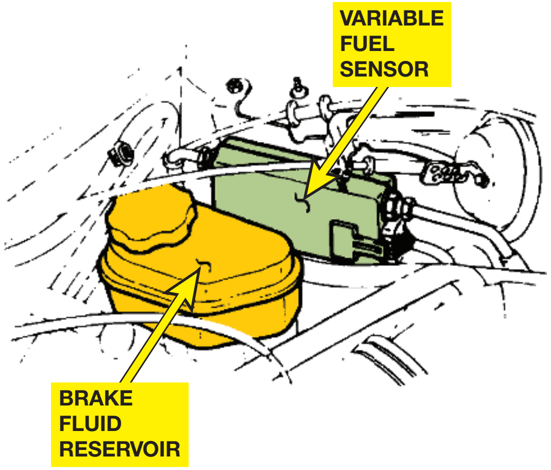

FIGURE 67–17 The location of the variable fuel sensor can vary, depending on the make and model of vehicle, but it is always in the fuel line between the fuel tank and the fuel injectors.

FREQUENTLY ASKED QUESTION

How Does a Sensorless Flex Fuel System Work?

Many General Motors flex fuel vehicles do not use a fuel compensation sensor and instead use the oxygen sensor to detect the presence of the lean mixture and the extra oxygen in the fuel.

The powertrain control module (PCM) then adjusts the injector pulse width and the ignition timing to optimize engine operation to the use of E85. This type of vehicle is called a **virtual flexible fuel vehicle (V-FFV)**. It can operate on pure gasoline or blends up to 85% ethanol.

FREQUENTLY ASKED QUESTION

How Long Can Oxygenated Fuel Be Stored before All of the Oxygen Escapes?

The oxygen in oxygenated fuels, such as E10 and E85, is not in a gaseous state like the CO_2 in soft drinks. The oxygen is part of the molecule of ethanol or other oxygenates and does not bubble out of the fuel. Oxygenated fuels, like any fuel, have a shelf life of about 90 days.

The benefits of E85 vehicles include the following:

- Reduced pollution
- Less CO_2 production
- Less dependence on imported oil

FLEX FUEL VEHICLE IDENTIFICATION Flexible fuel vehicles (FFVs) can be identified by the following:

- Emblems on the side, front, and/or rear of the vehicle
- Yellow fuel cap showing E85/gasoline (● **SEE FIGURE 67–19**.)
- Vehicle emission control information (VECI) label under the hood (● **SEE FIGURE 67–20**.)
- Vehicle identification number (VIN)

NOTE: For additional information on E85 and for the location of E85 stations in your area, go to www.e85fuel.com.

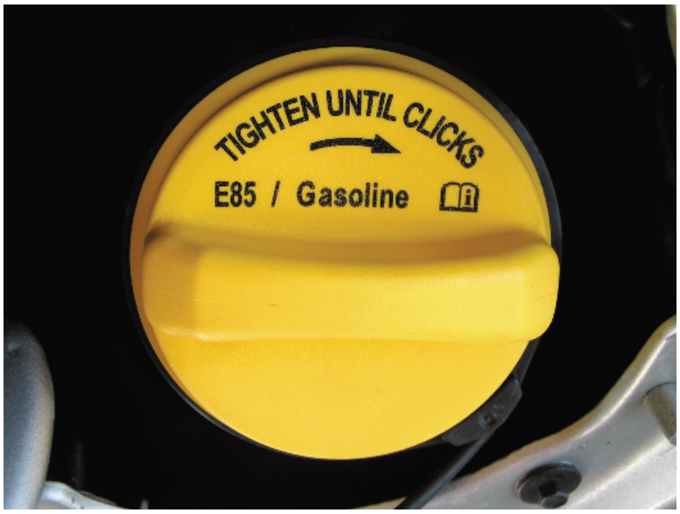

FIGURE 67–19 A flex fuel vehicle often has a yellow gas cap, which is labeled E85/gasoline.

PROPANE

Propane is the most widely used of all the alternative fuels mainly because of its use in fleets, which utilize a central refueling station. Propane is a by-product of petroleum refining of natural gas. In order to liquefy the fuel, it is stored in strong tanks at about 300 PSI (2,000 kPa). When sold as a fuel, it is also known as **liquified petroleum gas (LPG)** or **LP gas** because the propane is often mixed with about 10% of other gases, including the following:

- Butane
- Propylene
- Butylenes
- Mercaptan, to give the colorless and odorless propane a smell

Propane is nontoxic, but if inhaled can cause asphyxiation through lack of oxygen. Propane is heavier than air and lays near the floor if released into the atmosphere. Propane is commonly used in forklifts and other equipment located inside warehouses and factories because the exhaust from the engine using propane is not harmful. The heating value of propane is less than that of gasoline; therefore, more is required, which reduces the fuel economy. ● **SEE FIGURE 67–21**.

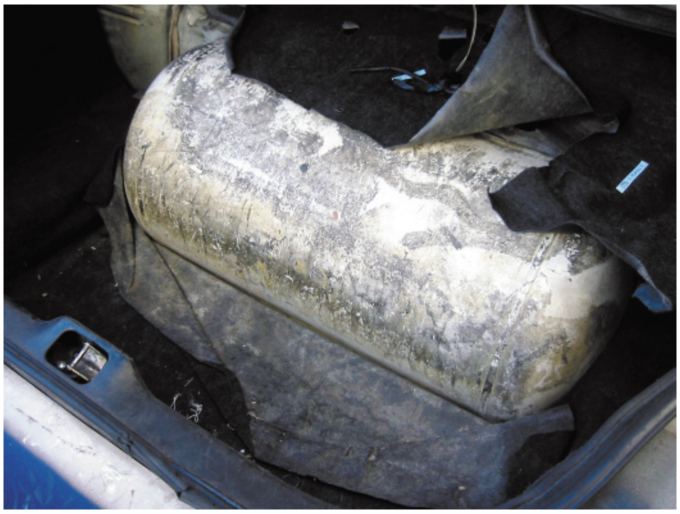

FIGURE 67–21 Propane fuel storage tank in the trunk of a Ford taxi.

COMPRESSED NATURAL GAS

CNG VEHICLE DESIGN Another alternative fuel that is often used in fleet vehicles is **compressed natural gas (CNG)**. Vehicles using this fuel are often referred to as **natural gas vehicles (NGVs)**. Look for the blue CNG label on vehicles designed to operate on compressed natural gas. ● **SEE FIGURE 67–22**.

Because natural gas must be compressed to 3,000 PSI (20,000 kPa) or more, the weight and cost of the storage container are major factors when it comes to preparing a vehicle to run on CNG. The tanks needed for CNG are typically constructed of 0.5 inch (3 mm) thick aluminum reinforced with fiberglass. ● **SEE FIGURE 67–23**.

The octane rating of CNG is about 130 and the cost per gallon is roughly half of the cost of gasoline. However, the heat value of CNG is also less, and therefore more is required to produce the same power; and the miles per gallon is less.

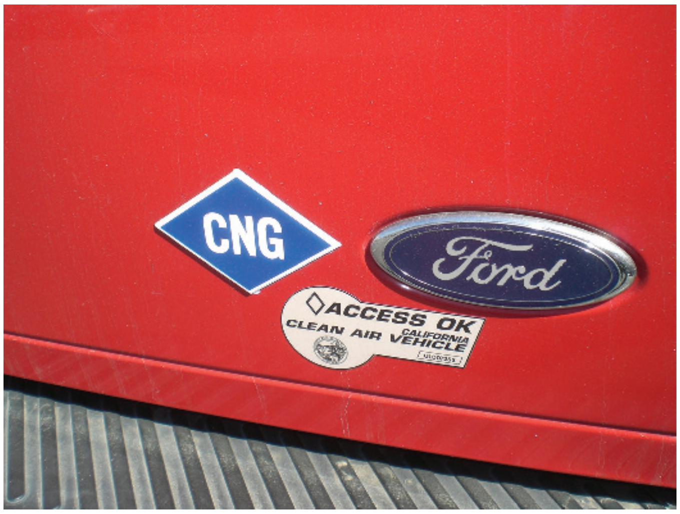

FIGURE 67–22 The blue sticker on the rear of this vehicle indicates that it is designed to use compressed natural gas. This Ford truck also has a sticker that allows it to be driven in the high occupancy vehicle (HOV) lane, even if there is just the driver because it is a CNG vehicle.

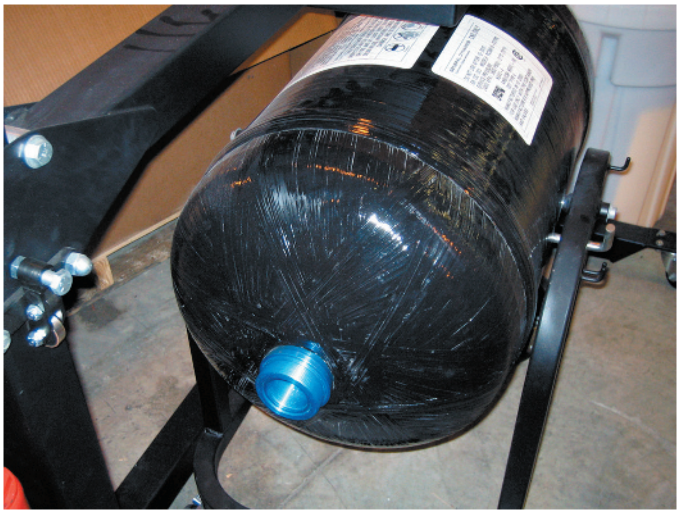

FIGURE 67–23 A CNG storage tank from a Honda Civic GX shown with the fixture used to support it while it is being removed or installed in the vehicle. Honda specifies that three technicians be used to remove or install the tank through the rear door of the vehicle due to the size and weight of the tank.

FREQUENTLY ASKED QUESTION

What Is the Amount of CNG Equal to in Gasoline?

To achieve the amount of energy of 1 gallon of gasoline, 122 ft^3 of compressed natural gas (CNG) is needed. While the octane rating of CNG is much higher than gasoline (130 octane), using CNG instead of gasoline in the same engine would result in a 10% to 20% reduction of power due to the lower heat energy that is released when CNG is burned in the engine.

CNG COMPOSITION Compressed natural gas is a blend of the following:

- Methane
- Propane
- Ethane
- N-butane
- Carbon dioxide
- Nitrogen

Once it is processed, compressed natural gas is at least 93% methane. Natural gas is nontoxic, odorless, and colorless in its natural state. It is odorized during processing, using ethyl mercaptan (“skunk”), to allow for easy leak detection. Natural gas is lighter than air and will rise when released into the air. Since CNG is already a vapor, it does not need heat to vaporize before it will burn, which improves cold start-up and results in lower emissions during cold operation. However, because it is already in a gaseous state, it displaces some of the air charge in the intake manifold, leading to a 10% reduction in engine power as compared to an engine operating on gasoline. Natural gas also burns slower than gasoline; therefore, the ignition timing must be advanced

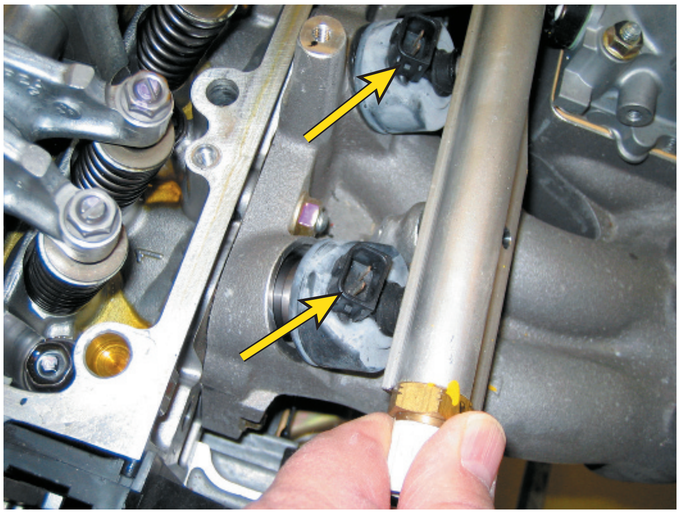

FIGURE 67–24 The fuel injectors used on this Honda Civic GX CNG engine are designed to flow gaseous fuel instead of liquid fuel and cannot be interchanged with any other type of injector.

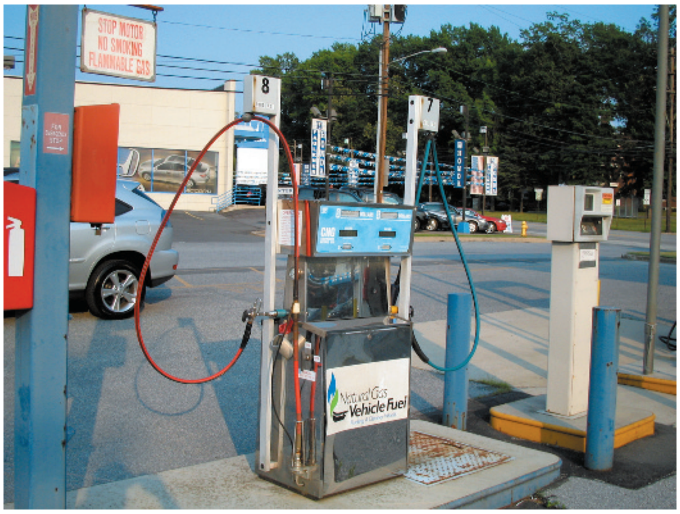

FIGURE 67–25 This CNG pump is capable of supplying compressed natural gas at either 3,000 PSI or 3,600 PSI. The price per gallon is higher for the higher pressure.

more when the vehicle operates on natural gas. The stoichiometric ratio, the point at which all the air and fuel is used or burned, is 16.5:1 compared to 14.7:1 for gasoline. This means that more air is required to burn 1 pound of natural gas than is required to burn 1 pound of gasoline. ● **SEE FIGURE 67–24**.

The CNG engine is designed to include

- Increased compression ratio
- Strong pistons and connecting rods
- Heat-resistant valves
- Fuel injectors designed for gaseous fuel instead of liquid fuel

CNG FUEL SYSTEMS When completely filled, the CNG tank has 3,600 PSI of pressure in the tank. When the ignition is turned on, the alternate fuel electronic control unit activates the high-pressure lock-off, which allows high-pressure gas to pass to the high-pressure regulator.

- The high-pressure regulator reduces the high-pressure CNG to approximately 150 to 170 PSI and sends it to the low-pressure lock-off. The low-pressure lock-off is also controlled by the alternate fuel electronic control unit and is activated at the same time as the high-pressure lock-off.
- From the low-pressure lock-off, the CNG is directed to the low-pressure regulator. This is a two-stage regulator that first reduces the pressure to approximately 4 to 6 PSI in the first stage and then to about 0.5 PSI in the second stage.
- From here, the low-pressure gas is delivered to the gas mass sensor/mixture control valve. This valve controls the air–fuel mixture. The CNG gas distributor adapter then delivers the gas to the intake stream.

CNG vehicles are designed for fleet use that usually have their own refueling capabilities. One of the drawbacks to using CNG is the time that it takes to refuel a vehicle. The ideal method of refueling is the slow-fill method. The slow filling method compresses the natural gas as the tank is being fueled. This method ensures that the tank will receive a full charge of CNG; however, this method can take three to five hours to accomplish. If more than one vehicle needs filling, the facility will need multiple CNG compressors to refuel the vehicles.

⚠ WARNING

Do not smoke or have an open flame in the area when working around or refueling any vehicle.

There are three commonly used CNG refilling station pressures:

P24: 2,400 PSI
P30: 3,000 PSI
P36: 3,600 PSI

Try to find and use a station with the highest refilling pressure. Filling at lower pressures will result in less compressed natural gas being installed in the storage tank, thereby reducing the driving range. ● **SEE FIGURE 67–25**.

The fast-fill method uses CNG that is already compressed. However, as the CNG tank is filled rapidly, the internal temperature of the tank will rise, which causes a rise in tank pressure. Once the temperature drops in the CNG tank, the pressure in the tank also drops, resulting in an incomplete charge in the CNG tank. This refueling method may take only about five minutes, but it will result in an incomplete charge to the CNG tank, reducing the driving range. ● **SEE CHART 67–2** for a comparison of the most frequently used alternative fuels.

DIESEL FUEL

FEATURES OF DIESEL FUEL Diesel fuel must meet an entirely different set of standards than gasoline. Diesel fuel contains 12% more heat energy than the same amount of gasoline. The fuel in a diesel engine is not ignited with a spark, but is ignited by the heat generated by high compression. The pressure of compression (400 to 700 PSI, or 2,800 to 4,800 kPa) generates temperatures of 1,200°F to 1,600°F (700°C to 900°C), which speeds the preflame reaction to start the ignition of fuel injected into the cylinder.

ALTERNATE FUEL COMPARISON CHART

CHARACTERISTIC	PROPANE	CNG	ETHANOL	REGULAR UNLEADED GAS
Octane	104	130	100	87–93
BTU per gallon	91,000	NA	83,000	114,000–125,000
Gallon equivalent	1.15	122 $ft^3 = 1$ gallon of gasoline	1.5	1
Onboard fuel storage	Liquid	Gas	Liquid	Liquid
Miles/gallon as compared to gas	85%	Varies with pressure	70%	100%
Relative tank size required to yield driving range equivalent to gas	Tank is 1.25 times larger	Tank is 3.5 times larger	Tank is 1.5 times larger	
Pressure	200 PSI	3,000–3,600 PSI	NA	NA
Cold weather capability	Good	Good	Poor	Good
Vehicle power	5%–10% power loss	10%–20% power loss	5% power increase	Standard
Toxicity	Nontoxic	Nontoxic	Toxic	Toxic
Corrosiveness	Noncorrosive	Noncorrosive	Corrosive	Minimally corrosive
Source	Natural gas/ petroleum refining	Natural gas/ crude oil	Sugar and starch crops/biomass	Crude oil

CHART 67–2

The characteristics of alternative fuels compared to regular unleaded gasoline show that all have advantages and disadvantages.

DIESEL FUEL REQUIREMENTS All diesel fuel must have the following characteristics:

- **Cleanliness.** It is imperative that the fuel used in a diesel engine be clean and free from water. Unlike the case with gasoline engines, the fuel is the lubricant and coolant for the diesel injector pump and injectors. Good-quality diesel fuel contains additives, such as oxidation inhibitors, detergents, dispersants, rust preventatives, and metal deactivators.
- **Low-temperature fluidity.** Diesel fuel must be able to flow freely at all expected ambient temperatures. One specification for diesel fuel is its “pour point,” which is the temperature below which the fuel will stop flowing.
- **Cloud point.** Another concern with diesel fuel at lower temperatures concerns **cloud point**, the low-temperature point when the waxes present in most diesel fuels tend to form crystals that can clog the fuel filter. Most diesel fuel suppliers distribute fuel with the proper pour point and cloud point for the climate conditions of the area.

CETANE NUMBER The cetane number for diesel fuel is the opposite of the octane number for gasoline. The **cetane number** is a measure of the ease with which the fuel can be ignited. The cetane rating of the fuel determines, to a great extent, its ability to start the engine at low temperatures and to provide smooth warmup and even combustion. The cetane rating of diesel fuel should be between 45 and 50. The higher the cetane rating, the more easily the fuel is ignited.

SULFUR CONTENT The sulfur content of diesel fuel is very important to the life of the engine. Sulfur in the fuel creates sulfuric acid during the combustion process, which can damage engine components and cause piston ring wear. Federal regulations are getting extremely tight on sulfur content to less than 15 parts per million (ppm). High-sulfur fuel contributes to acid rain.

DIESEL FUEL COLOR Diesel fuel intended for use on the streets and highways is either clear or green. Diesel fuel to be used on farms and off-road use is dyed red. ● **SEE FIGURE 67–26.**

GRADES OF DIESEL FUEL ASTM also classifies diesel fuel by volatility (boiling range) into the following grades:

Grade 1	This grade of diesel fuel has the lowest boiling point and the lowest cloud and pour points, as well as a lower BTU content (less heat per pound of fuel). As a result, grade 1 is suitable for use during low-temperature (winter) operation. Grade 1 produces less heat per pound of fuel compared to grade 2, and may be specified for use in diesel engines involved in frequent changes in load and speed, such as those found in city buses and delivery trucks.
Grade 2	This grade has a higher boiling point, cloud point, and pour point as compared with grade 1. It is usually specified where constant speed and high loads are encountered, such as in long-haul trucking and automotive diesel applications.

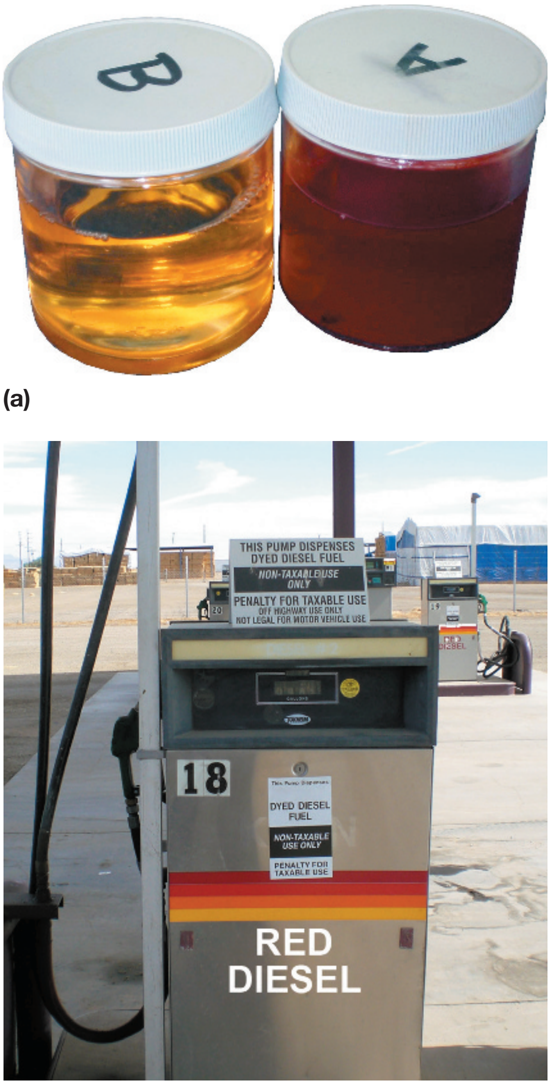

FIGURE 67–26 (a) Regular diesel fuel on the left has a clear or greenish tint, whereas fuel for off-road use is tinted red for identification. (b) This fuel pump in a farming area clearly states the red diesel fuel is for off-road use only because it is not taxed.

DIESEL FUEL SPECIFIC GRAVITY TESTING The density of diesel fuel should be tested whenever there is a driveability concern. The density or specific gravity of diesel fuel is measured in units of **API gravity**, which is an arbitrary scale expressing the gravity or density of liquid petroleum products devised jointly by the American Petroleum Institute and the National Bureau of Standards. The measuring scale is calibrated in terms of degrees API. Oil with the least specific gravity has the highest API gravity. The formula for determining API gravity is as follows:

$$\textbf{Degrees API gravity} = (141.5 \div \textbf{Specific gravity at } 60^\circ\text{F}) - 131.5$$

The normal API gravity for grade 1 diesel fuel is 39 to 44 (typically 40). The normal API gravity for grade 2 diesel fuel is 30 to 39 (typically 35). A hydrometer calibrated in API gravity units should be used to test diesel fuel. ● **SEE FIGURE 67–27**.

ULTRA-LOW-SULFUR DIESEL FUEL Diesel fuel is used in diesel engines and is usually readily available throughout the United States, Canada, and Europe, where many more cars are equipped with diesel engines. Diesel engines manufactured to 2007 or newer standards must use **ultra-low-sulfur diesel (ULSD)** fuel containing less than 15 ppm of sulfur compared to the older, low-sulfur specification of 500 ppm. The purpose of the lower sulfur amount in diesel fuel is to reduce emissions of sulfur oxides (SOx) and particulate matter (PM) from heavy-duty highway engines and vehicles that use diesel fuel. The emission controls used on 2007 and newer diesel engines require the use of ULSD for reliable operation.

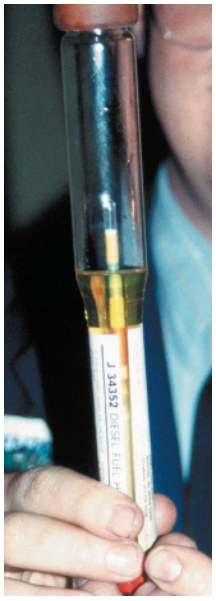

FIGURE 67–27 Testing the API viscosity of a diesel fuel sample using a hydrometer.

DIESEL FUEL ADDITIVES These types of additives include

Winter Conditioners—Winter conditioners are designed to reduce the **Cold Filter Plugging Point (CFPP)**. CFPP is lowest temperature at that a specified volume of diesel type of fuel can pass through a standardized filtration device in a specified time when cooled under certain conditions.

Multifunctional Conditioners—Many multifunctional additives increase the cetane rating of the fuel and helps keep injectors clean. By raising the cetane rating of the diesel fuel, engine power and fuel economy is improved. This type of additive is designed to be used year-round.

Microbicide—Microbes can grow in diesel fuel at the junction between the water and the diesel. Water is heavier than the diesel fuel and is near the bottom of the tank. Water in the fuel can be caused by condensation of moist air in the fuel tank and during transport and storage. A microbicide is designed to kill microorganisms including bacteria and fungi.

BIODIESEL

DEFINITION OF BIODIESEL **Biodiesel** is a domestically produced, renewable fuel that can be manufactured from vegetable oils, animal fats, or recycled restaurant greases. Biodiesel refers to the pure fuel before blending with diesel fuel. ● **SEE FIGURE 67–28**.

Biodiesel blends are denoted as BXX, with the "XX" representing the percentage of biodiesel contained in the blend (i.e., **B20** is 20% biodiesel, 80% petroleum diesel). Blends of 5% biodiesel with 95% petroleum diesel, called **B5**, can generally be used in

FREQUENTLY ASKED QUESTION

I Thought Biodiesel Was Vegetable Oil?

Biodiesel is vegetable oil with the glycerin component removed by means of reacting the vegetable oil with a catalyst. The resulting hydrocarbon esters are 16 to 18 carbon atoms in length, almost identical to the petroleum diesel fuel atoms. This allows the use of biodiesel fuel in a diesel engine with no modifications needed. Biodiesel-powered vehicles do not need a second fuel tank, whereas vehicles powered with vegetable oil do.

There are three main types of fuel used in diesel engines:

- Petroleum diesel, a fossil hydrocarbon with a carbon chain length of about 16 carbon atoms
- Biodiesel, a hydrocarbon with a carbon chain length of 16 to 18 carbon atoms
- Vegetable oil, a triglyceride with a glycerin component joining three hydrocarbon chains of 16 to 18 carbon atoms each, called **straight vegetable oil (SVO)**

Other terms used when describing vegetable oil include the following:

- **Pure plant oil (PPO)**, a term most often used in Europe to describe SVO
- **Waste vegetable oil (WVO)**, which could include animal or fish oils from cooking
- **Used cooking oil (UCO)**, a term used when the oil may or may not be pure vegetable oil

Vegetable oil is not liquid enough at common ambient temperatures for use in a diesel engine fuel delivery system designed for the lower viscosity petroleum diesel fuel. Vegetable oil needs to be heated to obtain a similar viscosity to biodiesel and petroleum diesel. This means a heat source needs to be provided before the fuel can be used in a diesel engine. This is achieved by starting on petroleum diesel or biodiesel fuel until the engine heat can be used to sufficiently warm a tank containing the vegetable oil. It also requires purging the fuel system of vegetable oil with petroleum diesel or biodiesel fuel prior to stopping the engine to avoid the vegetable oil thickening and solidifying in the fuel system away from the heated tank. The use of vegetable oil in its natural state does, however, eliminate the need to remove the glycerin component.

Many vehicle and diesel engine fuel system suppliers permit the use of biodiesel fuel that is certified as meeting testing standards. None permit the use of vegetable oil in its natural state.

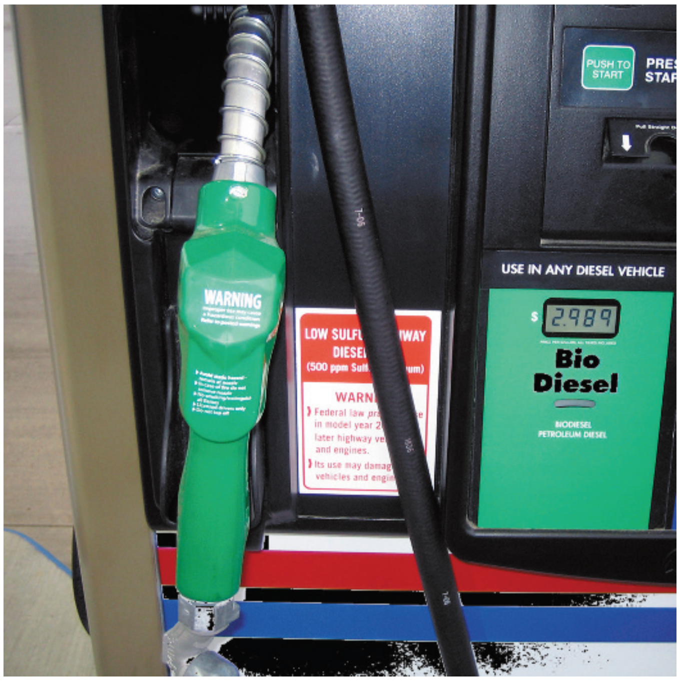

FIGURE 67–28 A biodiesel pump decal.

FUEL	NOZZLE DIAMETER	PUMP HANDLE COLOR (VARIES–NO ESTABLISHED STANDARD)
Gasoline	13/16 inch (21 mm)	Black, red, white, green, or blue
E10	13/16 inch (21 mm)	Black, red, white, green, or blue
E85	13/16 inch (21 mm)	Yellow or black
Diesel fuel	15/16 inch (24 mm)	Yellow, green, or black
Biodiesel	15/16 inch (24 mm)	Green
Truckstop diesel	1 1/4 or 1 1/2 inch (32 or 38 mm)	Varies

CHART 67–3

Fuel pump nozzle size is standardized except for use by over-the-road truckstops where high fuel volumes and speedy refills require larger nozzle sizes compared to passenger vehicle filling station nozzles.

FREQUENTLY ASKED QUESTION

What Are the Pump Nozzle Sizes?

Unleaded gasoline nozzles are smaller than those used for diesel fuel to help prevent fueling errors. However, it is still possible to fuel a diesel vehicle with gasoline.

● **SEE CHART 67–3** for the sizes and colors used for fuel pump nozzles.

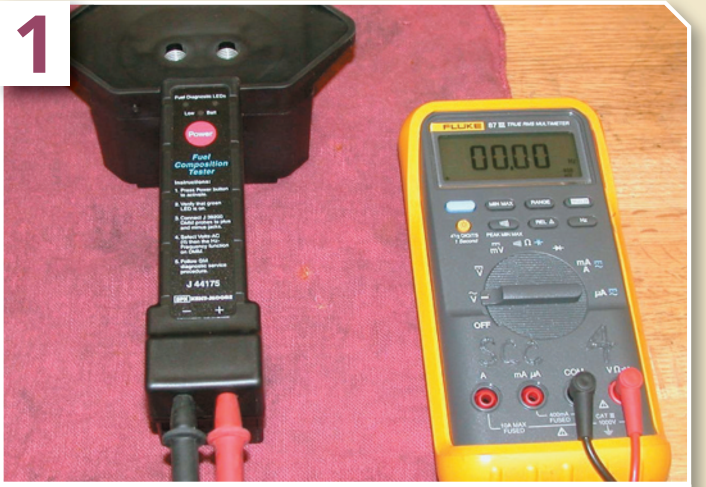
unmodified diesel engines. Some diesel-powered vehicles can use B20 (20% biodiesel). Dodge, for example, allows the use of B5 in all diesel vehicles and B20 only if the optional additional fuel filter is installed. Users should consult their engine warranty statement for more information on fuel blends of greater than 20% biodiesel.

In general, B20 costs 30 to 40 cents more per gallon than conventional diesel. Although biodiesel costs more than regular diesel fuel, fleet managers can make the switch to alternative fuels without purchasing new vehicles, acquiring new spare parts inventories, rebuilding refueling stations, or hiring new service technicians.

NOTE: For additional information on biodiesel and the locations where it can be purchased, visit www.biodiesel.org.

TESTING FOR ALCOHOL CONTENT IN GASOLINE

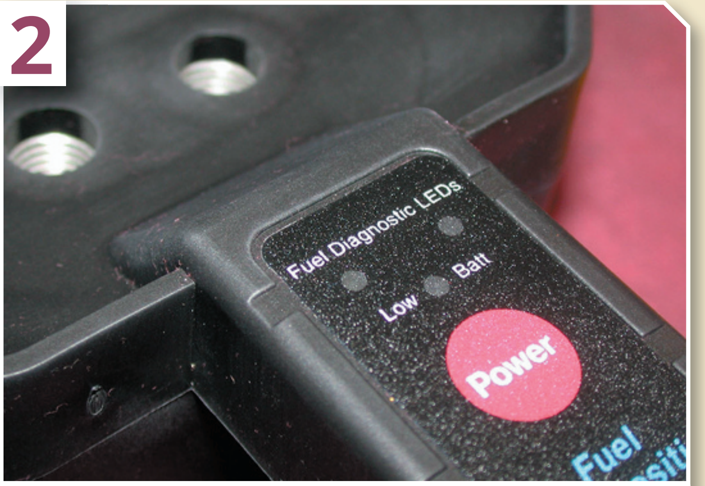
1



Fuel Composition Tester
J 44175
FLUKE
00.00

A fuel composition tester (SPX Kent-Moore J-44175) is the recommended tool to use to test the alcohol content of gasoline.

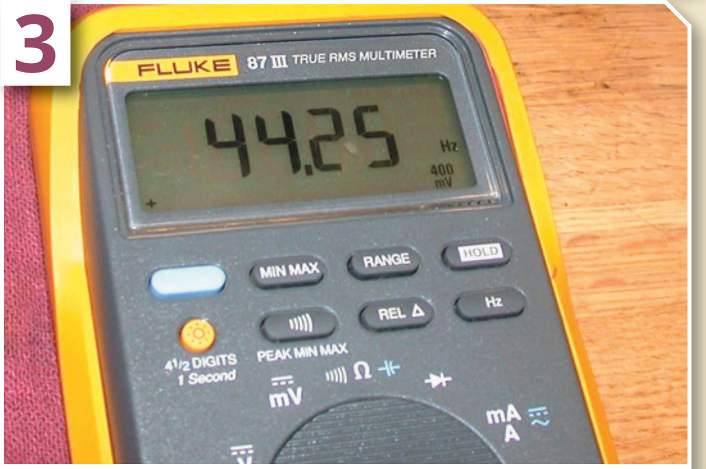
2



Fuel Diagnostic LEDs
Low
Batt
Power
Fuel

This battery-powered tester uses light-emitting diodes (LEDs), meter lead terminals, and two small openings for the fuel sample.

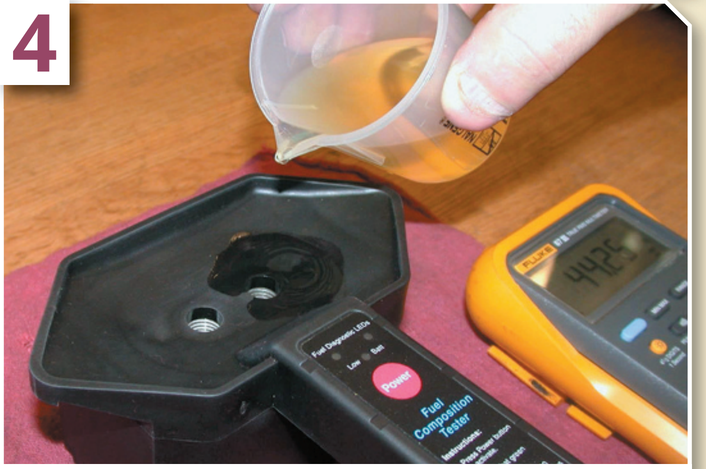
3



FLUKE 87 III TRUE RMS MULTIMETER
44.25
Hz
MIN MAX
RANGE
HOLD
REL Δ
Hz
PEAK MIN MAX
4½ DIGITS 1 Second
mV
mA A

The first step is to verify the proper operation of the tester by measuring the air frequency by selecting AC hertz on the meter. The air frequency should be between 35 Hz and 48 Hz.

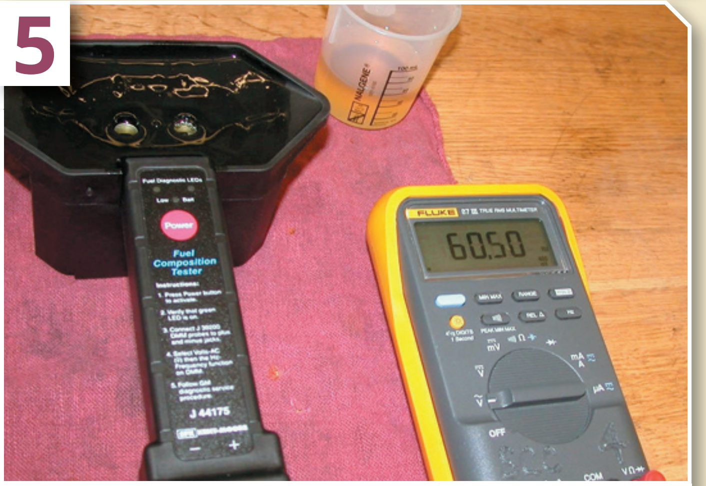
4



44.25
Power
Fuel Composition Tester

After verifying that the tester is capable of correctly reading the air frequency, gasoline is poured into the testing cell of the tool.

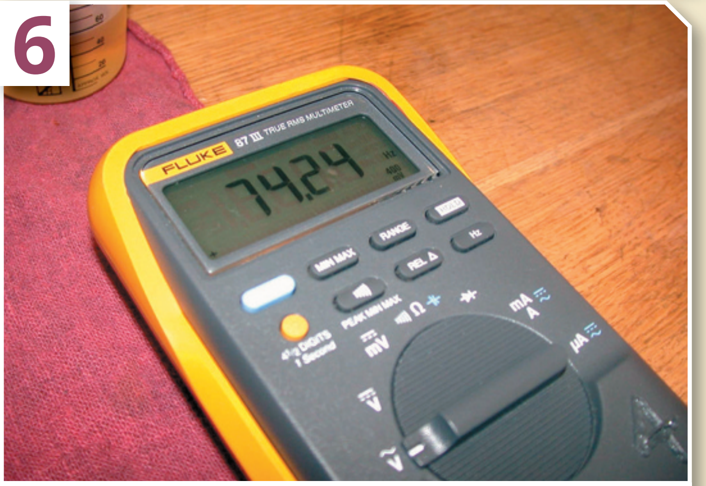
5



Fuel Composition Tester
J 44175
FLUKE
60.50

Record the AC frequency as shown on the meter and subtract 50 from the reading (e.g., 60.50 − 50.00 = 10.5). This number (10.5) is the percentage of alcohol in the gasoline sample.

6



FLUKE 87 III TRUE RMS MULTIMETER
74.24

Adding additional amounts of ethyl alcohol (ethanol) increases the frequency reading.

REVIEW QUESTIONS

1. What does the (R + M) ÷ 2 gasoline pump octane rating indicate?
2. What is stoichiometric?
3. How is a flexible fuel vehicle identified?
4. What are the sizes of the fuel nozzles for gasoline and diesel?
5. Biodiesel blends are identified by what designation?

CHAPTER QUIZ

1. Winter-blend gasoline ____________.
   - **a.** vaporizes more easily than summer-blend gasoline
   - **b.** has a higher RVP
   - **c.** can cause engine driveability problems if used during warm weather
   - **d.** All of the above
2. Technician A says that spark knock, ping, and detonation are different names for abnormal combustion. Technician B says that any abnormal combustion raises the temperature and pressure inside the combustion chamber and can cause severe engine damage. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
3. Technician A says to fill the gas tank as full as possible. Technician B says to stop filling the tank as soon as the nozzle clicks off. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
4. Technician A says that in going to high altitudes, engines produce lower power. Technician B says that most engine control systems can compensate the air–fuel mixture for changes in altitude. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
5. Propane gives ____________ miles per gallon when compared to gasoline.
   - **a.** more
   - **b.** less
   - **c.** the same
   - **d.** increased
6. What can be used to measure the alcohol content in gasoline?
   - **a.** Graduated cylinder
   - **b.** Electronic tester
   - **c.** Scan tool
   - **d.** Both a and b
7. E85 means that the fuel is made from ____________.
   - **a.** 85% gasoline and 15% ethanol
   - **b.** 85% ethanol and 15% gasoline
   - **c.** ethanol that has 15% water
   - **d.** pure ethyl alcohol
8. A flex fuel vehicle can be identified by ____________.
   - **a.** emblems on the side, front, and/or rear of the vehicle
   - **b.** VECI
   - **c.** VIN
   - **d.** All of the above
9. Which statement is true?
   - **a.** Propane and CNG are different name for the same fuel
   - **b.** All vehicles can use CNG
   - **c.** CNG is mostly methane
   - **d.** CNG has more energy per pound than gasoline
10. What is true about diesel fuel?
    - **a.** B5 is 95% biodiesel
    - **b.** If red in color, this means that fuel is untaxed and used for off-road only
    - **c.** Both gasoline and diesel fuel use the octane rating system
    - **d.** All of he above

IGNITION SYSTEM PARTS AND OPERATION

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss ignition systems.
- Discuss ignition coils.
- Discuss ignition switching and triggering.
- Describe ignition system operation.
- Describe the operation of waste-spark ignition systems.
- Describe the operation of coil-on-plug ignition systems.
- Discuss ignition timing.
- Discuss knock sensors.
- Describe the different types of spark plugs.

KEY TERMS:

Coil-on-plug (COP) ignition (also coil-by-plug, coil-near-plug, coil-over-plug) 819 • Companion cylinder 818 • Crankshaft position (CKP) sensor 817 • Camshaft position (CMP) sensor 817 • Detonation 821 • Electromagnetic interference (EMI) 819 • Hall-effect switch 817 • Igniter 816 • Ignition coil 815 • Ignition control module (ICM) 816 • Ignition timing 821 • Inductive reactance 816 • Initial timing 821 • Iridium spark plugs 823 • Knock sensor (KS) 822 • Magnetic sensor 817 • Mutual induction 816 • Paired cylinder 818 • Ping 821 • Platinum spark plugs 823 • Primary ignition circuit 816 • Saturation 816 • Schmitt trigger 817 • Secondary ignition circuit 816 • Self-induction 816 • Spark knock 821 • Switching 816 • Transistor 817 • Turns ratio 815 • Waste-spark ignition 818

IGNITION SYSTEM

PURPOSE AND FUNCTION The ignition system includes components and wiring necessary to create and distribute a high voltage (up to 40,000 volts or more) and send to the spark plug. A high-voltage arc occurs across the gap of a spark plug inside the combustion chamber. The spark raises the temperature of the air–fuel mixture and starts the combustion process inside the cylinder.

BACKGROUND All ignition systems apply battery voltage (close to 12 volts) to the positive side of the ignition coil(s) and pulse the negative side to ground on and off.

EARLY IGNITION SYSTEMS Before the mid-1970s, ignition systems used a mechanically opened set of contact points to make and break the electrical connection to ground. A cam lobe, located and driven by the distributor, opened the points. There was one lobe for each cylinder. The points used a rubbing block that was lubricated by applying a thin layer of grease on the cam lobe at each service interval. Each time the points opened, a spark was created in the ignition coil. The high-voltage spark then traveled to each spark plug through the distributor cap and rotor and the spark plug wires. The distributor was used twice in the creation of the spark.

1. The distributor was connected to the camshaft that rotated the distributor cam causing the points to open and close.
2. The distributor used a rotor to direct the high-voltage spark from the coil entering the center of the distributor cap to inserts connected to spark plug wires to each cylinder. ● **SEE FIGURE 68–1**.

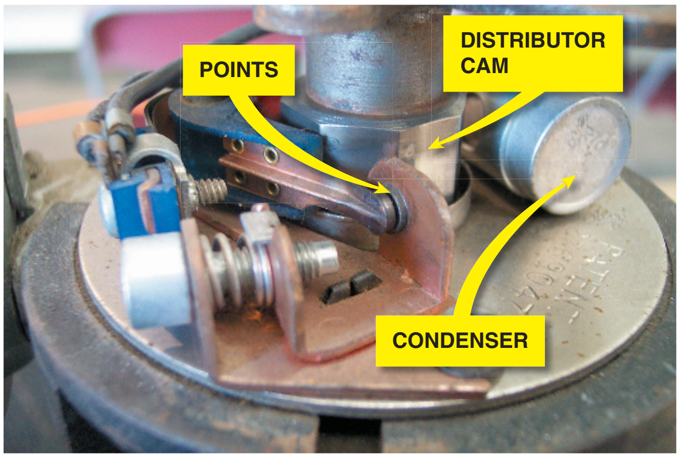

FIGURE 68–1 A point-type ignition system showing the distributor cam which opens the points.

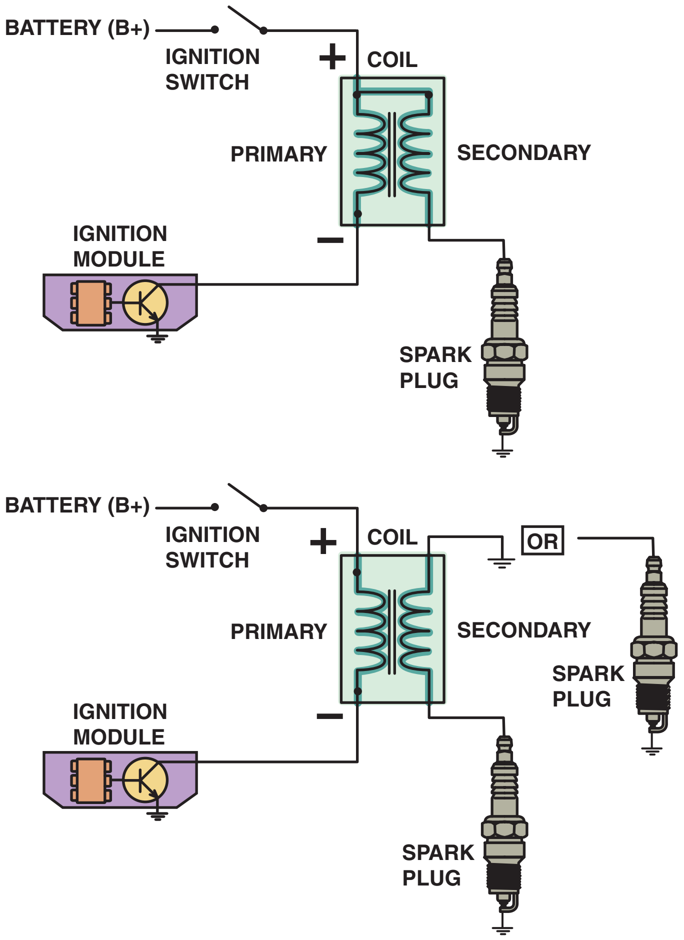

FIGURE 68–2 Some ignition coils are electrically connected, called married (top figure), whereas others use separate primary and secondary windings, called divorced (lower figure). The polarity (positive or negative) of a coil is determined by the direction in which the coil is wound.

DISTRIBUTOR IGNITION (DI) is the term specified by the Society of Automotive Engineers (SAE) for an ignition system that uses a distributor.

ELECTRONIC IGNITION (EI) is the term specified by the SAE for an ignition system that does not use a distributor. Types of EI systems include

1. **Waste-spark system.** This type of system uses one ignition coil to fire the spark plugs for two cylinders at the same time. ● **SEE FIGURE 68–2**.
2. **Coil-on-plug system.** This type of system uses a single ignition coil for each cylinder with the coil placed above or near the spark plug.

The ignition system includes components and wiring necessary to create and distribute a high voltage (up to 40,000 volts or more). All ignition systems apply voltage close to battery voltage (12 volts) to the positive side of the ignition coil and pulse the negative side to ground. When the coil negative lead is grounded, the primary (low-voltage) circuit of the coil is complete and a magnetic field is created around the coil windings. When the circuit is opened, the magnetic field collapses and induces a high-voltage spark in the secondary winding of the ignition coil. Early ignition systems used a mechanically opened set of contact points to make and break the electrical connection to ground. Electronic ignition uses a sensor, such as a pickup coil and reluctor (trigger wheel), or trigger to signal an electronic module that makes and breaks the primary connection of the ignition coil.

IGNITION COILS

PURPOSE AND FUNCTION The heart of any ignition system is the **ignition coil**. The coil creates a high-voltage spark by electromagnetic induction. Many ignition coils contain two separate, but electrically connected, windings of copper wire. Other coils are true transformers in which the primary and secondary windings are not electrically connected.

COIL CONSTRUCTION The center of an ignition coil contains a core of laminated soft iron (thin strips of soft iron). This core increases the magnetic strength of the coil. Surrounding the laminated core are approximately 20,000 turns of fine wire (approximately 42 gauge). These windings are called the secondary coil windings. Surrounding the secondary windings are approximately 150 turns of heavy wire (approximately 21 gauge). These windings are called the primary coil windings. The secondary winding has about 100 times the number of turns of the primary winding, referred to as the **turns ratio** (approximately 100:1). The E coil is so named because the laminated, soft-iron core is E-shaped, with the coil wire turns wrapped around the center "finger" of the E and the primary winding wrapped inside the secondary winding. ● **SEE FIGURES 68–3 AND 68–4**.

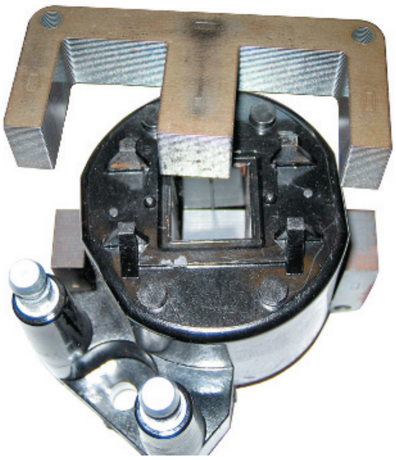

FIGURE 68–3 The steel lamination used in an E coil helps increase the magnetic field strength, which helps the coil produce higher energy output for a more complete combustion in the cylinders.

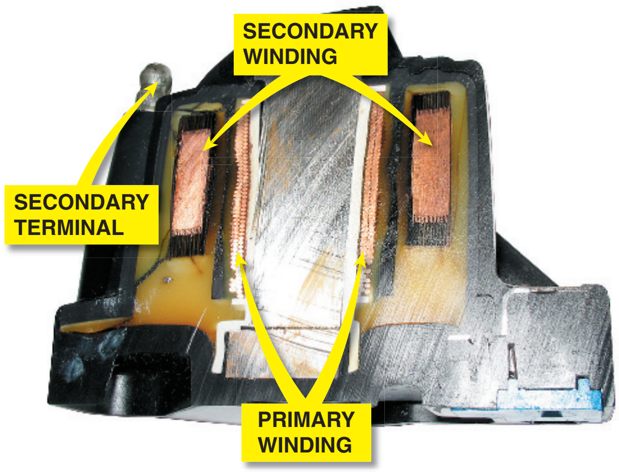

FIGURE 68–4 The primary windings are inside the secondary windings on this General Motors coil.

The primary windings of the coil extend through the case of the coil and are labeled as "positive" and "negative." The positive terminal of the coil attaches to the ignition switch, which supplies current from the positive battery terminal. The negative terminal is attached to an **ignition control module (ICM** or **igniter**), which opens and closes the primary ignition circuit by opening or closing the ground return path of the circuit. When the ignition switch is on, voltage should be available at *both* the positive terminal and the negative terminal of the coil if the primary windings of the coil have continuity.

SELF-INDUCTION When current starts to flow into a coil, an opposing current is created in the windings of the coil. This opposing current generation is caused by **self-induction** and is called **inductive reactance**. Inductive reactance is similar to resistance because it opposes any changes (increase or decrease) in current flow in a coil. Therefore, when an ignition coil is first energized, there is a slight delay of approximately 0.01 second before the ignition coil reaches its maximum magnetic field strength. The point at which a coil's maximum magnetic field strength is reached is called **saturation**.

MUTUAL INDUCTION In an ignition coil there are two windings, a primary and a secondary winding. When a *change* occurs in the magnetic field of one coil winding, a change also occurs in the other coil winding. Therefore, if the current is stopped from flowing (circuit is opened), the collapsing magnetic field cuts across the turns of the secondary winding and creates a high voltage in the secondary winding. This generation of an electric current in both coil windings is called **mutual induction**. The collapsing magnetic field also creates a voltage of up to 250 volts in the primary winding.

HOW IGNITION COILS CREATE 40,000 VOLTS All ignition systems use electromagnetic induction to produce a high-voltage spark from the ignition coil. Electromagnetic induction means that a current can be created in a conductor (coil winding) by a moving magnetic field. The magnetic field in an ignition coil is produced by current flowing through the primary windings of the coil. The current for the primary winding is supplied through the ignition switch to the positive terminal of the ignition coil. The negative terminal is connected to the ground return through an electronic ignition module (igniter).

If the primary circuit is completed, current (approximately 2 to 6 A) can flow through the primary coil windings. This flow creates a strong magnetic field inside the coil. When the primary coil winding ground return path connection is opened, the magnetic field collapses and induces a voltage of 250 to 400 volts in the primary winding of the coil, and a high-voltage (20,000 to 40,000 volts) low-amperage (20 to 80 mA) current in the secondary coil windings. This high-voltage pulse flows through the coil wire (if the vehicle is so equipped), distributor cap, rotor, and spark plug wires to the spark plugs. For each spark that occurs, the coil must be charged with a magnetic field and then discharged. The ignition components that regulate the current in the coil primary winding by turning it on and off are known collectively as the **primary ignition circuit**. The components necessary to create and distribute the high voltage produced in the secondary windings of the coil are called the **secondary ignition circuit**. ● **SEE FIGURE 68–4.** These circuits include the following components:

FREQUENTLY ASKED QUESTION

How Does the Computer Control the Ignition?

The powertrain control module (PCM) plays a key role in the final functioning of the ignition circuits. The PCM receives signals from all of the engine sensors and based on this information, uses an algorithm (computer program) to determine the best time to fire the spark plugs. For example, the sensors and how they could affect when the spark occurs include

Engine coolant temperature (ECT) sensor—The colder the engine, the more spark advance may be needed to achieve the highest possible engine output torque with lowest exhaust emissions.

Throttle position (TP) sensor—The PCM uses the TP sensor information to not only determine where the accelerator position is located but also at what rate it is changing. If the accelerator pedal is rapidly being depressed, spark timing may be delayed (retarded slightly) to help prevent spark knock.

Manifold absolute pressure (MAP) sensor—The MAP sensor is used to detect engine load. During a heavy load, less spark advance is needed to help prevent spark knock, whereas more spark advance is needed under light load conditions for the engine to achieve maximum fuel economy and the lowest possible exhaust emissions.

2. Distributor cap and rotor (if the vehicle is so equipped)
3. Spark plug wires
4. Spark plugs

● **SEE FIGURE 68–5.**

IGNITION SWITCHING AND TRIGGERING

For any ignition system to function, the primary current must be turned on to charge the coil and off to allow the coil to discharge, creating a high-voltage spark. This turning on and off of the primary circuit is called **switching**. The unit that does the switching is an electronic switch, such as a power transistor.

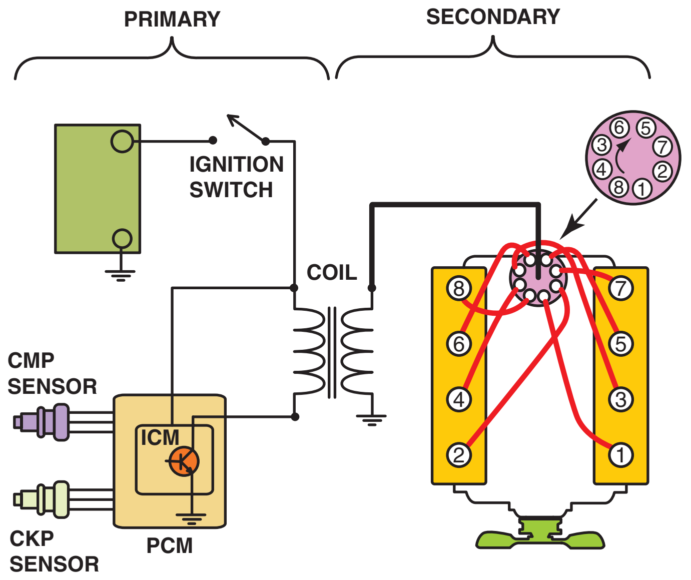

FIGURE 68–5 The primary ignition system is used to trigger, and therefore create the secondary (high-voltage) spark from the ignition coil.

This power transistor can be located in any of the following locations:

- In the ignition control module (ICM) as part of the coil-on-plug assembly
- In the ignition control module (ICM)
- In the powertrain control module (PCM)

The device that signals the switching of the coil on and off, or just on in most instances, is called the trigger. A trigger is typically a pickup coil in some distributor-type ignitions and a crankshaft position (CKP) sensor on electronic (waste-spark and coil-on-plug) and many distributor-type ignitions. There are two types of devices used for triggering, including the magnetic sensor or Hall-effect switch, and optical sensor.

IGNITION SYSTEM OPERATION

PRIMARY CIRCUIT To get a spark out of an ignition coil, the primary coil circuit must be turned on and off. This primary circuit current is controlled by a **transistor** (electronic switch) inside the ignition module (igniter).

The following are used as **crankshaft position (CKP) sensors** or **camshaft position (CMP) sensors**.

- **Hall-effect switch**—A **Hall-effect switch** also uses a stationary sensor and rotating trigger wheel (shutter). The Hall-effect switch requires a small input voltage to generate an output or signal voltage. Hall effect is the ability to generate a voltage signal in semiconductor material (gallium arsenate crystal) by passing current through it in one direction, and applying a magnetic field to it at a right angle to its surface. If the input current is held steady and the magnetic field fluctuates, an output voltage is produced that changes in proportion to field strength. Most Hall-effect switches have a Hall element or device, a permanent magnet, and a rotating ring of metal blades (shutters) similar to a trigger wheel (another method uses a stationary sensor with a rotating magnet). When the shutter blade enters the gap between the magnet and the Hall element, it creates a magnetic shunt that changes the field strength through the Hall element. This analog signal is sent to a **Schmitt trigger** inside the sensor itself, which converts the analog signal into a digital signal. A digital (on or off) voltage signal is created at a varying frequency to the ignition module or onboard computer. ● **SEE FIGURES 68–6 AND 68–7**.
- **Magnetic crankshaft position sensor**—A **magnetic sensor** uses the changing strength of the magnetic field surrounding a coil of wire to signal the module and computer. This signal is used by the electronics in the module and computer as to piston position and engine speed (RPM). ● **SEE FIGURES 68–8 AND 68–9**.

FREQUENTLY ASKED QUESTION

What Is Meant by the Firing Order?

Firing order means the order that the spark is distributed to the correct spark plug at the right time. The firing order of an engine is determined by crankshaft and camshaft design. The firing order is determined by the location of the spark plug wires in the distributor cap of an engine equipped with a distributor. The firing order is often cast into the intake manifold for easy reference. ● **SEE FIGURE 68–10**.

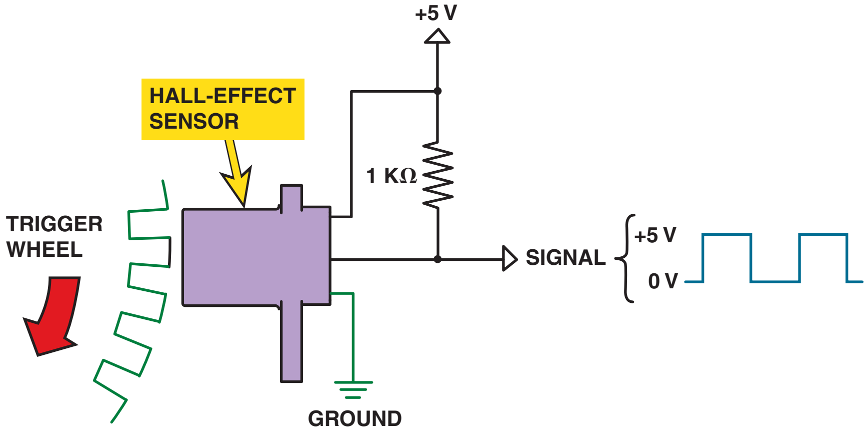

FIGURE 68–6 A Hall-effect sensor produces a digital on-off voltage signal whether it is used with a blade or a notched wheel.

FIGURE 68–7 Some Hall-effect sensors look like magnetic sensors. This Hall-effect camshaft reference sensor and crankshaft position sensor have an electronic circuit built in that creates a 0 to 5 volt signal as shown at the bottom. These Hall-effect sensors have three wires: a power supply (8 volts) from the computer (controller); a signal (0 to 5 volts); and a signal ground.

TECH TIP

The Tachometer Trick

When diagnosing a no-start or intermittent misfire condition, check the operation of the tachometer. If the tachometer does not indicate engine speed (no-start condition) or drops toward zero (engine misfire), the problem is due to a defect in the *primary* ignition circuit. The tachometer gets its signal from the pulsing of the primary winding of the ignition coil or the crankshaft position (CKP) sensor. The following components in the primary circuit could cause the tachometer to not work when the engine is cranking:

- Pickup coil
- Crankshaft position sensor
- Ignition module (igniter)
- Coil primary wiring

If the vehicle is not equipped with a tachometer, connect a scan tool and monitor engine RPM. Remember the following:

- No tachometer reading means the problem is in the primary ignition circuit.
- Tachometer reading okay means the problem is in the secondary ignition circuit or is a fuel-related problem.

WASTE-SPARK IGNITION SYSTEMS

OPERATION **Waste-spark ignition** is another name for distributorless-ignition system (DIS) or electronic ignition (EI). Waste-spark-ignition was introduced in the mid-1980s and uses the onboard computer to fire the ignition coils. These systems were first used on some Saabs and General Motors engines. A four-cylinder engine uses two ignition coils and a six-cylinder engine uses three ignition coils. Each coil is a true transformer in which the primary winding and secondary winding are not electrically connected. Each end of the secondary winding is connected to a cylinder exactly opposite the other in the firing order, which is called a **companion (paired) cylinder**.

● **SEE FIGURE 68–11**. This means that *both* spark plugs fire at the same time (within nanoseconds of each other). When one cylinder (e.g., 6) is on the compression stroke, the other cylinder (3) is on the exhaust stroke. This spark that occurs on the exhaust stroke is called the waste spark, because it does no useful work and is only used as a ground path for the secondary winding of the ignition coil. The voltage required to jump the spark plug gap on cylinder 3 (the exhaust stroke) is only 2 to 3 kV and provides the *ground circuit* for the secondary coil circuit. The remaining coil energy is used by the cylinder on the compression stroke. One spark plug of each pair always fires straight polarity and the other cylinder always fires reverse polarity. Spark plug life is not greatly-affected by the reverse polarity. If there is only one defective spark plug wire or spark plug, two cylinders may be affected.

FIGURE 68–11 A waste-spark system fires one cylinder while its piston is on the compression stroke and into paired or companion cylinders while it is on the exhaust stroke. In a typical engine, it requires only about 2 to 3 kV to fire the cylinder on the exhaust strokes. The remaining coil energy is available to fire the spark plug under compression (typically about 8 to 12 kV).

COIL-ON-PLUG IGNITION

Coil-on-plug (COP) ignition uses one ignition coil for each spark plug. This system is also called coil-by-plug, coil-near-plug, or coil-over-plug ignition. ● **SEE FIGURES 68–12, 68–13 AND 68–14.** The coil-on-plug system eliminates the spark plug wires, which are often sources of **electromagnetic interference (EMI)** that can cause problems to some computer signals. The vehicle computer controls the timing of the spark. Ignition timing also can be changed (retarded or advanced) on a cylinder-by-cylinder basis for maximum performance and to respond to knock sensor signals.

There are two basic types of coil-on-plug ignition:

- **Two-wire**—This design uses the vehicle computer to control the firing of the ignition coil. The two wires include ignition voltage feed and the pulse ground wire, which is controlled by the computer. All ignition timing and dwell control are handled by the computer.
- **Three-wire**—This design includes an ignition module at each coil. The three wires are:
    - Ignition voltage
    - Ground
    - Pulse from the computer to the built-in module

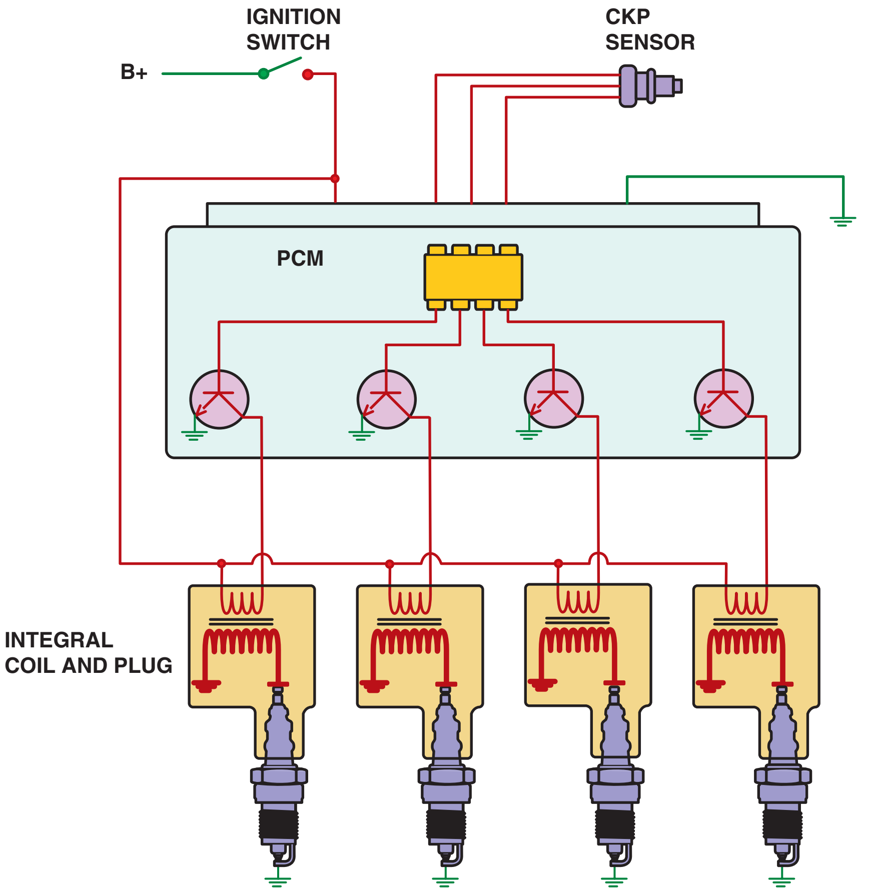

FIGURE 68–12 A typical two-wire coil-on-plug ignition system showing the triggering and the switching being performed by the PCM from input from the crankshaft position sensor.

TECH TIP

Odds Fire Straight

Waste-spark ignition systems fire two spark plugs at the same time. Most vehicle manufacturers use a waste-spark system that fires the odd-numbered cylinders (1, 3, and 5) by straight polarity (current flow from the top of the spark plug through the gap and to the ground electrode). The even-numbered -cylinders (2, 4, and 6) are fired reverse polarity, meaning that the spark jumps from the side electrode to the -center electrode. Some vehicle manufacturers equip their vehicles with platinum plugs with the expansive -platinum alloy only on one electrode as follows:

- On odd-numbered cylinders (1, 3, 5), the platinum is on the center electrode.
- On even-numbered cylinders (2, 4, 6), the platinum is on the ground electrode.

Replacement spark plugs use platinum on both electrodes (double platinum) and can, therefore, be placed in any cylinder location.

General Motors vehicles use a variety of coil-on-plug-type ignition systems. Many V-8 engines use a coil-near-plug system with individual coils and modules for each individual cylinder that are placed on the valve covers. Short secondary ignition spark plug wires are used to connect the output terminal of the ignition coil to the spark plug.

EXHAUST CAM PHASER SOLENOID
CAMSHAFT POSITION (CMP) SENSOR

FIGURE 68–13 An overhead camshaft engine equipped with variable valve timing on both the intake and exhaust camshafts and coil-on-plug ignition.

Most newer Chrysler engines use coil-over-plug-type ignition systems. Each coil is controlled by the PCM, which can vary the ignition timing separately for each cylinder based on signals the PCM receives from the knock sensor(s). For example, if the knock sensor detects that a spark knock has occurred after firing cylinder 3, then the PCM will continue to monitor cylinder 3 and retard timing on just this one cylinder if necessary to prevent-engine-damaging detonation.

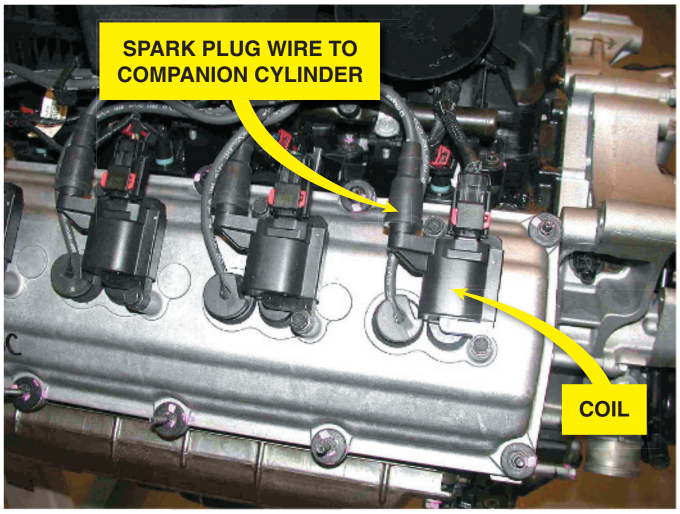

FIGURE 68–14 Chrysler Hemi V-8 that has two spark plugs per cylinder. The coil on top of one spark fires that plug plus, through a spark plug wire, fires a plug in the companion cylinder.

SAFETY TIP

Never Disconnect a Spark Plug Wire When the Engine Is Running!

Ignition systems produce a high-voltage pulse necessary to ignite a lean air–fuel mixture. If you disconnect a spark plug wire when the engine is running, this high-voltage spark could cause personal injury or damage to the ignition coil and/or ignition module.

IGNITION TIMING

THE NEED FOR SPARK ADVANCE **Ignition timing** refers to when the spark plug fires in relation to piston position. The time when the spark occurs depends on engine speed, and therefore, must be advanced (spark plugs fire some) as the engine rotates faster. The ignition in the cylinder takes a certain amount of time, usually 30 milliseconds (30/1000 of a second). This burning time is relatively constant throughout the entire engine speed range. For maximum efficiency from the expanding gases inside the combustion chamber, the burning of the air–fuel mixture should end by about 10 degrees after top dead center (ATDC). If the burning of the mixture is still occurring after that point, the expanding gases do not exert much force on the piston because it is moving away from the gases (the gases are "chasing" the piston).

Therefore, to achieve the goal of having the air–fuel mixture be completely burned by the time the piston reaches 10 degrees after top dead center, the spark must be advanced (occur sooner) as the engine speed increases. This timing advance is determined and controlled by the PCM on most vehicles. ● **SEE FIGURE 68–15.**

INITIAL TIMING If the engine is equipped with a distributor, it may be possible to adjust the base or the **initial timing**. The initial timing is usually set to fire the spark plug between zero degrees (top dead center or TDC) or slightly before TDC (BTDC). Ignition timing does change as the timing chain or gear wears and readjustment is often necessary on high-mileage engines. ● **SEE FIGURE 68–16**. Waste-spark and coil-on-plug ignitions cannot be adjusted.

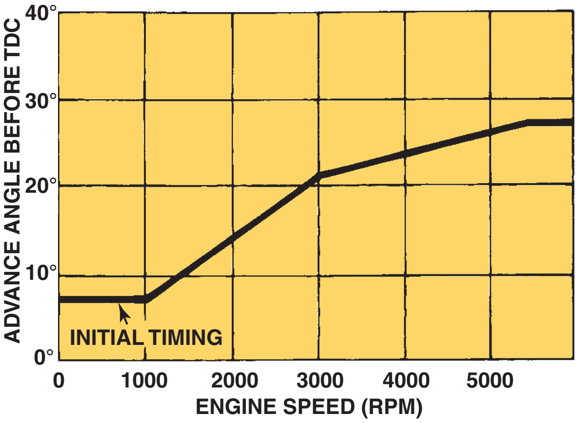

FIGURE 68–15 The initial timing is where the spark plug fires at idle speed. The computer then advances the timing based on engine speed and other factors.

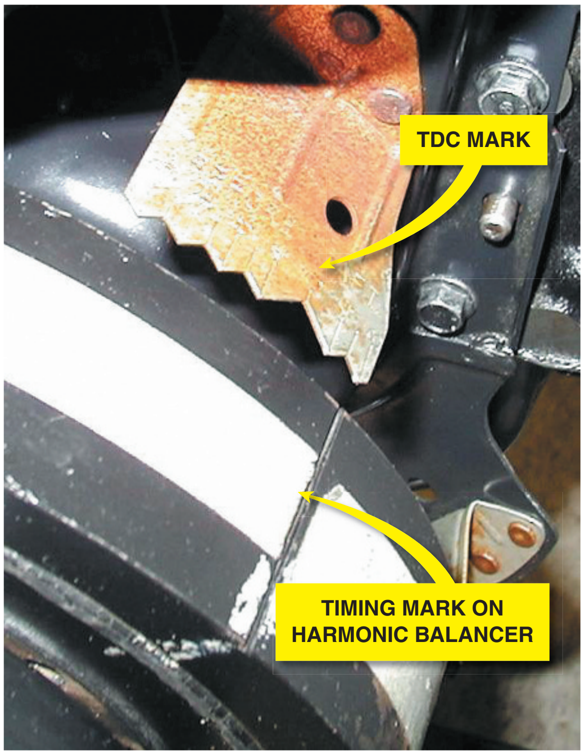

FIGURE 68–16 Ignition timing marks are found on the harmonic balancers that are equipped with distributor ignition.

KNOCK SENSORS

OPERATION Knock sensors are used to detect abnormal combustion, often called **ping**, **spark knock**, or **detonation**. Whenever abnormal combustion occurs, a rapid pressure increase occurs in the cylinder, creating a vibration in the engine block. It is this vibration that is detected by the knock sensor. The signal from the knock sensor is used by the PCM to retard the

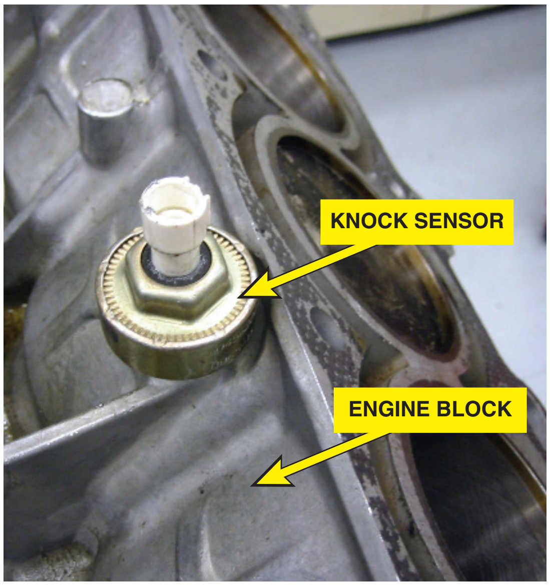

FIGURE 68–17 A knock sensor which is used by the powertrain control module (PCM) to detect engine detonation.

ignition timing until the knock is eliminated, thereby reducing the damaging effects of the abnormal combustion on pistons and other engine parts.

Inside the knock sensor is a piezoelectric element that generates a voltage when pressure or a vibration is applied to the unit. The knock sensor is tuned to the engine knock frequency, which ranges from 5 to 10 kHz, depending on the engine design. The voltage signal from the **knock sensor (KS)** is sent to the PCM. The PCM retards the ignition timing until the knocking stops. ● **SEE FIGURE 68–17**.

DIAGNOSING THE KNOCK SENSOR If a knock sensor diagnostic trouble code (DTC) is present, follow the specified testing procedure in the service information. A scan tool can be used to check the operation of the knock sensor, using the following procedure:

STEP 1 Start the engine and connect a scan tool to monitor ignition timing and/or knock sensor activity.

STEP 2 Create a simulated engine knocking sound by tapping on the engine block or cylinder head with a soft-faced mallet.

STEP 3 Observe the scan tool display. The vibration from the tapping should have been interpreted by the knock sensor as a knock, resulting in a knock sensor signal and a reduction in the spark advance.

A knock sensor also can be tested using a digital storage oscilloscope. ● **SEE FIGURE 68–18**.

NOTE: Some engine computers are programmed to ignore knock sensor signals when the engine is at idle speed to avoid having the noise from a loose accessory drive belt, or other accessory, interpreted as engine knock. Always follow the vehicle manufacturer's recommended testing procedure.

REPLACING A KNOCK SENSOR If replacing a knock sensor, be sure to purchase the exact replacement needed, because they often look the same, but the frequency range can vary according to engine design, as well as where it is located on the engine. Always tighten the knock sensor using a torque wrench and tighten to the specified torque to avoid causing damage to the piezoelectric element inside the sensor.

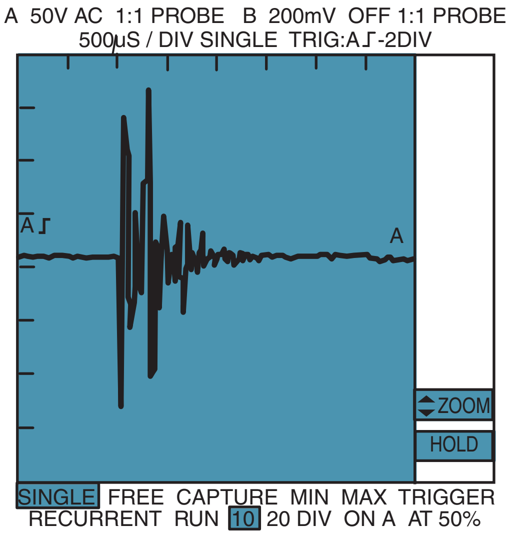

FIGURE 68–18 A typical waveform from a knock sensor during a spark knock event. This signal is sent to the computer which in turn retards the ignition timing. This timing retard is accomplished by an output command from the computer to either a spark advance control unit or directly to the ignition module.

SPARK PLUGS

TERMINOLOGY Spark plugs are manufactured from ceramic insulators inside a steel shell. The threads of the shell are rolled and a seat is formed to create a gastight seal with the cylinder head. ● **SEE FIGURE 68–19**. The physical difference in spark plugs includes

- **Reach.** This is the length of the threaded part of the plug.
- **Heat range.** The heat range of the spark plug refers to how rapidly the heat created at the tip is transferred to

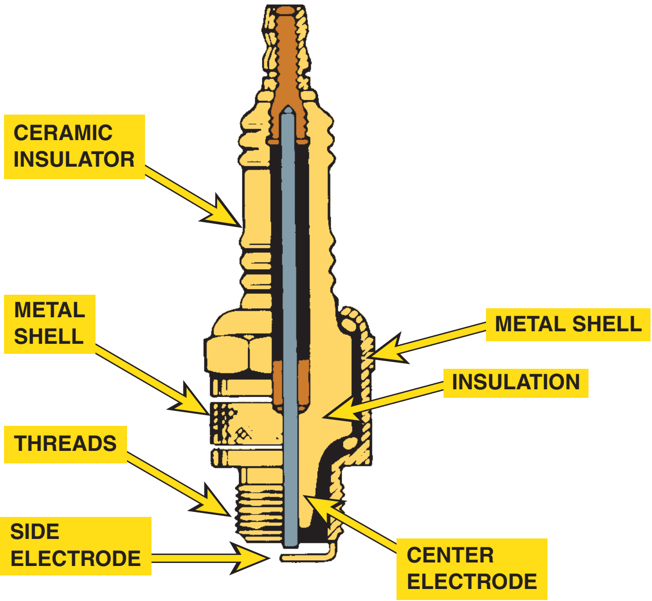

FIGURE 68–19 Parts of a typical spark plug.

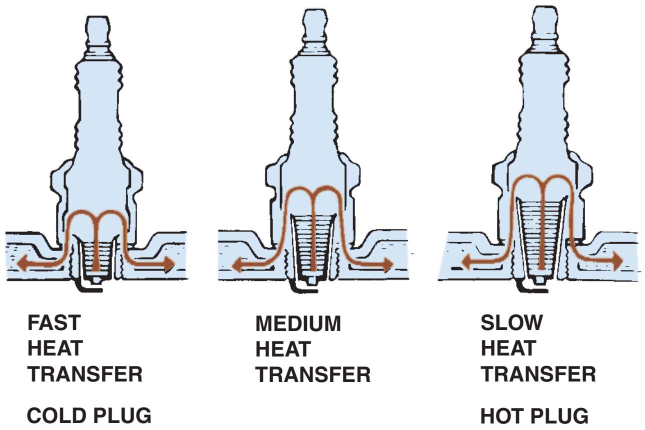

FIGURE 68–20 The heat range of a spark plug is determined by the distance the heat has to flow from the tip to the cylinder head.

the cylinder head. A plug with a long ceramic insulator path will run hotter at the tip than a spark plug that has a shorter path because the heat must travel farther. ● **SEE FIGURE 68–20**.

- **Type of seat.** Some spark plugs use a gasket and others rely on a tapered seat to seal.

RESISTOR SPARK PLUGS Most spark plugs include a resistor in the center electrode, which helps to reduce electromagnetic noise or radiation from the ignition system. The closer the resistor is to the actual spark or arc, the more effective it becomes. The value of the resistor is usually between 2,500 and 7,500 ohms.

PLATINUM SPARK PLUGS **Platinum spark plugs** have a small amount of the precious metal platinum welded onto the end of the center electrode, as well as on the ground or side electrode. Platinum is a grayish-white metal that does not react with oxygen and therefore, will not erode away as can occur with conventional nickel alloy spark plug electrodes. Platinum is also used as a catalyst in catalytic converters where it is able to start a chemical reaction without itself being consumed.

IRIDIUM SPARK PLUGS Iridium is a white precious metal and is the most corrosion-resistant metal known. Most **iridium spark plugs** use a small amount of iridium welded onto the tip of a small center electrode 0.0015 to 0.002 inches (0.4 to 0.6 mm) in diameter. The small diameter reduces the voltage required to jump the gap between the center and the side electrode, thereby reducing possible misfires. The ground or side electrode is usually tipped with platinum to help reduce electrode gap wear.

REVIEW QUESTIONS

1. How can 12 volts from a battery be changed to 40,000 volts for ignition?
2. How does a magnetic sensor work?
3. How does a Hall-effect sensor work?
4. How does a waste-spark ignition system work?
5. What does the heat range of a spark plug refer to?

CHAPTER QUIZ

1. The primary (low-voltage) ignition system must be working correctly before any spark occurs from a coil. Which component is not in the primary ignition circuit?
   a. Spark plug wiring
   b. Ignition module (igniter)
   c. Pickup coil (pulse generator)
   d. Ignition switch
2. An ignition coil contains _________.
   a. one coil winding
   b. two coil windings
   c. three coil windings
   d. four coil windings
3. A married ignition coil has _________.
   a. the secondary winding attached to separate spark plugs
   b. the primary winding connected to one side of the secondary winding
   c. the primary winding attached to the spark plug(s)
   d. Both a and c
4. A magnetic sensor uses a permanent magnet surrounded by a _________.
   a. shield
   b. coil of wire
   c. notched wheel
   d. plastic insulation
5. A _________ uses a stationary sensor and rotating trigger wheel (shutter).
   a. Schmitt trigger
   b. spark plug
   c. Hall-effect sensor
   d. PCM
6. The PCM uses what sensor(s) to determine when to fire the spark plug?
   a. ECT
   b. TP
   c. MAP
   d. All of the above
7. A COP ignition system can be called _________.
   a. coil-by-plug
   b. coil-near-plug
   c. coil-over-plug
   d. Any of the above
8. BTDC means _________.
   a. bottom top dead center
   b. before top dead center
   c. beyond top dead center
   d. Any of the above
9. What term describes the length of the threaded portion of a spark plug?
   a. Reach
   b. Range
   c. Seat angle
   d. None of these
10. What tools or equipment are needed to test a knock sensor?
   a. A soft-faced mallet
   b. Scan tool
   c. Both a and b
   d. Neither a nor b

IGNITION SYSTEM DIAGNOSIS AND SERVICE

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe the procedure used to check for spark.
- Describe the electronic ignition troubleshooting procedure.
- Describe ignition coil testing using an ohmmeter.
- Describe how to test magnetic sensors.
- Describe how to test Hall-effect sensors.
- Discuss visual inspection of the ignition system.
- Explain how to test for poor performance.
- Explain how to test for a no-start condition.
- Inspect and test ignition system secondary circuits.
- Describe spark plug service.
- Describe secondary ignition tests.
- Describe how to test the ignition system using an oscilloscope.
- Describe how to scope-test a waste-spark ignition system.
- Describe how to scope-test a coil-on-plug ignition system.
- Diagnose ignition system-related problems.

KEY TERMS:

Automatic shutdown (ASD) relay 825 • Dwell section 834 • Firing line 833 • Intermediate oscillations 834 • Remove and replace (R & R) 830 • Spark line 833 • Spark tester 824

CHECKING FOR SPARK

In the event of a no-start condition, the first step should be to check for secondary voltage out of the ignition coil or to the spark plugs. If the engine is equipped with a separate ignition coil, remove the coil wire from the center of the distributor cap, install a **spark tester**, and crank the engine. See the Tech Tip "Always Use a Spark Tester." A good coil and ignition system should produce a blue spark at the spark tester. ● **SEE FIGURES 69–1 AND 69–2**.

If the ignition system being tested does not have a separate ignition coil, disconnect any spark plug wire from a spark plug and, while cranking the engine, test for spark available at the spark plug wire, again using a spark tester.

NOTE: An intermittent spark should be considered a no-spark condition.

Typical causes of a no-spark (intermittent spark) condition include the following:

1. Weak ignition coil
2. Low or no voltage to the primary (positive) side of the coil
3. High resistance or open coil wire, or spark plug wire
4. Negative side of the coil not being pulsed by the ignition module, also called an ignition control module (ICM)
5. Defective pickup coil
6. Defective module

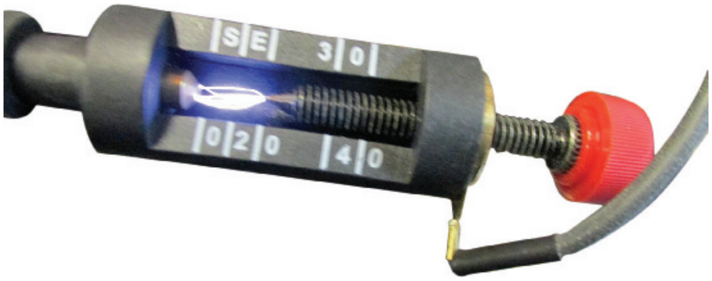

FIGURE 69–1 An adjustable spark tester that can be adjusted and should be set to at least 25,000 volts. The tester is connected to a disconnected spark plug wire or coil and the pigtail clipped to a good chassis ground. Cranking the engine should cause a spark to be seen from the spark tester.

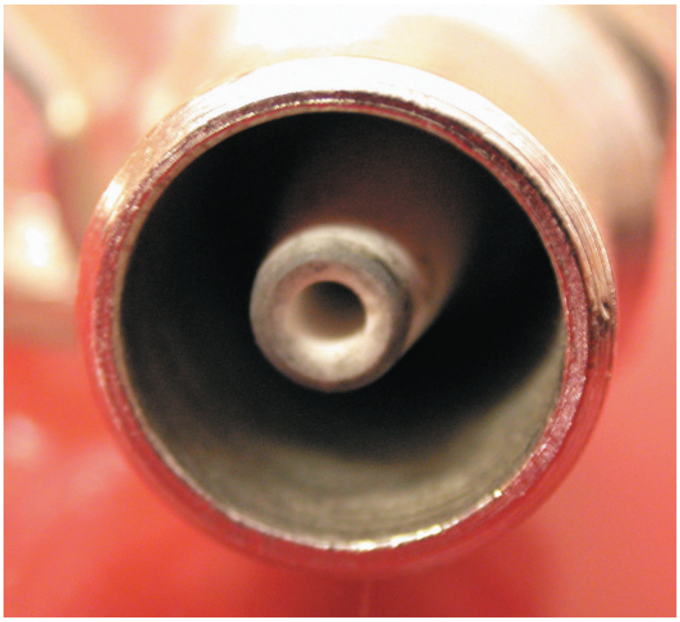

FIGURE 69–2 A close-up showing the recessed center electrode on a spark tester. It is recessed 3/8 inch into the shell and the spark must then jump another 3/8 inch to the shell for a total gap of 3/4 inch.

TECH TIP

Always Use a Spark Tester

A spark tester looks like a spark plug except it has a recessed center electrode and no side electrode. The tester commonly has an alligator clip attached to the shell so that it can be clamped on a good ground connection on the engine. A good ignition system should be able to cause a spark to jump this wide gap at atmospheric pressure. Without a spark tester, a technician might assume that the ignition system is okay because it can spark across a normal, grounded spark plug. The voltage required to fire a standard spark plug when it is out of the engine and not under pressure is about 3,000 volts or less. An electronic ignition spark tester requires a minimum of 25,000 volts to jump the 3/4 inch gap. Therefore, never assume that the ignition system is okay because it fires a spark plug–always use a spark tester. *Remember that an intermittent spark across a spark tester should be interpreted as a no-spark condition.*

CASE STUDY

The Weird Running Chevrolet Truck

An older Chevrolet pickup truck equipped with a V-8 engine was towed into a shop because it would not start. A quick check of the ignition system showed that the pickup coil had a broken wire between it and the ignition control module. The distributor was removed from the engine and the distributor shaft was removed, cleaned, and a replacement pickup coil was installed. The engine started, but ran rough and hesitated when the accelerator pedal was depressed. After an hour of troubleshooting, a careful inspection of the new pickup coil showed that the time core had six instead of eight points, meaning that the new pickup coil was meant for a V-6 instead of a V-8 engine. Replacing the pickup coil again solved the problem.

Summary:

Complaint—Customer stated that the truck would not start.
Cause—A visual inspection was used to determine a that a pickup coil wire was broken and was replaced but with the wrong part that was in the correct box.
Correction—Replacing the pickup coil with the right part fixed the truck.

ELECTRONIC IGNITION TROUBLESHOOTING PROCEDURE

When troubleshooting any electronic ignition system for no spark, follow these steps to help pinpoint the exact cause of the problem:

STEP 1 Turn the ignition on (engine off) and, using either a voltmeter or a test light, test for battery voltage available at the positive terminal of the ignition coil. If the voltage is not available, check for an open circuit at the ignition switch or wiring. Also check the condition of the ignition fuse (if used).

NOTE: Many Chrysler group products use an automatic shutdown (ASD) relay to power the ignition coil. The ASD relay will not supply voltage to the coil unless the engine is cranking and the computer senses a crankshaft sensor signal. This little known fact has fooled many technicians.

STEP 2 Connect the voltmeter or test light to the negative side of the coil and crank the engine. The voltmeter should fluctuate or the test light should blink, indicating that the primary coil current is being turned on and off. If there is no pulsing of the negative side of the coil, the problem is a defective pickup, electronic control module, or wiring.

IGNITION COIL TESTING USING AN OHMMETER

If an ignition coil is suspected of being defective, a simple ohmmeter check can be performed to test the resistance of the primary and secondary winding inside the coil. For accurate resistance measurements, the wiring to the coil should be removed before testing. To test the primary coil winding resistance, take the following steps (● **SEE FIGURE 69–3**):

STEP 1 Set the meter to read low ohms.

STEP 2 Measure the resistance between the positive terminal and the negative terminal of the ignition coil. Most coils

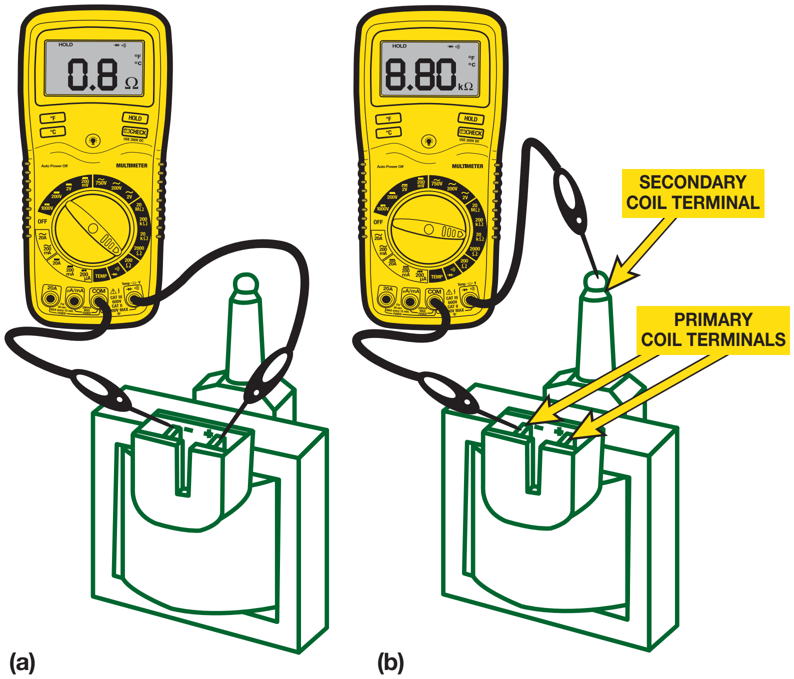

FIGURE 69–3 (a) Set the digital meter to read Ohms and measure between the two primary terminals of the coil. Most coils are less than 1 ohm. (b) To measure the secondary winding, connect 1 meter lead to one of the primary terminals and the other to the secondary terminal.

will give a reading between 1 and 3 ohms; however, some coils should indicate less than 1 ohm. Check the manufacturer's specifications for the exact resistance values.

To test the secondary coil winding resistance, follow these steps:

STEP 1 Set the meter to read kilohms (kΩ).

STEP 2 Measure the resistance between primary terminal and the secondary coil tower. The normal resistance of most coils ranges between 6,000 and 30,000 ohms. Check the manufacturer's specifications for the exact resistance values.

TESTING MAGNETIC SENSORS

First of all, magnetic sensors must be tested to see if they will stick to iron or steel, indicating that the magnetic strength of the sensors is okay. If the permanent magnet inside the sensor has cracked, the result is two weak magnets.

If the sensor is removed from the engine, hold a metal (steel) object against the end of the sensor. It should exert a strong magnetic pull on the steel object. If not, replace the sensor. Second, the sensor can be tested using a digital meter set to read ohms or AC volts. ● **SEE FIGURE 69–4**.

TESTING HALL-EFFECT SENSORS

As with any other sensor, the output of the Hall-effect sensor should be tested first. Using a digital voltmeter, check for the presence of changing voltage (pulsed on and off or digital DC) when the engine is being cranked. The best test is to use an oscilloscope and observe the waveform. ● **SEE FIGURE 69–5**.

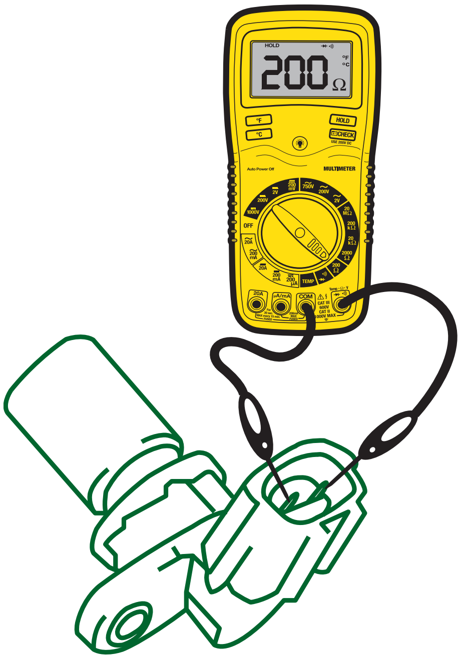

FIGURE 69–4 Measuring the resistance of an magnetic crankshaft position (CKP) sensor using an ohmmeter.

IGNITION SYSTEM DIAGNOSIS USING VISUAL INSPECTION

One of the first steps in the diagnosis process is to perform a thorough visual inspection of the ignition system, including the following:

- Check all spark plug wires for proper routing. All plug wires should be in the factory wiring separator and be clear of any metallic object that could cause damage to the insulation and cause a short-to-ground fault.

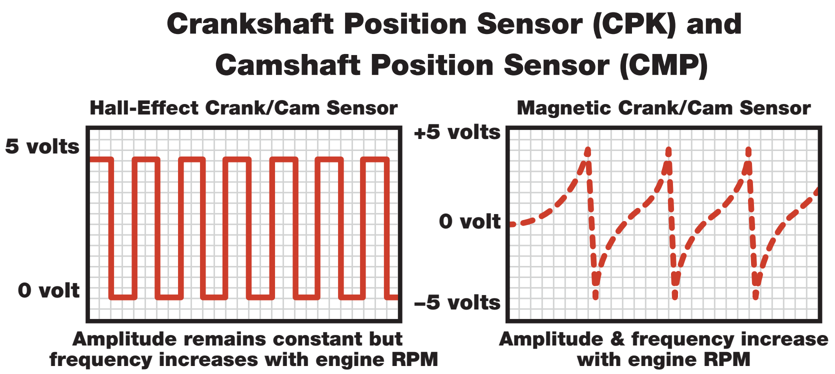

FIGURE 69–5 A Hall-effect sensor produces a square waveform, whereas a magnetic sensor produces an analog waveform when viewed on the scope.

TECH TIP

Bad Wire? Replace the Coil!

When performing engine testing (such as a compression test), always ground the coil wire. Never allow the coil to discharge without a path to ground for the spark. High-energy electronic ignition systems can produce 40,000 volts or more of electrical pressure. If the spark cannot arc to ground, the coil energy can (and usually does) arc inside the coil itself, creating a low-resistance path to the primary windings or the steel laminations of the coil. ● **SEE FIGURE 69–6**. This low-resistance path is called a track and could cause an engine misfire under load even though all of the remaining component parts of the ignition system are functioning correctly. Often these tracks do not show up on any coil test, including most scopes. Because the track is a lower-resistance path to ground than normal, it requires that the ignition system be put under a load for it to be detected, and even then, the problem (engine misfire) may be intermittent.

Therefore, when disabling an ignition system, perform one of the following procedures to prevent possible ignition coil damage:

1. Remove the power source wire from the ignition system to prevent any ignition operation.
2. On distributor-equipped engines, remove the secondary coil wire from the center of the distributor cap and connect a jumper wire between the disconnected coil wire and a good engine ground. This ensures that the secondary coil energy will be safely grounded and prevents high-voltage coil damage.

TECH TIP

The Magnetic Pickup Tool Test

All ignition coils are pulsed on and off by the ignition control module or PCM. When the coil charges and discharges, the magnetic field around the coil changes. This pulsing of the coil can be observed by holding the magnetic end of a pickup tool near an operating ignition coil. The magnet at the end of the pickup tool will move as the magnetic field around the coil changes. ● **SEE FIGURE 69–7**.

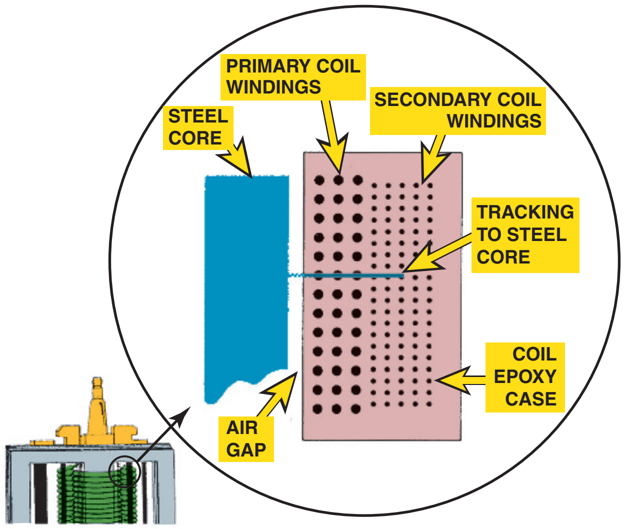

FIGURE 69–6 A track inside an ignition coil is not a short, but rather it is a low-resistance path or hole that has been burned through from the secondary wiring to the steel core.

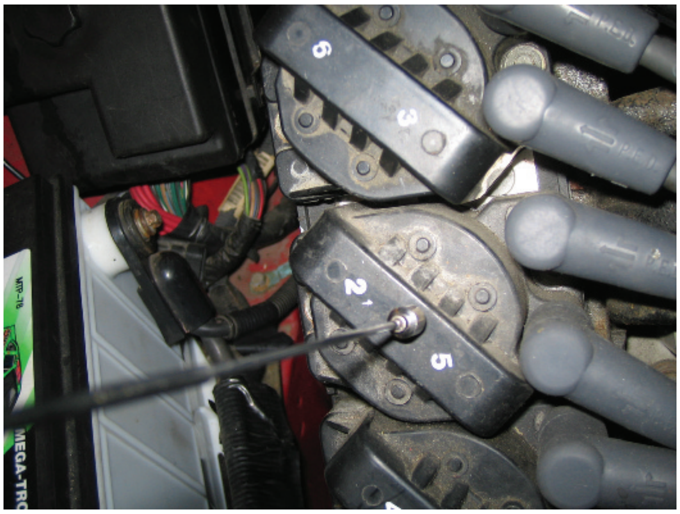

FIGURE 69–7 If the coil is working, the end of the magnetic pickup tool will move with the changes in the magnetic field around the coil.

- Check that all spark plug wires are securely attached to the spark plugs and to the distributor cap or ignition coil(s).
- Remove the spark plugs and check for excessive wear or other visible faults. Replace if needed.

NOTE: According to research conducted by General Motors, about one-fifth (20%) of all faults are detected during a *thorough visual inspection!*

TESTING FOR POOR PERFORMANCE

A simple method of testing distributorless (waste-spark systems) ignition with the engine off involves removing the spark plug wires (or connectors) from the spark plugs (or coils or distributor cap) and installing short lengths (2 inches) of rubber vacuum hose in series.

NOTE: For best results, use rubber hose that is electrically conductive. Measure the vacuum hose with an ohmmeter. Suitable vacuum hose should give a reading of less than 10,000 ohms (10 kΩ) for a length of about 2 inches. ● SEE FIGURES 69–7 AND 69–8.

STEP 1 Start the engine and ground out each cylinder one at a time by touching the tip of a grounded test light to the rubber vacuum hose. Even though the computer will increase idle speed and fuel delivery to compensate for the grounded spark plug wire, a technician should watch for a change in the operation of the engine. If no change is observed or heard, the cylinder being grounded is obviously weak or defective. Check the spark plug wire or connector with an ohmmeter to be certain of continuity.

STEP 2 Check all cylinders by grounding them out one at a time. If one weak cylinder is found (very little RPM drop), check the other cylinder using the same ignition coil (except on engines that use an individual coil for each cylinder). If both cylinders are affected, the problem could be an open spark plug wire, defective spark plug, or defective ignition coil.

STEP 3 To help eliminate other possible problems and determine exactly what is wrong, switch the suspected ignition coil to another position (if possible).

- If the problem now affects the other cylinders, the ignition coil is defective and must be replaced.
- If the problem does not "change positions" with changing the position of the ignition coil, the control module affecting the suspected coil or either cylinder's spark plug or spark plug wire could be defective.

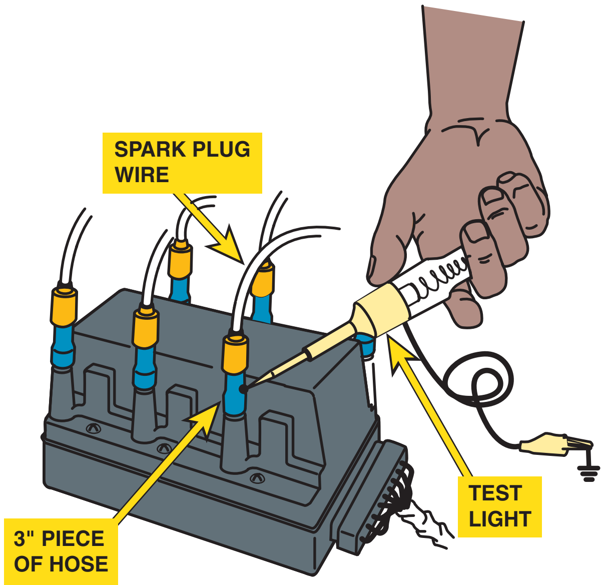

FIGURE 69–8 Using a vacuum hose and a grounded testlight to ground one cylinder at a time on a DIS. This works on all types of ignition systems and provides a method for grounding out one cylinder at a time without fear of damaging any component. Use a standard 12-volt test light that uses a bulb because if an LED test light is used, the high-voltage with harm the electronic circuit inside the test light.

TESTING FOR A NO-START CONDITION

A no-start condition (with normal engine cranking speed) can be the result of either no spark or no fuel delivery.

Computerized engine control systems use the ignition primary pulses as a signal to inject fuel–a port or throttle-body injection (TBI) style of fuel–injection system. If there is no pulse, there is no squirt of fuel. To determine exactly what is wrong, follow these steps:

STEP 1 Test the output signal from the crankshaft sensor. Most computerized engines with distributorless ignitions use a crankshaft position sensor. These sensors are either the Hall-effect type or the magnetic type. The sensors must be able to produce either a sine or a digital signal. A meter set on AC volts should read a voltage across the sensor leads when the engine is being cranked. If there is no AC voltage output, replace the sensor.

STEP 2 If the sensor tests okay in step 1, check for a changing AC voltage signal at the ignition module.

NOTE: Step 2 checks the wiring between the crankshaft position sensor and the ignition control module.

STEP 3 If the ignition control module is receiving a changing signal from the crankshaft position sensor, it must be capable of switching the power to the ignition coils on and off. Remove a coil or coil package, and with the ignition switched to on (run), check for voltage at the positive terminal of the coil(s).

NOTE: Several manufacturers program the current to the coils to be turned off within several seconds of the ignition being switched to on if no pulse is received by the computer. This circuit design helps prevent ignition coil damage in the event of a failure in the control circuit or driver error, by keeping the ignition switch on (run) without operating the starter (start position). Some Chrysler engines do not supply power to the positive (+) side of the coil until a crank pulse is received by the computer, which then energizes the coil(s) and injectors through the automatic shutdown (ASD) relay.

STEP 4 If the module is not pulsing the negative side of the coil or not supplying battery voltage to the positive side of the coil, replace the ignition control module.

NOTE: Before replacing the ignition control module, be certain that it is properly grounded (where applicable) and that the module is receiving ignition power from the ignition circuit.

CAUTION: Most distributorless (waste-spark) ignition systems can produce 40,000 volts or more, with energy levels high enough to cause personal injury. Do not open the circuit of an electronic ignition secondary wire because damage to the system (or to you) can occur.

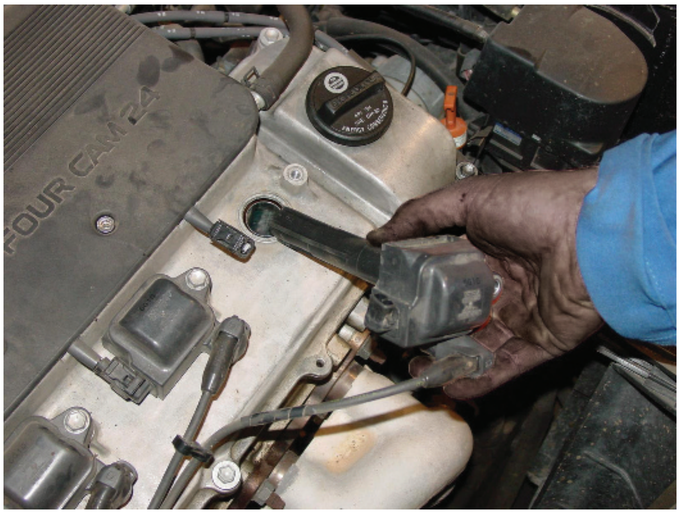

FIGURE 69–9 When checking a coil-on-plug (COP) assembly, check that the primary and secondary wiring looks normal and that the coil is not discolored from arcing or corrosion.

SECONDARY IGNITION INSPECTION

COP AND WASTE SPARK INSPECTION If a misfire is being diagnosed, perform a thorough visual inspection of the coil-on-plug (COP) assembly and look for evidence of carbon track or heat-related faults to the plug boot. ● **SEE FIGURE 69–9.**

Check ignition coils of waste spark and coil-on-plug (COP) systems for signs of carbon tracks (black lines) or corrosion.

When checking a waste spark-type ignition system, check that the coils are clean and that the spark plug wires are attached to the specified coil and coil terminal. ● **SEE FIGURES 69–10 AND 69–11**.

SPARK PLUG WIRE INSPECTION Spark plug wires should be visually inspected for cuts or defective insulation and checked for resistance with an ohmmeter. Good spark plug wires should measure less than 10,000 ohms per foot of length. ● **SEE FIGURES 69–12 AND 69–13**. Faulty spark plug wire insulation can cause hard starting or no starting in damp weather conditions.

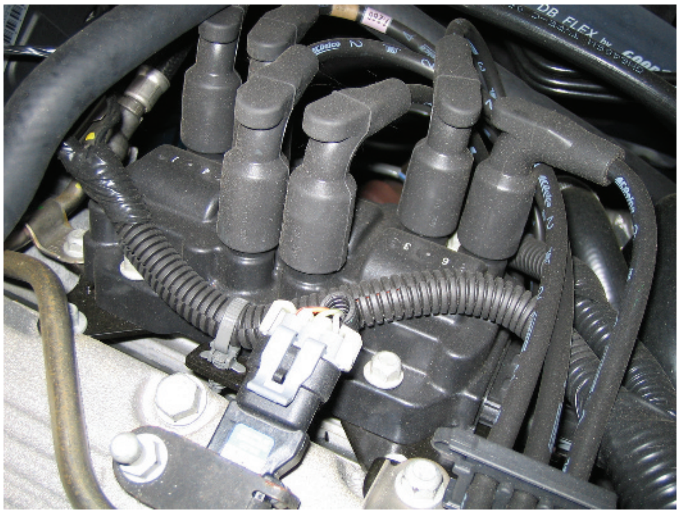

FIGURE 69–10 When checking a waste spark-type ignition system, check that the secondary wires are attached to the correct coil terminal and that the wiring is correctly routed to help avoid cross-fire.

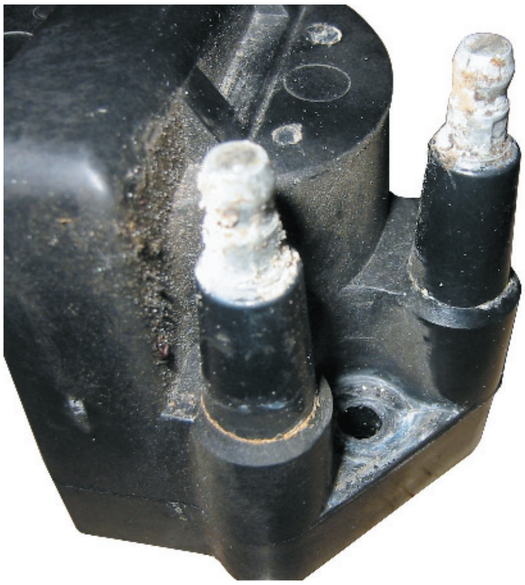

FIGURE 69–11 Corroded terminals on a waste-spark coil can cause misfire diagnostic trouble codes to be set.

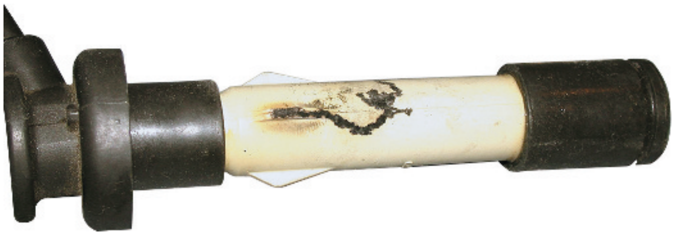

FIGURE 69–12 This spark plug boot on an overhead camshaft engine has been arcing to the valve cover causing a misfire to occur.

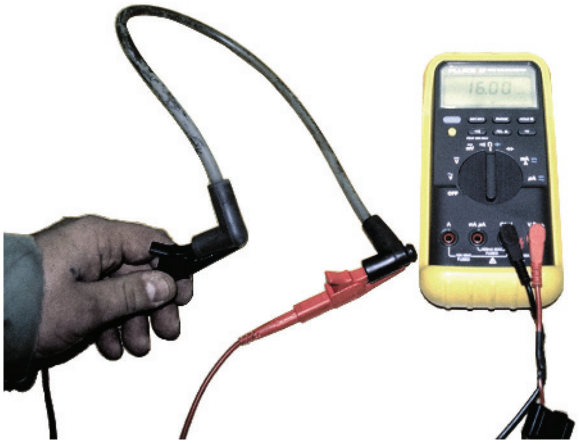

FIGURE 69–13 Measuring the resistance of a spark plug wire with a multimeter set to the ohms position. The reading of 16.03 kΩ (16,030 ohms) is okay because the wire is about 2 feet long. Maximum allowable resistance for a spark plug wire this long would be 20 kΩ (20,000 ohms). High resistance spark plug wires can cause an engine misfire especially during acceleration.

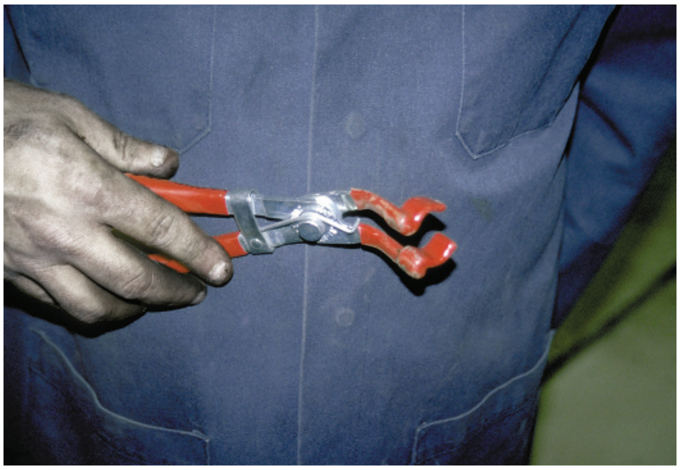

FIGURE 69–14 Spark plug wire boot pliers are a handy addition to any tool box.

TECH TIP

Spark Plug Wire Pliers Are a Good Investment

Spark plug wires are often difficult to remove. Using a good-quality spark plug wire plier, such as shown in ● **SEE FIGURE 69–14**, saves time and reduces the chance of harming the wire during removal..

TECH TIP

Route the Wires Right!

High voltage is present through spark plug wires when the engine is running. Surrounding the spark plugs in a magnetic field that can affect other circuits or components of the vehicle. For example, if a spark plug wire is routed too closely to the signal wire from a mass airflow (MAF) sensor, the induced signal from the ignition wire could create a false MAF signal to the computer. The computer, not able to detect that the signal was false, would act on the MAF signal and command the appropriate amount of fuel based on the false MAF signal.

To prevent any problems associated with high-voltage spark plug wires, be sure to route them as manufactured, using all the factory holding brackets and wiring combs. ● **SEE FIGURE 69–15**. If the factory method is unknown, most factory service information shows the correct routing.

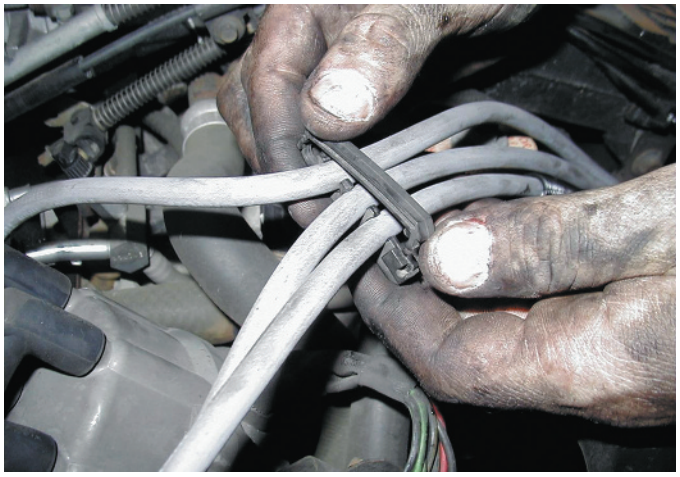

FIGURE 69–15 Always take the time to install spark plug wires back into the original holding brackets (wiring combs).

SPARK PLUG SERVICE

THE NEED FOR SERVICE Spark plugs should be inspected when an engine performance problem occurs and should be replaced at specified intervals to ensure proper ignition system performance. Most spark plugs have a service life of over 20,000 miles (32,000 kilometers). Platinum-tipped original equipment spark plugs have a typical service life of 60,000 to 100,000 miles (100,000 to 160,000 kilometers). Used spark plugs should *not* be cleaned and reused unless absolutely necessary. The labor required to **remove and replace (R & R)** spark plugs is the same whether the spark plugs are replaced or cleaned. Although cleaning spark plugs often restores proper engine operation, the service life of cleaned spark plugs is definitely shorter than that of new spark plugs. *Platinum-tipped spark plugs should not be regapped!* Using a gapping tool can break the platinum after it has been used in an engine.

Be certain that the engine is cool before removing spark plugs, especially on engines with aluminum cylinder heads. To help prevent dirt from getting into the cylinder of an engine while removing a spark plug, use compressed air or a brush to remove dirt from around the spark plug before removal. ● **SEE FIGURES 69–16 THROUGH 69–18**.

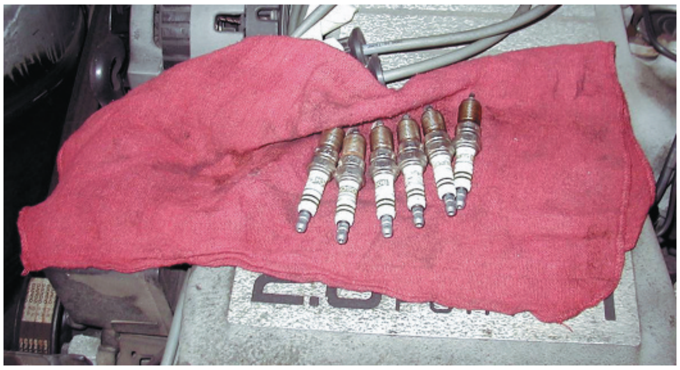

FIGURE 69–16 When removing spark plugs, it is wise to arrange them so that they can be compared and any problem can be identified with a particular cylinder.

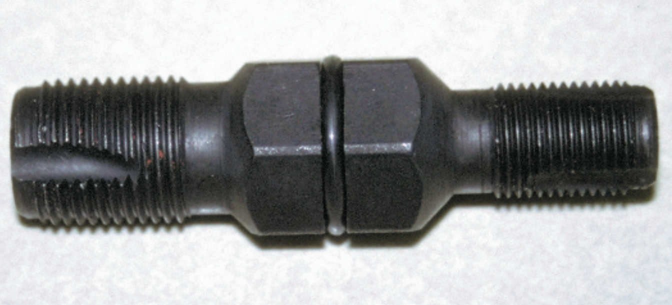

FIGURE 69–17 A spark plug thread chaser is a low-cost tool that hopefully will not be used often, but is necessary to use to clean the threads before new spark plugs are installed.

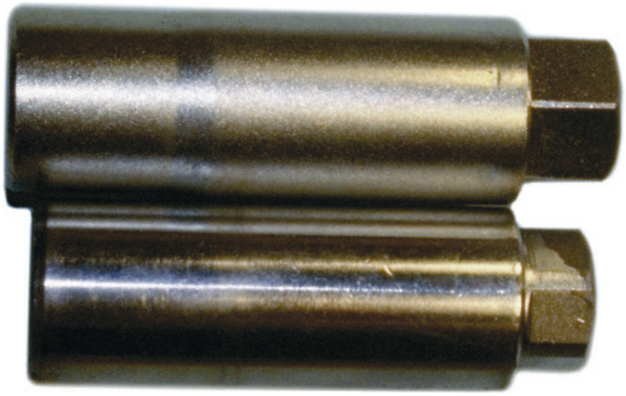

FIGURE 69–18 Since 1991, General Motors engines have been equipped with slightly (1/8 inch or 3 mm) longer spark plugs. This requires that a longer spark plug socket should be used to prevent the possibility of cracking a spark plug during installation. The longer socket is shown next to a normal 5/8 inch spark plug socket.

SPARK PLUG INSPECTION Spark plugs are the windows to the inside of the combustion chamber. A thorough visual inspection of the spark plugs often can lead to the root cause of an engine performance problem. Two indications on spark plugs and their possible root causes in engine performance include the following:

1. **Carbon fouling.** If the spark plug(s) has *dry black carbon* (soot), the usual causes include
   - Excessive idling
   - Slow-speed driving under light loads that keeps the spark plug temperatures too low to burn off the deposits
   - Overrich air–fuel mixture
   - Weak ignition system output
2. **Oil fouling.** If the spark plug has *wet, oily* deposits with little electrode wear, oil may be getting into the combustion chamber from the following:
   - Worn or broken piston rings
   - Defective or missing valve stem seals

NOTE: If the deposits are heavier on the side of the plug facing the intake valve, the cause is usually due to excessive valve stem clearance or defective intake valve stem seals.

When removing spark plugs, place them in order so that they can be inspected to check for engine problems that might affect one or more cylinders. All spark plugs should be in the same condition, and the color of the center insulator should be light tan or gray. If all the spark plugs are black or dark, the engine should be checked for conditions that could cause an overly rich air–fuel mixture or possible oil burning. If only one or a few spark plugs are black, check those cylinders for proper firing (possible defective spark plug wire) or an engine condition affecting only those particular cylinders. ● **SEE FIGURES 69–19 THROUGH 69–22**.

If all spark plugs are white, check for possible overadvanced ignition timing or a vacuum leak causing a lean air–fuel mixture. If only one or a few spark plugs are white, check for a vacuum leak affecting the fuel mixture only to those particular cylinders.

NOTE: The engine computer "senses" rich or lean air–fuel ratios by means of input from the oxygen sensor. If one cylinder is lean, the computer may make all other cylinders richer to compensate.

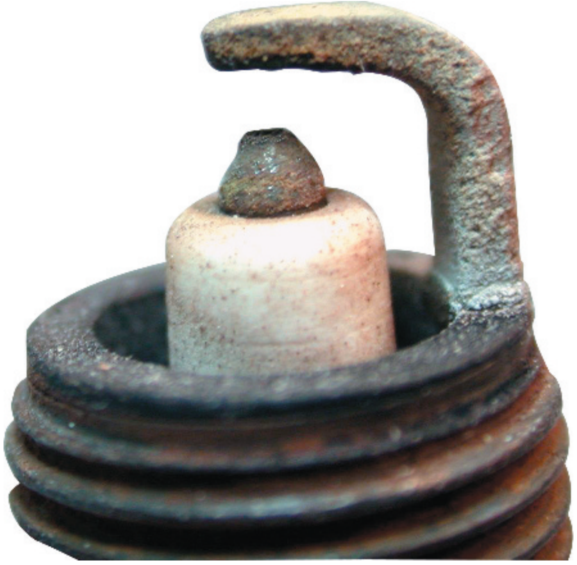

FIGURE 69–19 A normally worn spark plug that has a tapered platinum-tipped center electrode.

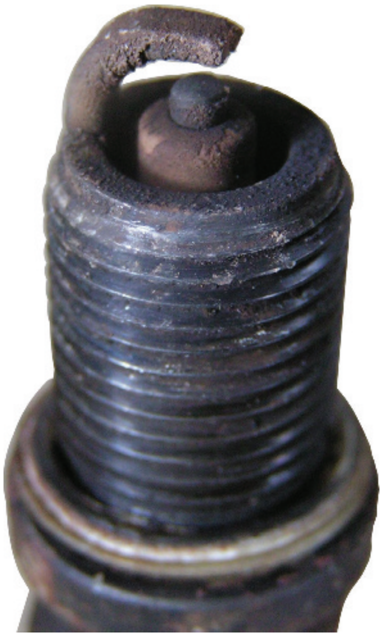

FIGURE 69–20 A worn spark plug showing fuel and/or oil deposits.

Inspect all spark plugs for wear by first checking the condition of the center electrode. As a spark plug wears, the center electrode becomes rounded. If the center electrode is rounded, higher ignition system voltage is required to fire the spark plug. When installing spark plugs, always use the correct tightening torque to ensure proper heat transfer from the spark plug shell to the cylinder head. ● **SEE CHART 69–1**.

NOTE: General Motors does not recommend the use of antiseize compound on the threads of spark plugs being installed in an aluminum cylinder head because the spark plug will be overtightened. This excessive tightening torque places the threaded portion of the spark plug too far into the combustion chamber where carbon can accumulate and result in the spark plugs being difficult to remove. If antiseize compound is used on spark plug threads, reduce the tightening torque by 40%. Always follow the vehicle manufacturer's recommendations.

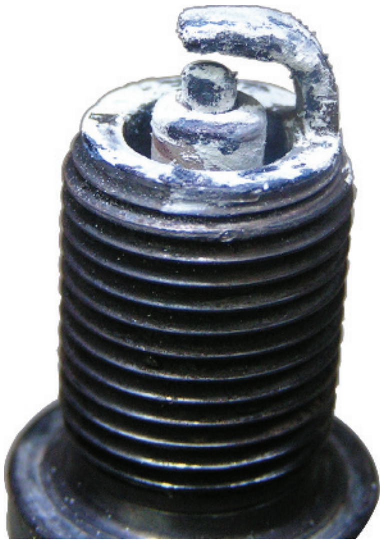

FIGURE 69–21 A spark plug from an engine that had a blown head gasket. The white deposits could be from the additives in the coolant.

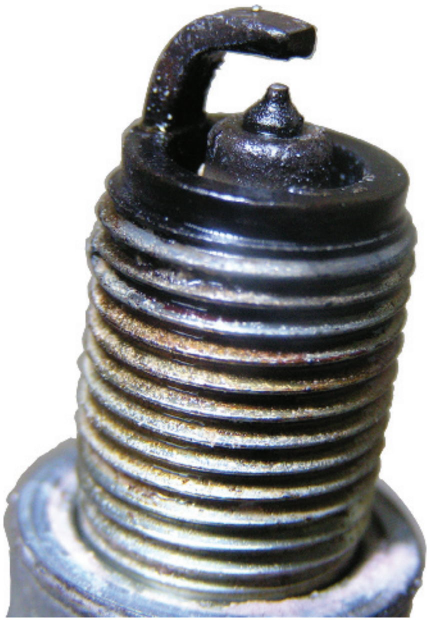

FIGURE 69–22 A platinum tipped spark plug that is fuel soaked indicating a fault with the fuel system or the ignition system causing the spark plug to not fire.

CHART 69–1

Typical spark plug tightening torque based on type of spark plug and the cylinder head material.

TECH TIP

Two-Finger Trick

To help prevent overtightening a spark plug when a torque wrench is not available, simply use two fingers on the ratchet handle. Even the strongest service technician cannot overtighten a spark plug by using two fingers.

TECH TIP

Use Original Equipment Manufacturer's Spark Plugs

A technician at an independent service center replaced the spark plugs in a Buick with new Champion brand spark plugs of the correct size, reach, and heat range. When the customer returned to pay the bill, he inquired as to the brand name of the replacement parts used for the tune-up. When told that Champion spark plugs were used, he stopped signing his name on the check he was writing. He said that he owned 1,000 shares of General Motors stock and he owned two General Motors vehicles and he expected to have General Motors parts used in his General Motors vehicles. The service manager had the technician replace the spark plugs with AC brand spark plugs because this brand was used in the engine when the vehicle was new. Even though most spark plug manufacturers produce spark plugs that are correct for use, many customers prefer that original equipment manufacturer (OEM) spark plugs be used in their engines.

QUICK AND EASY SECONDARY IGNITION TESTS

Engine running problems often are caused by defective or out-of-adjustment ignition components. Many ignition problems involve the high-voltage secondary ignition circuit. Following are some quick and easy secondary ignition tests:

TEST 1 If there is a crack in a distributor cap, coil, or spark plug, or if there is a defective spark plug wire, a spark may be visible at night. Because the highest voltage is required during partial throttle acceleration, the technician's assistant should accelerate the engine slightly with the gear selector in drive or second gear (if manual transmission) and the brake firmly applied. If any spark is visible or a "snapping" sound is heard, the location should be closely inspected and the defective parts replaced. A blue glow or "corona" around the shell of the spark plug is normal and not an indication of a defective spark plug.

TEST 2 For intermittent problems, use a spray bottle to apply a water mist to the spark plugs, and spark plug wires. ● **SEE FIGURE 69–23**. With the engine running, the water may cause an arc through any weak insulating materials and cause the engine to misfire or stall.

FIGURE 69–23 A water spray bottle is an excellent diagnostic tool to help find an intermittent engine misfire caused by a break in a secondary ignition circuit component.

NOTE: Adding a little salt or liquid soap to the water makes the water more conductive and also makes it easier to find those hard-to-diagnose intermittent ignition faults.

TEST 3 To determine if the rough engine operation is due to secondary ignition problems, connect a 12-volt test light to the negative side (sometimes labeled "tach") of the coil. Connect the other lead of the test light to the positive lead of the coil. With the engine running, the test light should be dim and steady in brightness. If there is high resistance in the secondary circuit (such as that caused by a defective spark plug wire), the test light will pulse brightly at times. If the test light varies noticeably, this indicates that the secondary voltage cannot find ground easily and is feeding back through the primary windings of the coil. This feedback causes the test light to become brighter.

SCOPE-TESTING THE IGNITION SYSTEM

Any automotive scope with the correct probes or adapters will show an ignition system pattern. All ignition systems must charge and discharge an ignition coil. With the engine off, most scopes will display a horizontal line. With the engine running, this horizontal (zero) line is changed to a pattern that will have sections both above and below the zero line. Sections of this pattern that are above the zero line indicate that the ignition coil is discharging. Sections of the scope pattern below the zero line indicate charging of the ignition coil. The height of the scope pattern indicates voltage. The length (from left to right) of the scope pattern indicates time.

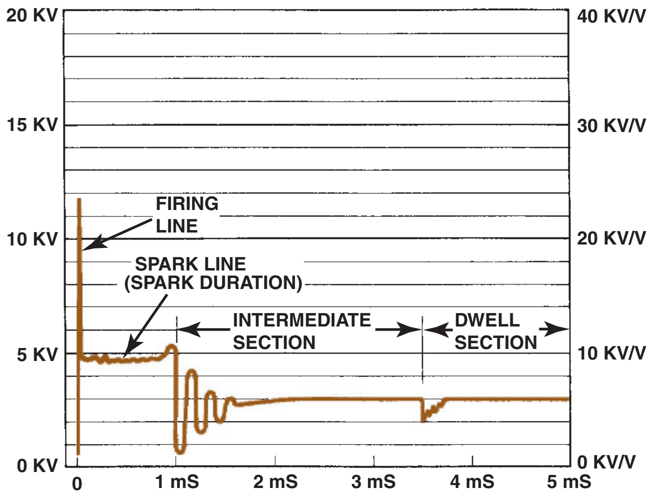

FIGURE 69–24 Typical secondary ignition oscilloscope pattern.

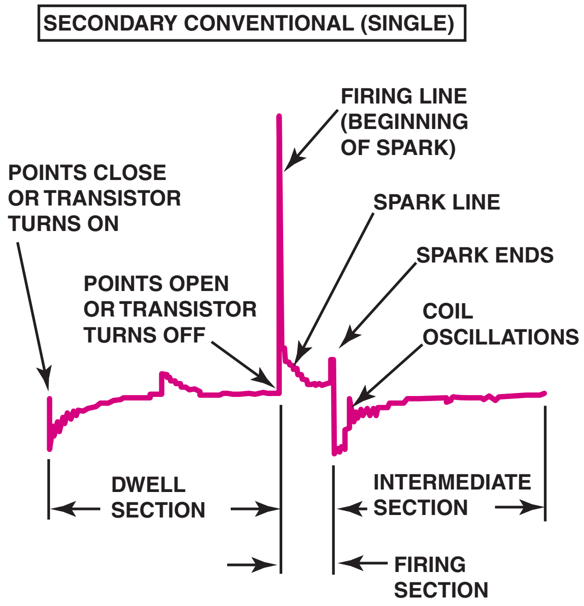

SECONDARY CONVENTIONAL (SINGLE)
FIRING LINE (BEGINNING OF SPARK)
POINTS CLOSE OR TRANSISTOR TURNS ON
SPARK LINE
SPARK ENDS
POINTS OPEN OR TRANSISTOR TURNS OFF
COIL OSCILLATIONS
DWELL SECTION
INTERMEDIATE SECTION
FIRING SECTION

FIGURE 69–25 The scope shows one cylinder at a time on a COP-type ignition system.

FIRING LINE The leftmost vertical (upward) line is called the **firing line**. The height of the firing line should be between 5,000 and 15,000 volts (5 and 15 kV) with not more than a 3 kV difference between the highest and the lowest cylinder's firing line. ● **SEE FIGURES 69–24 AND 69–25.**

The height of the firing line indicates the *voltage* required to fire the spark plug. It requires a high voltage to make the air inside the cylinder electrically conductive (to ionize the air). A higher than normal height (or height higher than that of other cylinders) can be caused by one or more of the following:

1. Spark plug gapped too wide
2. Lean fuel mixture
3. Defective spark plug wire

If the firing lines are higher than normal for *all* cylinders, possible causes include one or more of the following:

1. Excessive wearing of all spark plugs
2. Defective coil wire (the high voltage could still jump across the open section of the wire to fire the spark plugs)

SPARK LINE The **spark line** is a short horizontal line immediately after the firing line. The height of the spark line represents the voltage required to maintain the spark across the spark plug after the spark has started. The height of the spark line should be one-fourth of the height of the firing line (between 1.5 and 2.5 kV). The length (from left to right) of the line represents the length of time for which the spark lasts (duration or burn time). The spark duration should be between 0.8 and 2.2 milliseconds (usually between 1.0 and 2.0 ms). The spark stops at the end (right side) of the spark line.

INTERMEDIATE OSCILLATIONS After the spark has stopped, some energy remains in the coil. This remaining energy dissipates in the coil windings and the entire secondary circuit. The **intermediate oscillations** are also called the "ringing" of the coil as it is pulsed.

The secondary pattern amplifies any voltage variation occurring in the primary circuit because of the turns ratio between the primary and secondary windings of the ignition coil. A correctly operating ignition system should display five or more "bumps" (oscillations) (three or more for a GM HEI system).

TRANSISTOR-ON POINT After the intermediate oscillations, the coil is empty (not charged), as indicated by the scope pattern being on the zero line for a short period. When the transistor turns on an electronic system, the coil is being charged. Note that the charging of the coil occurs slowly (coil-charging oscillations) because of the inductive reactance of the coil.

DWELL SECTION Dwell is the amount of time that the current is charging the coil from the transistor-on point to the transistor-off point. At the end of the **dwell section** is the beginning of the next firing line. This point is called "transistor off" and indicates that the primary current of the coil is stopped, resulting in a high-voltage spark out of the coil.

Many scopes are equipped with a **millisecond (ms) sweep**. This means that the scope will sweep only that portion of the pattern that can be shown during a 5- or 25-ms setting. Following are guidelines for spark line length:

- 0.8 ms—too short
- 1.5 ms—average
- 2.2 ms—too long

If the spark line is too short, possible causes include the following:

1. Spark plug(s) gap is too wide
2. High-resistance spark plug wire
3. Air–fuel mixture too lean (vacuum leak, broken valve spring, etc.)

If the spark line is too long, possible causes include the following:

1. Fouled spark plug(s)
2. Spark plug(s) gap is too narrow
3. Shorted spark plug or spark plug wire

Many scopes do not have a millisecond scale. Some scopes are labeled in degrees and/or percentage (%) of dwell. The following chart can be used to determine acceptable spark line length. ● **SEE CHART 69–2**.

NORMAL SPARK LINE LENGTH (AT 700 TO 1,200 RPM)			
NUMBER OF CYLINDERS	MILLISECONDS	PERCENTAGE (%) OF DWELL SCALE	DEGREES (°)
4	1.0–2.0	3–6	3–5
6	1.0–2.0	4–9	2–5
8	1.0–2.0	6–13	3–6

CHART 69–2

Spark line length depends on the number of cylinders and the engine speed.

SPARK LINE SLOPE Downward-sloping spark lines indicate that the voltage required to maintain the spark duration is decreasing during the firing of the spark plug. This downward slope usually indicates that the spark energy is finding ground through spark plug deposits (the plug is fouled) or other ignition problems. ● **SEE FIGURE 69–26**.

An upward-sloping spark line usually indicates a mechanical engine problem. A defective piston ring or valve would tend to seal better in the increasing pressures of combustion. As the spark plug fires, the effective increase in pressures increases the voltage required to maintain the spark, and the height of the spark line rises during the duration of the spark. ● **SEE FIGURE 69–27**.

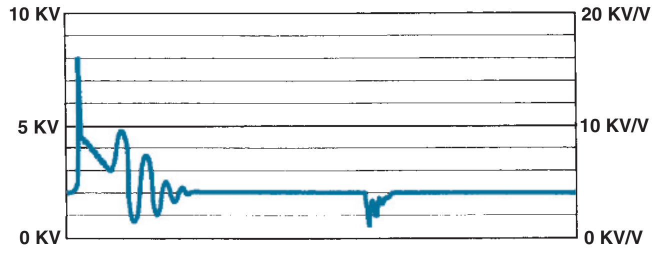

FIGURE 69–26 A downward-sloping spark line usually indicates high secondary ignition system resistance or an excessively rich air–fuel mixture.

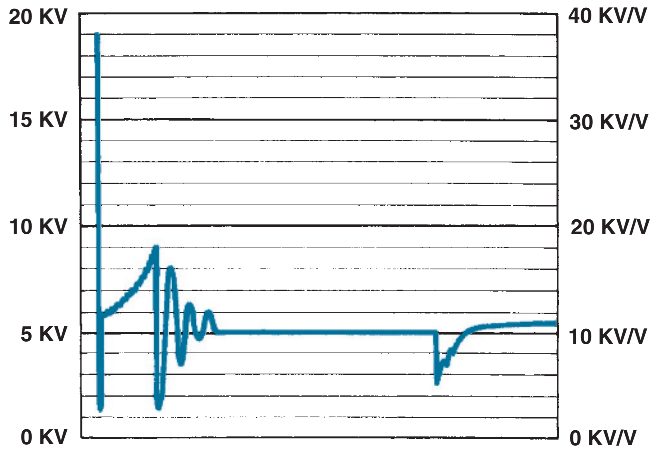

FIGURE 69–27 An upward-sloping spark line usually indicates a mechanical engine problem or a lean air–fuel mixture.

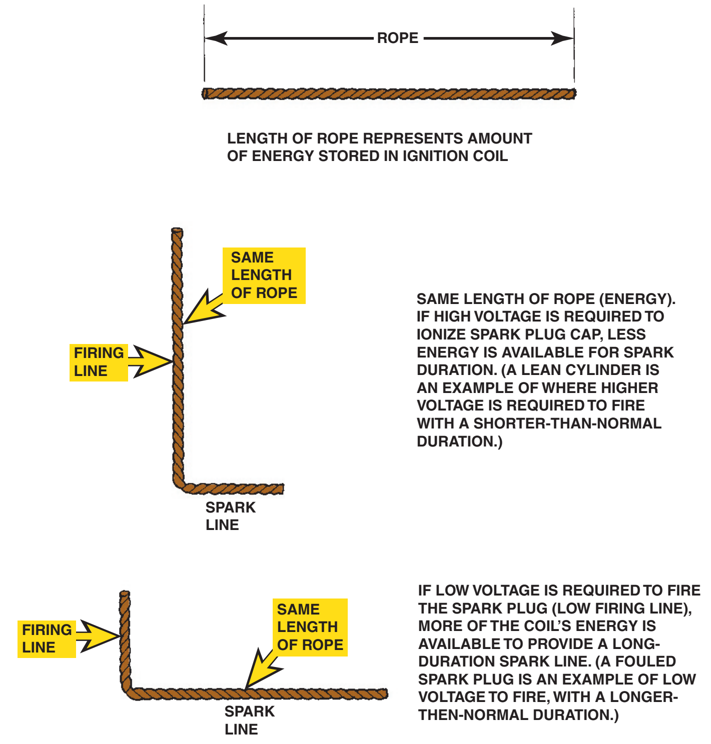
An upward-sloping spark line can also indicate a lean air–fuel mixture. Typical causes include

1. Clogged injector(s)
2. Vacuum leak
3. Sticking intake valve

● **SEE FIGURE 69–28** for an example showing the relationship between the firing line and the spark line.

READING THE INTERMEDIATE SECTION The intermediate section should have three or more oscillations (bumps) for a correctly operating ignition system. Because approximately 250 volts are in the primary ignition circuit when the spark stops flowing across the spark plugs, this voltage is reduced by about 75 volts per oscillation. Additional resistances in the primary circuit would decrease the number of oscillations. If there are fewer than three oscillations, possible problems include the following:

1. Shorted ignition coil
2. Loose or high-resistance primary connections on the ignition coil or primary ignition wiring



ROPE
LENGTH OF ROPE REPRESENTS AMOUNT OF ENERGY STORED IN IGNITION COIL
SAME LENGTH OF ROPE
FIRING LINE
SPARK LINE
SAME LENGTH OF ROPE (ENERGY). IF HIGH VOLTAGE IS REQUIRED TO IONIZE SPARK PLUG CAP, LESS ENERGY IS AVAILABLE FOR SPARK DURATION. (A LEAN CYLINDER IS AN EXAMPLE OF WHERE HIGHER VOLTAGE IS REQUIRED TO FIRE WITH A SHORTER-THAN-NORMAL DURATION.)
FIRING LINE
SAME LENGTH OF ROPE
SPARK LINE
IF LOW VOLTAGE IS REQUIRED TO FIRE THE SPARK PLUG (LOW FIRING LINE), MORE OF THE COIL'S ENERGY IS AVAILABLE TO PROVIDE A LONG-DURATION SPARK LINE. (A FOULED SPARK PLUG IS AN EXAMPLE OF LOW VOLTAGE TO FIRE, WITH A LONGER-THAN-NORMAL DURATION.)

FIGURE 69–28 The relationship between the height of the firing line and length of the spark line can be illustrated using a rope. Because energy cannot be destroyed, the stored energy in an ignition coil must dissipate totally, regardless of engine operating conditions.

SCOPE-TESTING A WASTE-SPARK IGNITION SYSTEM

A handheld digital storage oscilloscope can be used to check the pattern of each individual cylinder. Some larger scopes can be connected to all spark plug wires, and therefore are able to display both power and waste-spark waveforms. ● **SEE FIGURE 69–29**. Because the waste spark does not require as high a voltage level as the cylinder on the power stroke, the waste form will be normally lower.

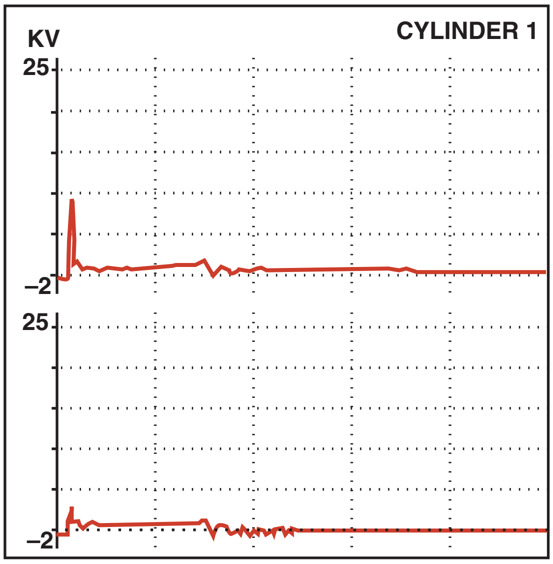


FIGURE 69–29 A dual-trace scope pattern showing both the power and the waste spark from the same coil (cylinders 1 and 6). Note that the firing line is higher on the cylinder that is under compression (power); otherwise, both patterns are almost identical.

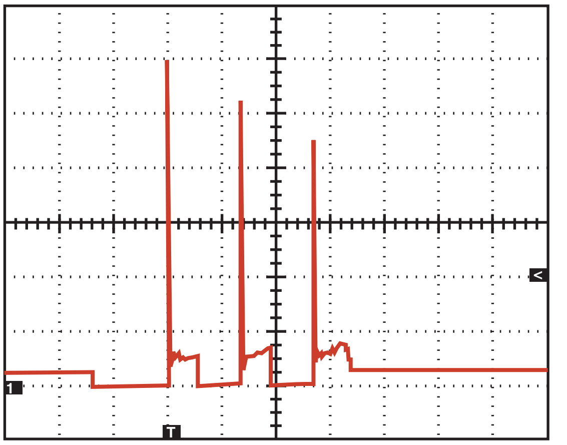

FIGURE 69–30 A secondary waveform of a Ford 4.6 liter V-8, showing three sparks occurring at idle speed.

SCOPE-TESTING A COIL-ON-PLUG IGNITION SYSTEM

In a coil-on-plug type of ignition system, each individual coil can be shown on a scope. By using a multichannel scope and the proper cables and adapters, the waveform for all of the cylinders can be viewed at the same time. Always follow the scope equipment manufacturer's instructions. ● **SEE FIGURE 69–30**.

IGNITION SYSTEM SYMPTOM GUIDE

PROBLEM	POSSIBLE CAUSES AND/OR SOLUTIONS
No spark out of the coil	• Possible open in the ignition switch circuit • Possible defective ignition module (if electronic ignition coil) • Possible defective pickup coil or Hall-effect switch (if electronic ignition) • Possible shorted condenser
Weak spark out of the coil	• Possible high-resistance coil wire or spark plug wire • Possible poor ground between the distributor or module and the engine block
Engine misfire	• Possible defective (open) spark plug wire • Possible worn or fouled spark plugs • Possible defective pickup coil • Possible defective module • Possible poor electrical connections at the pickup coil and/or module

REVIEW QUESTIONS

1. Why should a spark tester be used to check for spark rather than a standard spark plug?
2. How do you test a pickup coil for resistance and AC voltage output?
3. What harm can occur if the engine is cranked or run with an open (defective) spark plug wire?
4. What are the sections of a secondary ignition scope pattern?
5. What can the slope of the spark line indicate about the engine?

CHAPTER QUIZ

1. A spark tester should be used to check for spark because ______________.
   - **a.** a spark tester requires at least 25,000 volts to fire
   - **b.** it is connected to the CKP sensor to check its output
   - **c.** it can detect a cracked spark plug
   - **d.** it can detect the gap of the spark plugs
2. An engine misfire could be the result of a ______________.
   - **a.** defective coil
   - **b.** fouled spark plug
   - **c.** defective spark plug wire
   - **d.** Any of the above
3. A CKP sensor can be checked with a DMM set to measure ______________.
   - **a.** ohms
   - **b.** DC volts
   - **c.** AC volts
   - **d.** Both a and c
4. Typical primary coil resistance specifications usually range from ______________ ohms.
   - **a.** 100 to 450
   - **b.** 500 to 1,500
   - **c.** less than 1 to 3
   - **d.** 6,000 to 30,000
5. Typical secondary coil resistance specifications usually range from ______________ ohms.
   - **a.** 100 to 450
   - **b.** 500 to 1,500
   - **c.** 1 to 3
   - **d.** 6,000 to 30,000
6. What should be inspected as part of a visual inspection of the ignition system?
   - **a.** Spark plug wires for proper routing
   - **b.** Spark plug gap
   - **c.** Coil polarity
   - **d.** All of the above
7. What part of the scope pattern shows the duration of the spark?
   - **a.** Firing line
   - **b.** Spark line
   - **c.** Intermediate section
   - **d.** Dwell section
8. Which can be used to test for a fault with a cylinder on a waste-spark system?
   - **a.** Using a timing light to check for spark
   - **b.** Using short sections of rubber hose attached to the coil terminals
   - **c.** An LED test light
   - **d.** Any of the above
9. Two technicians are discussing a no-start (no-spark) condition. Technician A says that an open pickup coil could be the cause. Technician B says that a defective ignition control module (ICM) could be the cause. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
10. A water spray bottle is often used to find ______________.
    - **a.** leaking secondary insulation
    - **b.** a cracked spark plug
    - **c.** an improperly tightened spark plug
    - **d.** Both a and b

Chapter 70

COMPUTER FUNDAMENTALS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain the purpose and function of onboard computers.
- Explain the parts and characteristics of digital computers.
- List input sensors to an automotive computer.
- List output devices (actuators) controlled by the computer.

KEY TERMS:

Actuator 838 • Analog-to-digital (AD) converter 838 • Clock generator 839 • Controller 837 • CPU 839 • Digital computer 839 • Duty cycle 842 • E^2PROM 838 • ECA 837 • ECM 837 • ECU 837 • EEPROM 838 • Engine mapping 839 • Input 838 • Input conditioning 838 • KAM 838 • Nonvolatile RAM 838 • Output drivers 841 • Powertrain control module (PCM) 837 • PROM 838 • PWM 841 • RAM 838 • ROM 838 • SAE 837

COMPUTER FUNDAMENTALS

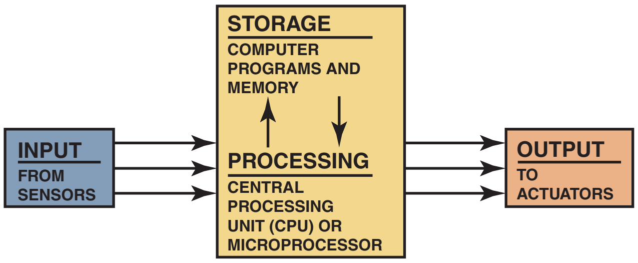
PURPOSE AND FUNCTION Modern automotive control systems consist of a network of electronic sensors, actuators, and computer modules designed to regulate the powertrain and vehicle support systems. The onboard automotive computer has many names. It may be called an **electronic control unit (ECU)**, **electronic control module (ECM)**, **electronic control assembly (ECA)**, or a **controller**, depending on the manufacturer and the computer application. The **Society of Automotive Engineers (SAE)** bulletin J1930 standardizes the name as a **powertrain control module (PCM)**. The PCM coordinates engine and transmission operation, processes data, maintains communications, and makes the control decisions needed to keep the vehicle operating. Not only is it capable of operating the engine and transmission, but it is also able to perform the following:

- Undergo self-tests (40% of the computing power is devoted to diagnosis)
- Set and store diagnostic trouble codes (DTCs)
- Communicate with the technician using a scan tool

VOLTAGE SIGNALS Automotive computers use voltage to send and receive information. Voltage is electrical pressure and does not flow through circuits, but it can be used as a signal. A computer converts input information or data into voltage signal combinations that represent number combinations. A computer processes the input voltage signals it receives by computing what they represent, and then delivering the data in computed or processed form.

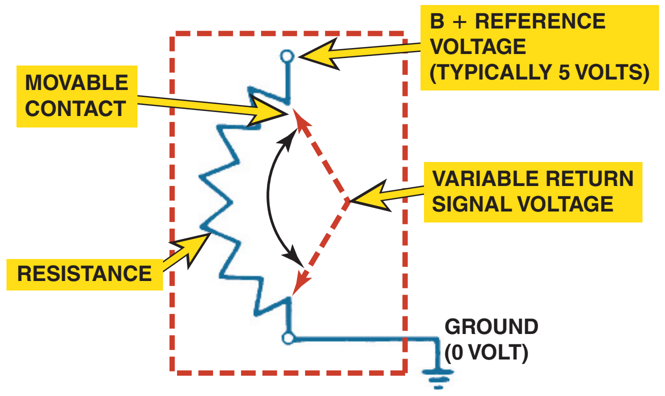
BASIC FUNCTIONS The operation of every computer can be divided into four basic functions. ● **SEE FIGURE 70–1**.

- **Input.** Receives voltage signals from sensors
- **Processing.** Performs mathematical calculations



STORAGE
COMPUTER PROGRAMS AND MEMORY
INPUT
FROM SENSORS
PROCESSING
CENTRAL PROCESSING UNIT (CPU) OR MICROPROCESSOR
OUTPUT
TO ACTUATORS

FIGURE 70–1 All computer systems perform four basic functions: input, processing, storage, and output.



B + REFERENCE VOLTAGE (TYPICALLY 5 VOLTS)
MOVABLE CONTACT
VARIABLE RETURN SIGNAL VOLTAGE
RESISTANCE
GROUND (0 VOLT)

FIGURE 70–2 A potentiometer uses a movable contact to vary resistance and send an analog voltage right to the PCM.

- **Storage.** Includes short-term and long-term memory
- **Output.** Controls an output device by either turning it on or off

INPUT FUNCTIONS First, the computer receives a voltage signal (input) from an input device. **Input** is a signal from a device that can be as simple as a button or a switch on an instrument panel, or a sensor on an automotive engine. ● **SEE FIGURE 70–2** for a typical type of automotive sensor.

Vehicles use various mechanical, electrical, and magnetic sensors to measure factors, such as vehicle speed, throttle position, engine RPM, air pressure, oxygen content of exhaust gas, airflow, engine coolant temperature, and status of electrical circuits (on-off). Each sensor transmits its information in the form of voltage signals. The computer receives these voltage signals, but before it can use them, the signals must undergo a process called **input conditioning**. This process includes amplifying voltage signals that are too small for the computer circuitry to handle. Input conditioners generally are located inside the computer, but a few sensors have their own input conditioning circuitry.

A digital computer changes the analog input signals (voltage) to digital bits (*bi*nary digi*ts*) of information through an **analog-to-digital (AD) converter** circuit. The binary digital number is used by the computer in its calculations or logic networks. ● **SEE FIGURE 70–3**.

PROCESSING The term *processing* is used to describe how input voltage signals received by a computer are handled through a series of electronic logic circuits maintained in its programmed instructions. These logic circuits change the input voltage signals, or data, into output voltage signals or commands.

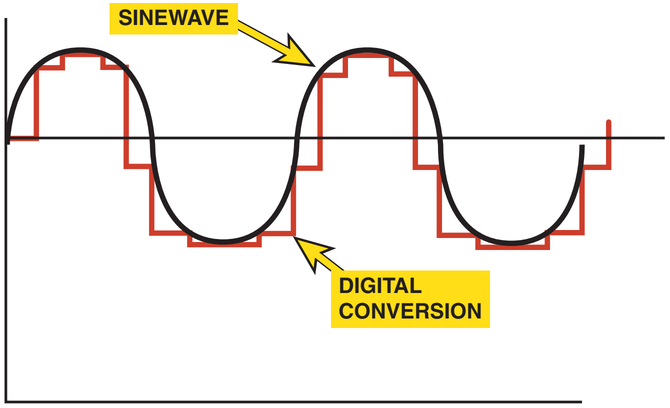


FIGURE 70–3 An AD converter changes analog (variable) voltage signals into digital signals that the PCM can process.

STORAGE Storage is the place where the program instructions for a computer are stored in electronic memory. Some programs may require that certain input data be stored for later reference or future processing. In others, output commands may be delayed or stored before they are transmitted to devices elsewhere in the system.

Computers have two types of memory.

1. Permanent memory is called **read-only memory (ROM)** because the computer can only read the contents; it cannot change the data stored in it. This data is retained even when power to the computer is shut off. Part of the ROM is built into the computer, and the rest is located in an integrated circuit (IC) chip called a **programmable read-only memory (PROM)** or calibration assembly. Many chips are erasable, meaning that the program can be changed. These chips are called erasable programmable read-only memory, or EPROM. Since the early 1990s, most programmable memory has been electronically erasable, meaning that the program in the chip can be reprogrammed by using a scan tool and the proper software. This computer reprogramming is usually called *reflashing*. These chips are electrically erasable programmable read-only memory, abbreviated **EEPROM** or **E^{2}PROM.**

   All vehicles equipped with onboard diagnosis second generation, called OBD-II, are equipped with EEPROMs.

2. Temporary memory is called **random-access memory (RAM)**, because the computer can write or store new data into it as directed by the computer program, as well as read the data already in it. Automotive computers use two types of RAM memory.

   - Volatile RAM memory is lost whenever the ignition is turned off. However, a type of volatile RAM called **keep-alive memory (KAM)** can be wired directly to battery power. This prevents its data from being erased when the ignition is turned off. One example of RAM and KAM is the loss of station settings in a programmable radio when the battery is disconnected. Because all the settings are stored in RAM, they have to be reset when the battery is reconnected. System trouble codes are commonly stored in RAM and can be erased by disconnecting the battery.
   - **Nonvolatile RAM** memory can retain its information even when the battery is disconnected. One use for this type of RAM is the storage of odometer information in an electronic speedometer. The memory chip retains the mileage accumulated by the vehicle. When speedometer replacement is necessary, the odometer chip is removed and installed in the new speedometer unit. KAM is used primarily in conjunction with adaptive strategies.

OUTPUT FUNCTIONS After the computer has processed the input signals, it sends voltage signals or commands to other devices in the system, such as system actuators. An **actuator** is an electrical or mechanical output device that converts electrical energy into a mechanical action, such as:

- Adjusting engine idle speed
- Operating fuel injectors

- Ignition timing control
- Altering suspension height

COMPUTER COMMUNICATION A typical vehicle can have many computers, also called modules or controllers. Computers also can communicate with, and control, each other through their output and input functions. This means that the output signal from one computer system can be the input signal for another computer system through a data network.

DIGITAL COMPUTERS

PARTS OF A COMPUTER The software consists of the programs and logic functions stored in the computer's circuitry. The hardware is the mechanical and electronic parts of a computer.

- **Central processing unit.** The microprocessor is the **central processing unit (CPU)** of a computer. Because it performs the essential mathematical operations and logic decisions that make up its processing function, the CPU can be considered the brain of a computer. Some computers use more than one microprocessor, called a coprocessor. The digital computer can process thousands of digital signals per second because its circuits are able to switch voltage signals on and off in billionths of a second. It is called a **digital computer** because it processes zeros and ones (digits) and needs to have any variable input signals, called analog inputs, converted to digital form before it can function. ● **SEE FIGURE 70–4**.
- **Computer memory.** Other integrated circuit (IC) devices store the computer operating program, system sensor input data, and system actuator output data—information that is necessary for CPU operation.
- **Computer programs.** By operating a vehicle on a dynamometer and manually adjusting the variable factors such as speed, load, and spark timing, it is possible to determine the optimum output settings for the best driveability, economy, and emission control. This is called engine mapping. ● **SEE FIGURE 70–5**.

Engine mapping creates a three-dimensional performance graph that applies to a given vehicle and powertrain combination. Each combination is mapped in this manner to produce a PROM or EEPROM calibration. This allows an automaker to use one basic computer for all models.

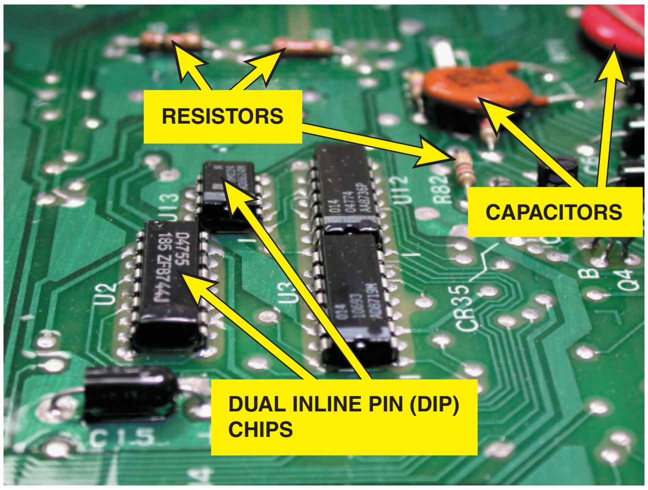

FIGURE 70–4 Many electronic components are used to construct a typical vehicle computer including chips, resistors, and capacitors.

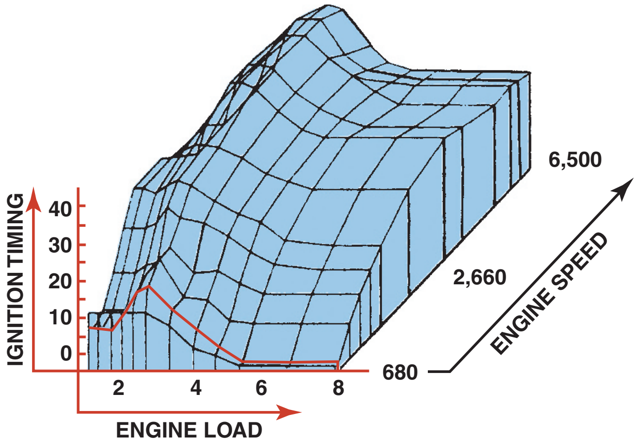

FIGURE 70–5 Typical engine map developed from testing and used by the vehicle computer to provide the optimum ignition timing for all engine speeds and load combinations.

Many older-vehicle computers used a single PROM that plugged into the computer.

NOTE: If the computer needs to be replaced, the PROM or calibration module must be removed from the defective unit and installed in the replacement computer. Since the mid-1990s, PCMs do not have removable calibration PROMs, and must be programmed or flashed using a scan tool before being put into service.

CLOCK RATES AND TIMING The microprocessor receives sensor input voltage signals, processes them by using information from other memory units, and then sends voltage signals to the appropriate actuators. The microprocessor communicates by transmitting long strings of 0s and 1s in a language called binary code; but the microprocessor must have some way of knowing when one signal ends and another begins. That is the job of a crystal oscillator called a **clock generator**. ● **SEE FIGURE 70–6**.

The computer's crystal oscillator generates a steady stream of one-bit-long voltage pulses. Both the microprocessor and the

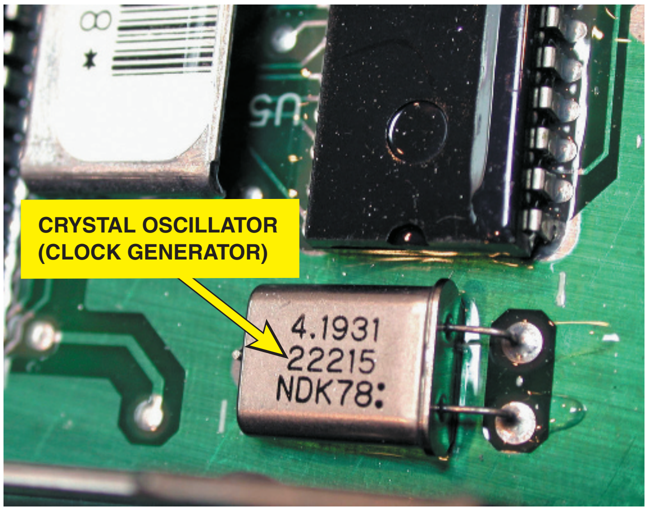

FIGURE 70–6 The clock generator produces a series of pulses that are used by the microprocessor and other components to stay in step with each other at a steady rate.

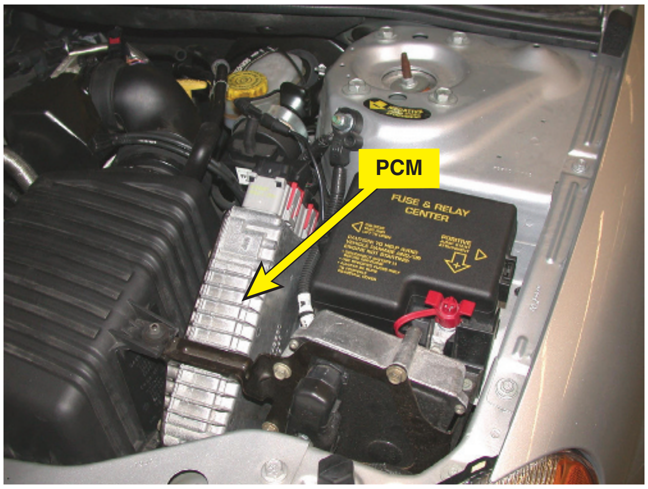

FIGURE 70–7 A powertrain control module (PCM) under the hood where it can be exposed to air for cooling.

memories monitor the clock pulses while they are communicating. Because they know how long each voltage pulse should be, they can distinguish between a 01 and a 0011. To complete the process, the input and output circuits also watch the clock pulses.

COMPUTER SPEEDS Not all computers operate at the same speed; some are faster than others. The speed at which a computer operates is specified by the cycle time, or clock speed, required to perform certain measurements. Cycle time or clock speed is measured in megahertz (4.7 MHz, 8 MHz, 15 MHz, 18 MHz, and 32 MHz, which is the clock speed of most vehicle computers today).

CONTROL MODULE LOCATIONS Onboard computers vary in size from a small module to a notebook-size box. Most other computers are installed in the passenger compartment either under the instrument panel or in a side kick panel where they can be shielded from physical damage caused by temperature extremes, dirt, and vibration, or interference by the high currents and voltages of various underhood systems. ● **SEE FIGURE 70–7**.

COMPUTER INPUT SENSORS

The vehicle computer uses signals (voltage levels) from the following sensors:

- **Engine speed (revolutions per minute, or RPM) sensor.** This signal comes from the primary ignition signal in the ignition control module (ICM) or directly from the crankshaft position (CKP) sensor.
- **Switches or buttons for accessory operation.** Many accessories use control buttons that signal the body computer to turn on or off an accessory, such as the windshield wiper or heated seats.
- **Manifold absolute pressure (MAP) sensor.** This sensor detects engine load by using a signal from a sensor that measures the vacuum in the intake manifold.
- **Mass airflow (MAF) sensor.** This sensor measures the mass (weight and density) of the air flowing through the sensor and entering the engine.
- **Engine coolant temperature (ECT) sensor.** This sensor measures the temperature of the engine coolant. This is a sensor used for engine controls and for automatic air-conditioning control operation.
- **Oxygen sensor (O2S).** This sensor measures the oxygen in the exhaust stream. There are as many as four oxygen sensors in some vehicles.
- **Throttle position (TP) sensor.** This sensor measures the throttle opening and is used by the computer for engine control and the shift points of the automotive transmission/transaxle.
- **Vehicle speed (VS) sensor.** This sensor measures the vehicle speed using a sensor located at the output of the transmission/transaxle or by monitoring sensors at the wheel speed sensors. This sensor is used by the speedometer, cruise control, and airbag systems.

COMPUTER OUTPUTS

OUTPUT CONTROLS After the computer has processed the input signals, it sends voltage signals or commands to other devices in the system. A vehicle computer can do only two things.

1. Turn a device on.
2. Turn a device off.

Typical output devices include the following:

- **Operate actuators.** An actuator is an electrical or mechanical device that converts electrical energy into heat, light, or motion to control engine idle speed, suspension height, ignition timing, and other output devices.
- **Network communication.** Computers also can communicate with another computer system through a network.
- **Fuel injectors.** The computer can vary the amount of time in milliseconds the injectors are held open, thereby controlling the amount of fuel supplied to the engine.
- **Blower motor control.** Many blower motors are controlled by the body computer by pulsing the current on and off to maintain the desired speed.
- **Transmission shifting.** The computer provides a ground to the shift solenoids and torque converter clutch (TCC) solenoid. The operation of the automatic transmission/transaxle is optimized based on vehicle sensor information.
- **Idle speed control.** The computer can control the idle air control (IAC) or electronic throttle control (ETC) to maintain engine idle speed and to provide an increased idle speed as needed.
- **Evaporative emission control solenoids.** The computer can control the flow of gasoline fumes from the charcoal canister to the engine and seal off the system to perform a fuel system leak detection test as part of the OBD-II system requirements.

Most outputs work electrically in one of three ways:

1. Digital
2. Pulse-width modulated
3. Switched

Digital control is mostly used for computer communications and involves voltage signals that are transmitted and received in packets.

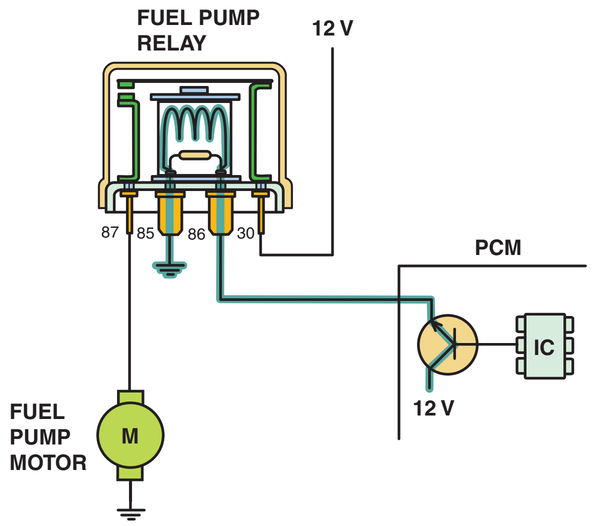

FIGURE 70–8 A typical output driver. In this case, the PCM applies voltage to the fuel pump relay coil to energize the fuel pump.

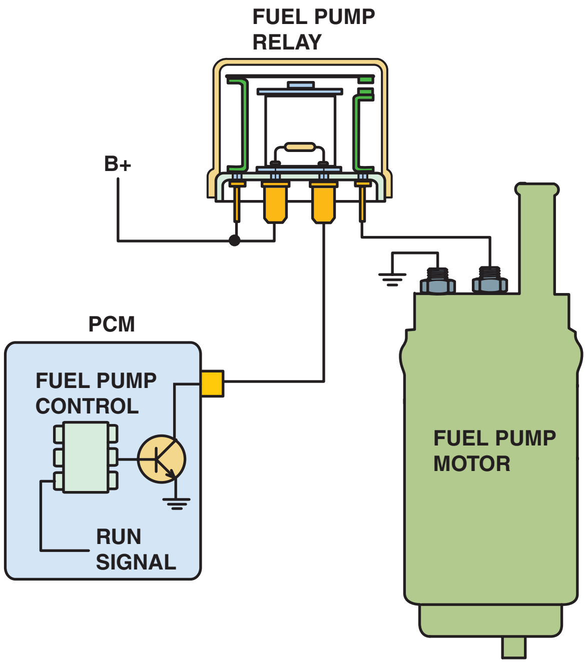

FIGURE 70–9 A typical low-side driver (LSD) which uses a control module to control the ground side of the relay coil.

Pulse-width control allows a device, such as a blower motor, to be operated at variable speed by changing the amount of time electrical power is supplied to the device.

A switched output is an output that is either on or off. In many circuits, the PCM uses a relay to switch a device on or off, because the relay is a low-current device that can switch to a higher current device. Most computer circuits cannot handle high amounts of current. By using a relay circuit, the PCM provides the output control to the relay, which in turn provides the output control to the device. The relay coil, which the PCM controls, typically draws less than 0.5 ampere. The device that the relay controls may draw 30 amperes or more.

OUTPUT DRIVERS

The PCM switches are actually transistors, and are often called **output drivers**. ● **SEE FIGURE 70–8**.

There are two basic types of output drivers:

1. **Low-side drivers.** The low-side drivers (LSDs) are transistors inside the computer that complete the ground path of the relay coil. Ignition (key-on) voltage and battery voltage are supplied to the relay. The ground side of the relay coil is connected to the transistor inside the computer. In the example of a fuel pump relay, when the transistor turns "on," it will complete the ground for the relay coil, and the relay will then complete the power circuit between the battery power and the fuel pump. A relatively low current flows through the relay coil and transistor that is inside the computer. This causes the relay to switch and provides the fuel pump with battery voltage. The majority of switched outputs have typically been low-side drivers. ● **SEE FIGURE 70–9**.

   Low-side drivers can often perform a diagnostic circuit check by monitoring the voltage from the relay to check that the control circuit for the relay is complete. A low-side driver, however, cannot detect a short-to-ground.
2. **High-side drivers.** The high-side drivers (HSDs) control the power side of the circuit. In these applications when the transistor is switched on, voltage is applied to the device. A ground has been provided to the device so when the high-side driver switches, the device will be energized. In some applications, high-side drivers are used instead of low-side drivers to provide better circuit protection. General Motors vehicles use a high-side driver to control the fuel pump relay instead of a low-side driver. In the event of an accident, should the circuit to the fuel pump relay become grounded, a high-side driver will cause a short circuit, which will cause the fuel pump relay to de-energize. High-side drivers inside modules can detect electrical faults such as a lack of continuity when the circuit is not energized. ● **SEE FIGURE 70–10**.

PULSE-WIDTH MODULATION

Pulse-width modulation (PWM) is a method of controlling an output using a digital signal. Instead of just turning devices on or off, the computer can control the amount of on-time. For example, a solenoid could be a PWM device. If, for

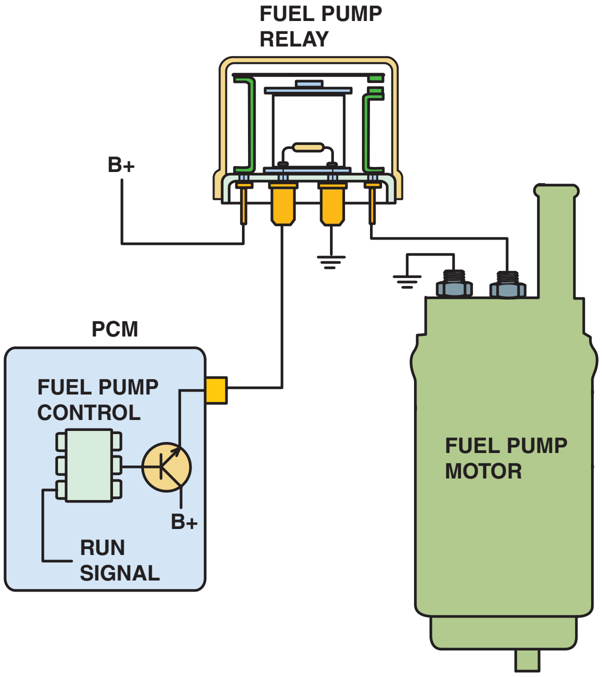

FIGURE 70–10 A typical module-controlled high-side driver (HSD) where the module itself supplies the electrical power to the device. The logic circuit inside the module can detect circuit faults including continuity of the circuit and if there is a short-to-ground in the circuit being controlled.

example, a vacuum solenoid is controlled by a switched driver, switching either on or off would mean that either full vacuum would flow through the solenoid or no vacuum would flow through the solenoid. However, to control the amount of vacuum that flows through the solenoid, pulse-width modulation could be used. A PWM signal is a digital signal, usually 0 and 12 volts, which is cycling at a fixed frequency. Varying the length of time that the signal is on provides a signal that can vary the on- and off-time of an output. The ratio of on-time relative to the period of the cycle is referred to as **duty cycle**. ● **SEE FIGURE 70–11**.

Depending on the frequency of the signal, which is usually fixed, this signal will turn the device on and off a fixed number of times per second. When, for example, the voltage is high (12 volts) 90% of the time and low (0 volt) the other 10% of the time, the signal has a 90% duty cycle. In other words, if this signal were applied to the vacuum solenoid, the solenoid would be on 90% of the time. This would allow more vacuum to flow through the solenoid. The computer has the ability to vary this on- and off-time or pulse-width modulation at any rate between 0% and 100%. A good example of pulse-width modulation is the cooling fan speed control. The speed of the cooling fan is controlled by varying the amount of on-time that the battery voltage is applied to the cooling fan motor.

- 100% duty cycle: fan runs at full speed
- 75% duty cycle: fan runs at 3/4 speed
- 50% duty cycle: fan runs at 1/2 speed
- 25% duty cycle: fan runs at 1/4 speed

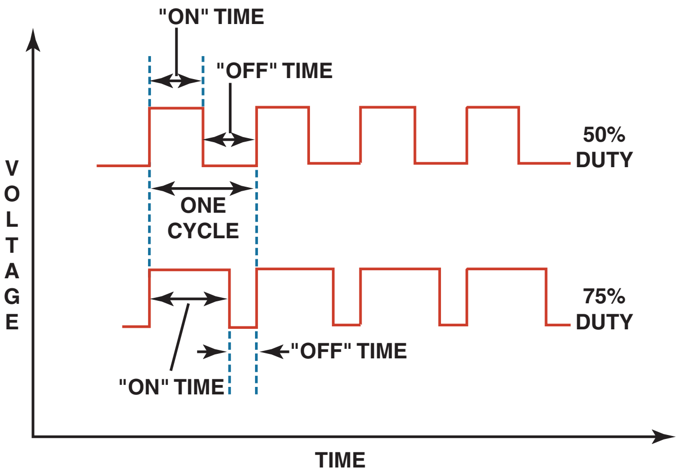

FIGURE 70–11 Both the top and bottom pattern have the same frequency. However, the amount of on-time varies. Duty cycle is the percentage of the time during a cycle that the signal is turned on.

The use of PWM, therefore, results in precise control of an output device to achieve the amount of cooling needed and conserve electrical energy compared to simply timing the cooling fan on high when needed. PWM may be used to control vacuum through a solenoid, the amount of purge of the evaporative purge solenoid, the speed of a fuel pump motor, control of a linear motor, or even the intensity of a lightbulb.

REVIEW QUESTIONS

1. What part of the vehicle computer is considered to be the brain?
2. What is the difference between volatile and nonvolatile RAM?
3. What are four input sensors?
4. What are four output devices?
5. How does using pulse-width modulation control devices?

CHAPTER QUIZ

1. What unit of electricity is used as a signal for a computer?
   a. Volt
   b. Ohm
   c. Ampere
   d. Watt
2. The four basic computer functions include ________________.
   a. writing, processing, printing, and remembering
   b. input, processing, storage, and output
   c. data gathering, processing, output, and evaluation
   d. sensing, calculating, actuating, and processing
3. All OBD-II vehicles use what type of read-only memory?
   a. ROM
   b. PROM
   c. EPROM
   d. EEPROM
4. The "brain" of the computer is the ________________.
   a. PROM
   b. RAM
   c. CPU
   d. AD converter
5. Which of these is NOT a function of the PCM?
   a. Self-tests
   b. Communicate with a scan tool
   c. Tire inflation
   d. Store DTCs
6. Which item is a computer input sensor?
   a. RPM
   b. Throttle position
   c. Engine coolant temperature
   d. All of the above
7. Which item is a computer output device?
   a. Fuel injector
   b. Transmission shift solenoid
   c. Evaporative emission control solenoid
   d. All of the above
8. The SAE term for the vehicle computer is ________________.
   a. PCM
   b. ECM
   c. ECA
   d. controller
9. What two things can a vehicle computer actually perform (output)?
   a. Store and process information
   b. Turn something on or turn something off
   c. Calculate and vary temperature
   d. Control fuel and timing only
10. Analog signals from sensors are changed to digital signals for processing by the computer through which type of circuit?
   a. Digital
   b. Analog
   c. Analog-to-digital converter
   d. PROM

Chapter 71

TEMPERATURE AND THROTTLE POSITION SENSORS

LEARNING OBJECTIVES:

After studying this chapter, the reader will be able to:

- Describe the purpose and function of engine coolant temperature sensors.
- Describe how to inspect and test temperature sensors.
- Explain the function and testing of intake air temperature sensors, including sensor DTCs.
- Discuss the other temperature sensors that may be found on vehicles.
- Describe the construction and function of a TP sensor.
- Discuss TP sensor input.
- Discuss the PCM uses for the TP sensor.
- Describe how to test the TP sensor, including sensor DTCs.

KEY TERMS:

Cylinder head temperature (CHT) 848 • Engine coolant temperature (ECT) 843 • Engine fuel temperature (EFT) 848 • Negative temperature coefficient (NTC) 844 • Potentiometer 849 • Skewed 851 • Throttle position (TP) sensor 849 • Throttle-body temperature (TBT) 847 • Transmission fluid temperature (TFT) 848

ENGINE COOLANT TEMPERATURE SENSORS

PURPOSE AND FUNCTION Computer-equipped vehicles use an **engine coolant temperature (ECT)** sensor. When the engine is cold, the fuel mixture must be richer to prevent stalling and engine stumble. When the engine is warm, the fuel mixture can be leaner to provide maximum fuel economy with the lowest possible exhaust emissions. Because the computer controls spark timing and fuel mixture, it will need to know the engine temperature. An engine coolant temperature sensor screwed into the engine coolant passage will provide the computer with this information. ● **SEE FIGURE 71–1**. This will be the most important (high-authority) sensor while the engine is cold. The ignition timing can also be tailored to engine (coolant) temperature. A hot engine cannot have the spark timing as far advanced as can a cold engine. The ECT sensor is also used as an important input for the following:

- Idle air control (IAC) position
- Oxygen sensor closed-loop status
- Canister purge on/off times
- Idle speed

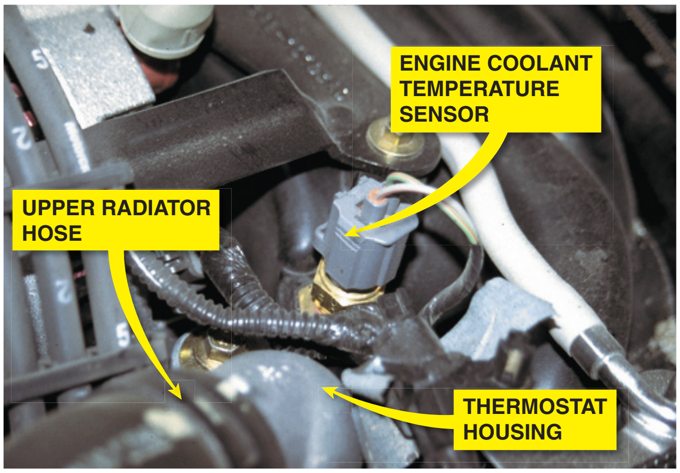

FIGURE 71–1 A typical engine coolant temperature (ECT) sensor. ECT sensors are located near the thermostat housing on most engines.

ECT SENSOR CONSTRUCTION Engine coolant temperature sensors are constructed of a semiconductor material that decreases in resistance as the temperature of the sensor increases. Coolant sensors have very high resistance when the coolant is cold and low resistance when the coolant is hot.

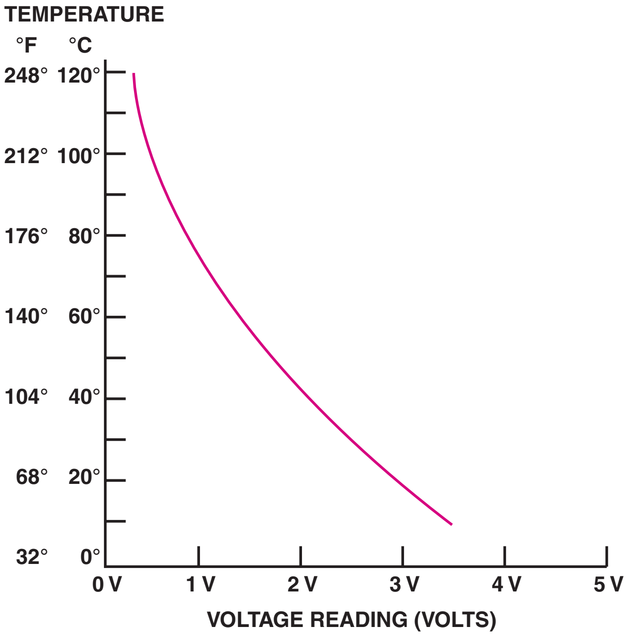

FIGURE 71–2 A typical ECT sensor temperature versus voltage curve.

This is referred to as having a **negative temperature coefficient (NTC)**, which is opposite to the situation with most other electrical components. ● **SEE FIGURE 71–2**. Therefore, if the coolant sensor has a poor connection (high resistance) at the wiring connector, the computer will supply a richer-than-normal fuel mixture based on the resistance of the coolant sensor. Poor fuel economy and a possible-rich code can be caused by a defective sensor or high resistance in the sensor wiring. If the sensor was shorted or defective and had too low a resistance, a leaner-than-normal fuel mixture would be supplied to the engine. A too-lean fuel mixture can cause driveability problems and a possible-lean computer code.

STEPPED ECT CIRCUITS Some vehicle manufacturers use a step-up resistor to effectively broaden the range of the ECT sensor. Chrysler and General Motors vehicles use the same sensor as a non-stepped ECT circuit, but instead apply the sensor voltage through two different resistors.

- When the temperature is low, usually below 120°F (50°C), the ECT sensor voltage is applied through a high-value resistor inside the PCM.
- When the temperature is high, usually above 120°F (50°C), the ECT sensor voltage is applied through a much lower resistance value inside the PCM. ● **SEE FIGURE 71–3**.

The purpose of this extra circuit is to give the PCM a more accurate reading of the engine coolant temperature compared to the same sensor with only one circuit. ● **SEE FIGURE 71–4**.

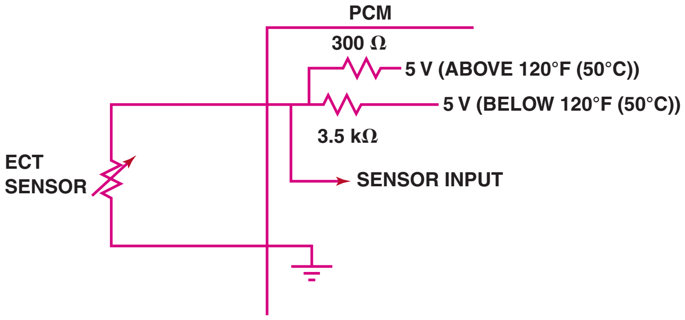

FIGURE 71–3 A typical two-step ECT circuit showing that when the coolant temperature is low, the PCM applies a 5-volt reference voltage to the ECT sensor through a higher resistance compared to when the temperature is higher.

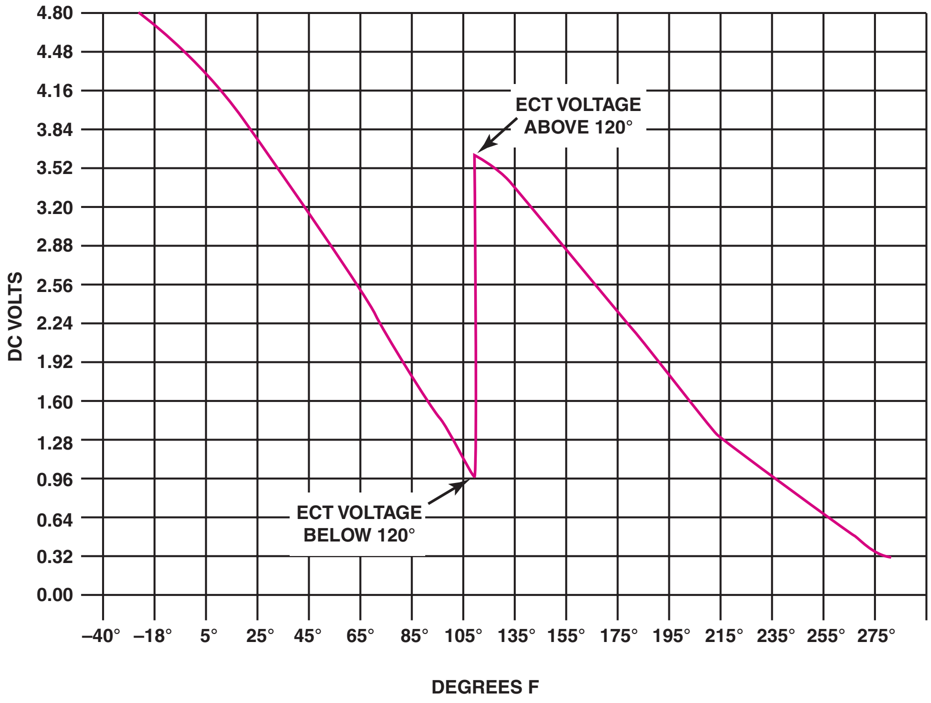

FIGURE 71–4 The transition between steps usually occurs at a temperature that would not interfere with cold engine starts or the cooling fan operation. In this example, the transition occurs when the sensor voltage is about 1 volt and rises to about 3.6 volts.

TESTING THE ENGINE COOLANT TEMPERATURE SENSOR

TESTING THE ENGINE COOLANT TEMPERATURE BY VISUAL INSPECTION The correct functioning of the engine coolant temperature sensor depends on the following items that should be checked or inspected:

- **Properly filled cooling system.** Check that the radiator reservoir bottle is full and that the radiator itself is filled to the top.

CAUTION: Be sure that the radiator is cool before removing the radiator cap to avoid being scalded by hot coolant.

The ECT sensor must be submerged in coolant to be able to indicate the proper coolant temperature.

- **Proper pressure maintained by the radiator cap.** If the radiator cap is defective and cannot allow the cooling system to become pressurized, air pockets could develop. These air pockets could cause the engine to operate at a hotter-than-normal temperature and prevent proper temperature measurement, especially if the air pockets occur around the sensor.
- **Proper antifreeze–water mixture.** Most vehicle manufacturers recommend a 50/50 mixture of antifreeze and water as the best compromise between freezing protection and heat transfer ability.
- **Proper operation of the cooling fan.** If the cooling fan does not operate correctly, the engine may get overheated.

TESTING THE ECT USING A MULTIMETER Both the resistance (in ohms) and the voltage drop across the sensor can be measured and compared with specifications. ● **SEE FIGURE 71–5.** Some vehicles use the PCM to attach another resistor in the ECT circuit to provide a more accurate measure of the engine temperature. ● **SEE FIGURE 71–6.** ● **SEE CHART 71–1** for an example of typical ECT sensor specifications.

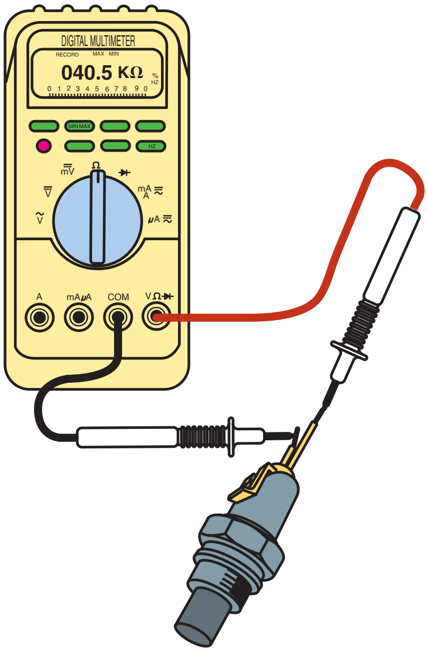

FIGURE 71–5 Measuring the resistance of the ECT sensor. The resistance measurement can then be compared with specifications. (Courtesy of Fluke Corporation)

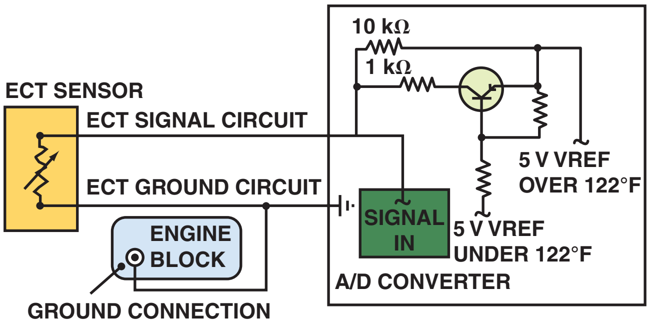

FIGURE 71–6 When the voltage drop reaches approximately 1.20 volts, the PCM turns on a transistor. The transistor connects a 1 kΩ resistor in parallel with the 10 kΩ resistor. Total circuit resistance now drops to around 909 ohms. This function allows the PCM to have full binary control at cold temperatures up to approximately 122°F and a second full binary control at temperatures greater than 122°F.

GENERAL MOTORS ECT SENSOR WITHOUT PULL-UP RESISTOR

°F	°C	OHMS	VOLTAGE DROP ACROSS SENSOR
−40	−40	100,000 +	4.95
18	−8	14,628	4.68
32	0	9,420	4.52
50	10	5,670	4.25
68	20	3,520	3.89
86	30	2,238	3.46
104	40	1,459	2.97
122	50	973	2.47
140	60	667	2.00
158	70	467	1.59
176	80	332	1.25
194	90	241	0.97
212	100	177	0.75

CHART 71–1

If resistance values match the approximate coolant temperature and there is still a coolant sensor trouble code, the problem is generally in the wiring between the sensor and the computer. Always consult the manufacturers' recommended procedures for checking this wiring. If the resistance values do not match, the sensor may need to be replaced.

Normal operating temperature varies with vehicle make and model. Some vehicles are equipped with a thermostat with an opening temperature of 180°F (82°C) whereas other vehicles use a thermostat that is 195°F (90°C) or higher. Before replacing the ECT sensor, be sure that the engine is operating at the temperature specified by the manufacturer. Most manufacturers recommend checking the ECT sensor after the cooling fan has cycled twice, indicating a fully warmed engine. To test for voltage at the ECT sensor, select DC volts on a digital meter and carefully back probe the sensor wire and read the voltage. ● **SEE FIGURE 71–7.**

TESTING THE ECT SENSOR USING A SCAN TOOL Follow the scan tool manufacturer's instructions and connect a scan tool to the data link connector (DLC) of the vehicle. Comparing the

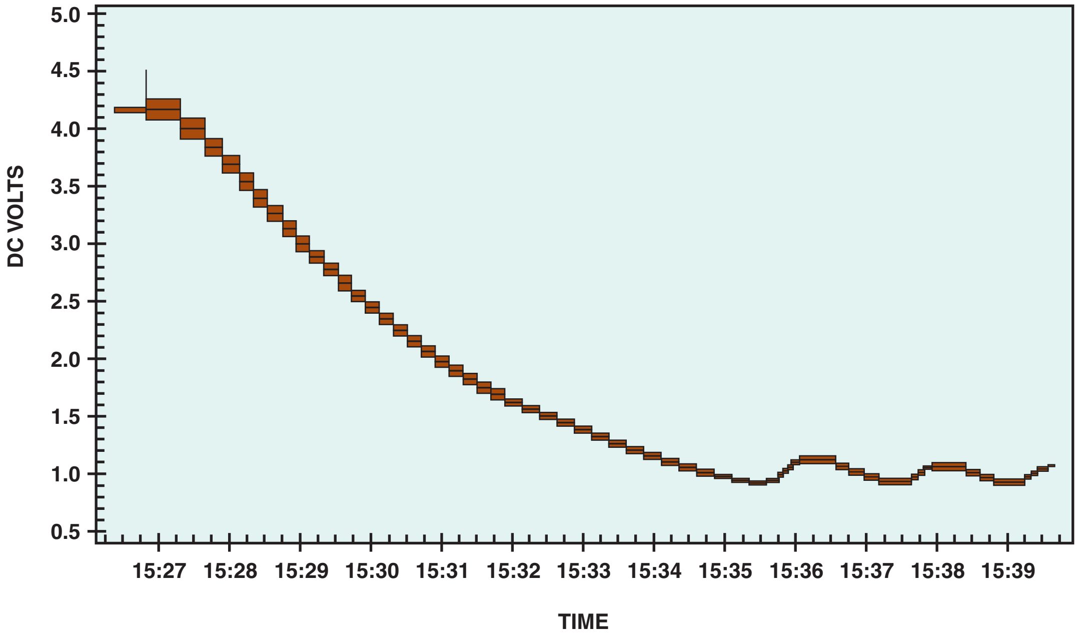

FIGURE 71–7 An ECT sensor being tested using a digital meter set to DC volts. A chart showing the voltage decrease of the ECT sensor as the temperature increases from a cold start. The bumps at the bottom of the waveform represent temperature decreases when the thermostat opens and is controlling coolant temperature.

temperature of the engine coolant as displayed on a scan tool with the actual temperature of the engine is an excellent method to test an engine coolant temperature sensor.

1. Record the scan tool temperature of the coolant (ECT).
2. Measure the actual temperature of the coolant using an infrared pyrometer or contact-type temperature probe.

NOTE: Often the coolant temperature gauge in the dash of the vehicle can be used to compare with the scan tool temperature. Although not necessarily accurate, it may help to diagnose a faulty sensor, especially if the temperature shown on the scan tool varies greatly from the temperature indicated on the dash gauge.

The maximum difference between the two readings should be 10℉ (5℃) If the actual temperature varies by more than 10℉ from the temperature indicated on the scan tool, check the ECT sensor wiring and connector for damage or corrosion. If the connector and wiring are okay, check the sensor with a DVOM for resistance and compare with the actual engine temperature chart. If that checks out okay, check the computer.

NOTE: Some manufacturers use two coolant sensors, one for the dash gauge and one for the computer.

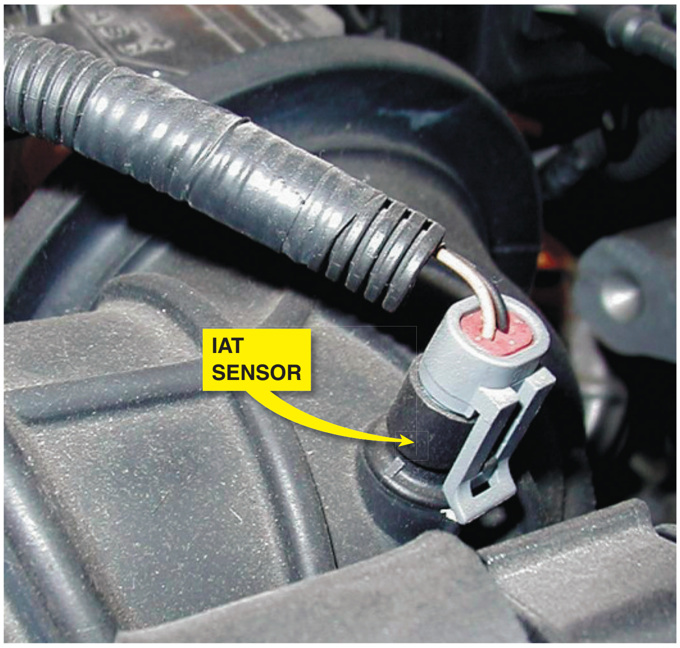

FIGURE 71–8 The IAT sensor on this General Motors 3800 V-6 engine is in the air passage duct between the air cleaner housing and the throttle body.

INTAKE AIR TEMPERATURE SENSOR

PURPOSE AND FUNCTION The intake air temperature (IAT) sensor is a negative temperature coefficient (NTC) thermistor that decreases in resistance as the temperature of the sensor increases. The IAT sensor can be located in one of the following locations:

- In the air cleaner housing.
- In the air duct between the air filter and the throttle body, as shown in ● **FIGURE 71–8**.
- Built into the mass air flow (MAF) or airflow sensor. Most MAF sensors use three wires. If a MAF sensor has five wires, it also includes an IAT sensor built in as part of the assembly. If more than five wires, the MAF sensor may be equipped with a humidity sensor also.
- Screwed into the intake manifold where it senses the temperature of the air entering the cylinders.

NOTE: An IAT installed in the intake manifold is the most likely to suffer damage due to an engine backfire, which can often destroy the sensor.

TECH TIP

Quick and Easy ECT Test

To check that the wiring and the computer are functioning, regarding the ECT sensor, connect a scan tool and look at the ECT temperature display.

STEP 1 Unplug the connector from the ECT sensor. The temperature displayed on the scan tool should read about −40°C

NOTE: −40° Celsius is also −40° Fahrenheit. This is the point where both temperature scales meet.

STEP 2 With the connector still removed from the ECT sensor, use a fused jumper lead and connect the two terminals of the connector together. The scan tool should display about 285°F (140°C)

This same test procedure will work for the IAT and most other temperature sensors.

CASE STUDY

The Case of the Hot Audi

The owner of Audi A3 Quattro took the vehicle to a shop and mentioned that the engine temperature gauge was indicting that the engine was running hot. A check engine light was also on. A scan tool was used to retrieve a DTC P0116 (Engine Coolant Temperature (ECT) Sensor 1 Circuit Range/Performance). Another shop had replaced the thermostat, water pump, and ECT sensor (at the radiator outlet), which did not fix the overheat problem.

The service technician looked at the scan tool data and noticed that the ECT was showing a temperature of over 240° (112°C), yet the upper radiator hose was not hot. Checking service information, the technician discovered that this engine has two ECT sensors, one in the radiator outlet and another one located on the engine block. The DTC was referencing the ECT located on the engine block, designated G62 in service information. The technician checked the resistance of G62 and found it to be out of specifications. Replacing this ECT sensor resulted in both ECT sensors reading the same temperature with key on, engine off (KOEO). The DTC was cleared and the vehicle was driven, which confirmed that the root cause had been found.

Summary:

Complaint—The temperature gauge was showing that the engine was overheating and the check engine light was on.
Cause—One of the two ECT sensors was out of specification causing both the incorrect dash temperature reading and a stored diagnostic trouble code.
Correction—Replacing the ECT sensor located on the engine block (G62) corrected both issues.

The purpose and function of the intake air temperature sensor is to provide the engine computer (PCM) the temperature of the air entering the engine. The IAT sensor information is used for fuel control (adding or subtracting fuel) and spark timing, depending on the temperature of incoming air.

The IAT sensor is used as an input sensor by the PCM to control many functions including

- If the air temperature is low, the PCM will modify the amount of fuel delivery and add fuel.
- If the air temperature is high, the PCM will subtract the calculated amount of fuel.
- Spark timing is also changed, depending on the temperature of the air entering the engine. The timing is advanced if the temperature is cold and retarded from the base-programmed timing if the temperature is hot.
- Cold air is more dense, contains more oxygen, and therefore requires a richer mixture to achieve the proper air–fuel mixture. Air at 32°F (0°C) is 14% denser than air at 100°F (38°C).
- Hot air is less dense, contains less oxygen, and therefore requires less fuel to achieve the proper air–fuel mixture.

The IAT sensor is a low-authority sensor and is used by the computer to modify the amount of fuel and ignition timing as determined by the engine coolant temperature sensor.

The IAT sensor is used by the PCM as a backup in the event that the ECT sensor is determined to be inoperative.

NOTE: Some engines use a throttle-body temperature (TBT) sensor to sense the temperature of the air entering the engine, instead of an intake air temperature sensor.

Engine temperature is most accurately determined by looking at the engine coolant temperature sensor. In certain conditions, the IAT has an effect on performance and driveability. One such condition is a warm engine being stopped in very cold weather. In this case, when the engine is restarted, the ECT may be near normal operating temperature such as 200°F (93°C) yet the air temperature could be −20°F (−30°C) In this case, the engine requires a richer mixture due to the cold air than the ECT would seem to indicate.

TESTING THE INTAKE AIR TEMPERATURE SENSOR If the intake air temperature sensor circuit is damaged or faulty, a diagnostic trouble code is set and the malfunction indicator lamp (MIL) may or may not turn on depending on the condition and the type and model of the vehicle. To diagnose the IAT sensor follow these steps:

STEP 1 After the vehicle has been allowed to cool for several hours, using a scan tool, observe the IAT, and compare it to the engine coolant temperature. The two temperatures should be within 5°F of each other.

STEP 2 Perform a thorough visual inspection of the sensor and the wiring. If the IAT is screwed into the intake manifold, remove the sensor and check for damage.

STEP 3 Check the voltage.

FREQUENTLY ASKED QUESTION

What Exactly Is an NTC Sensor?

A negative temperature coefficient (NTC) thermistor is a semiconductor whose resistance decreases as the temperature increases. In other words, the sensor becomes more electrically conductive as the temperature increases. Therefore, when a voltage is applied, typically 5 volts, the signal voltage is high when the sensor is cold because the sensor has a high resistance and little current flows through to ground. ● **SEE FIGURE 71–9**.

However, when the temperature increases, the sensor becomes more electrically conductive and takes more of the 5 volts to ground, resulting in a lower signal voltage as the sensor warms.

OTHER TEMPERATURE SENSORS

AUTOMATIC TRANSMISSION FLUID TEMPERATURE SENSOR

The **transmission fluid temperature (TFT)**, also called *transmission oil temperature (TOT),* sensor is an important sensor for the proper operation of the automatic transmission. A TFT sensor is a NTC thermistor that decreases in resistance as the temperature of the sensor increases.

The transmission fluid temperature signal is used by the powertrain control module (PCM) to perform certain strategies based on the temperature of the automatic transmission fluid. For example:

- If the temperature of the automatic transmission fluid is low (typically below 32°F [0°C]), the shift points may be delayed and overdrive disabled. The torque converter clutch also may not be applied to assist in the heating of the fluid.
- If the temperature of the automatic transmission fluid is high (typically above 260°F [130°C]), the overdrive is disabled and the torque converter clutch is applied to help reduce the temperature of the fluid.

NOTE: Check service information for the exact shift strategy based on high and low transmission fluid temperatures for the vehicle being serviced.

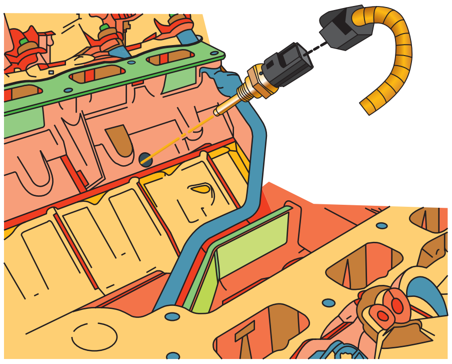

FIGURE 71–10 Some engines are equipped with a cylinder head temperature (CHT) sensor, which is used by the PCM along with the ECT to determine the temperature of the engine.

CYLINDER HEAD TEMPERATURE SENSOR Some vehicles are equipped with **cylinder head temperature (CHT)** sensors.

If the cylinder head temperature sensor is not providing the correct readings, the engine can have a variety of issues such as stalling, long cranking times, and hesitation while accelerating. ● **SEE FIGURE 71–10**.

ENGINE FUEL TEMPERATURE (EFT) SENSOR Some vehicles, such as many Ford vehicles that are equipped with an electronic returnless type of fuel injection, use an **engine fuel temperature (EFT)** sensor to give the PCM information regarding the temperature and, therefore, the density of the fuel. Check service information for the exact location, if equipped, and how to test and service the sensor.

EXHAUST GAS RECIRCULATION (EGR) TEMPERATURE SENSOR Some engines, such as Toyota, are equipped with exhaust gas recirculation (EGR) temperature sensors. EGR is a well-established method for reduction of NO_x emissions in internal combustion engines. The exhaust gas contains unburned hydrocarbons, which are recirculated in the combustion process. Recirculation is controlled by valves, which operate as a function of exhaust gas speed, load, and temperature. The gas reaches a temperature of about 850°F (450°C) for which a special heavy-duty glass-encapsulated NTC sensor is available.

The PCM monitors the temperature in the exhaust passage between the EGR valve and the intake manifold. If the temperature increases when the EGR is commanded on, the PCM can determine that the valve or related components are functioning.

ENGINE OIL TEMPERATURE SENSOR Engine oil temperature sensors are used on many General Motors vehicles and are used as an input to the oil life monitoring system. The computer program inside the PCM calculates engine oil life based on run time, engine RPM, and oil temperature.

TEMPERATURE SENSOR DIAGNOSTIC TROUBLE CODES The OBD-II diagnostic trouble codes that relate to temperature sensors include both high- and low-voltage codes, as well as intermittent codes. ● **SEE CHART 71–2**.

DIAGNOSTIC TROUBLE CODE	DESCRIPTION	POSSIBLE CAUSES
P0112	IAT sensor low voltage	■ IAT sensor internally shorted-to-ground ■ IAT sensor wiring shorted-to-ground ■ IAT sensor damaged by backfire (usually associated with IAT sensors that are mounted in the intake manifold) ■ Possible defective PCM
P0113	IAT sensor high voltage	■ IAT sensor internally (electrically) open ■ IAT sensor signal, circuit, or ground circuit open ■ Possible defective PCM
P0117	ECT sensor low voltage	■ ECT sensor internally shorted-to-ground ■ The ECT sensor circuit wiring shorted-to-ground ■ Possible defective PCM
P0118	ECT sensor high voltage	■ ECT sensor internally (electrically) open ■ ECT sensor signal, circuit, or ground circuit open ■ Engine operating in an overheated condition ■ Possible defective PCM

CHART 71–2

Selected temperature sensor-related diagnostic trouble codes.

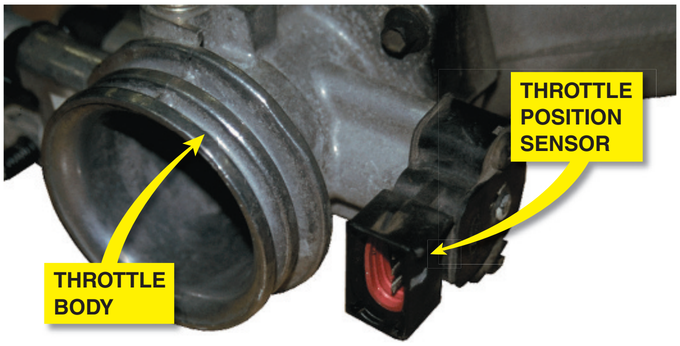

FIGURE 71–11 A typical TP sensor mounted on the throttle body of this port-injected engine.

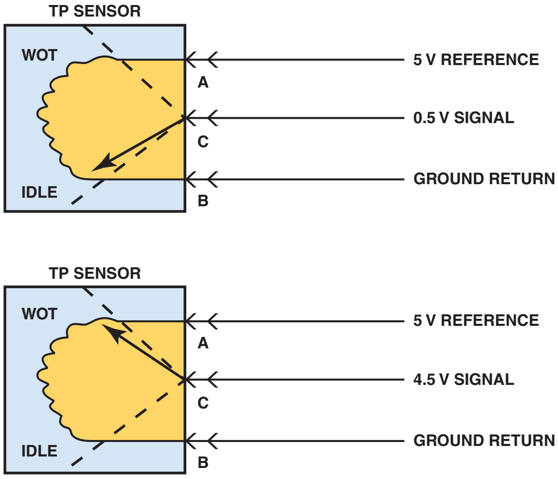

FIGURE 71–12 The signal voltage from a throttle position increases as the throttle is opened because the wiper arm is closer to the 5-volt reference. At idle, the resistance of the sensor winding effectively reduces the signal voltage output to the computer.

THROTTLE POSITION SENSOR CONSTRUCTION

PURPOSE AND FUNCTION Before the introduction of electronic throttle control (ECT) systems (throttle-by-wire), engines used a single **throttle position (TP) sensor** to signal to the powertrain control module (PCM) the position of the throttle.

POTENTIOMETERS A potentiometer is a variable-resistance sensor with three terminals. One end of the resistor receives reference voltage, while the other end is grounded. The third terminal is attached to a movable contact that slides across the resistor to vary its resistance. Depending on whether the contact is near the supply end or the ground end of the resistor, return voltage is high or low. ● **SEE FIGURES 71–11 AND 71–12.**

Throttle position (TP) sensors are among the most common potentiometer-type sensors. The computer uses their input to determine the amount of throttle opening and the rate of change.

A typical sensor has three wires:

- A 5-volt reference feed wire from the computer
- Signal return (a ground wire back to the computer)
- A voltage signal wire back to the computer; as the throttle is opened, the voltage to the computer changes

Normal throttle position voltage on most vehicles is about 0.5 volt at idle (closed throttle) and 4.5 volts at wide-open throttle (WOT).

NOTE: The TP sensor voltage at idle is usually about 10% of the TP sensor voltage when the throttle is wide open, but can vary from as low as 0.3 to 1.2 volts, depending on the make and model of vehicle.

TP SENSOR COMPUTER INPUT FUNCTIONS

- The computer senses any change in throttle position and changes the fuel mixture and ignition timing. The actual change in fuel mixture and ignition timing is also partly determined by the other sensors, such as the manifold pressure (engine vacuum), engine RPM, the coolant temperature, and oxygen sensor(s). Some throttle position sensors are adjustable and should be set according to the exact engine manufacturer's specifications.
- The throttle position sensor signals the PCM to pulse additional fuel from the injectors when the throttle is depressed. Because the air can quickly flow into the engine when the throttle is opened, additional fuel must be supplied to prevent the air–fuel mixture from going lean, causing the engine to hesitate when the throttle is depressed. If the TP sensor is unplugged or defective, the engine may still operate satisfactorily, but hesitate upon acceleration.
- The PCM supplies the TP sensor with a regulated voltage that ranges from 4.8 to 5.1 volts. This reference voltage is usually referred to as a 5-volt reference or "Vref." The TP output signal is an input to the PCM, and the TP sensor ground also flows through the PCM.

See the Ford throttle position sensor chart for an example of how sensor voltage changes with throttle angle.

FORD THROTTLE POSITION (TP) SENSOR CHART

THROTTLE ANGLE (DEGREES)	VOLTAGE (V)
0	0.50
10	0.97
20	1.44
30	1.90
40	2.37
50	2.84
60	3.31
70	3.78
80	4.24

NOTE: Generally, any reading higher than 80% represents wide-open throttle to the computer.

PCM USES FOR THE TP SENSOR

The TP sensor is used by the powertrain control module (PCM) for the following reasons:

- **Clear Flood Mode** If the throttle is depressed to the floor during engine cranking, the PCM will either greatly reduce or entirely eliminate any fuel-injector pulses to aid in clearing a flooded engine. If the throttle is depressed to the floor and the engine is not flooded with excessive fuel, the engine may not start.
- **Torque Converter Clutch Engagement and Release** The torque converter clutch will be released if the PCM detects rapid acceleration to help the transmission deliver maximum torque to the drive wheels. The torque converter clutch is applied when the vehicle is lightly accelerating and during cruise conditions to improve fuel economy.
- **Rationality Testing for MAP and MAF Sensors** As part of the rationality tests for the MAP and/or MAF sensor, the TP sensor signal is compared to the reading from other sensors to determine if they match. For example, if the throttle position sensor is showing wide-open throttle, the MAP and/or MAF reading should also indicate that this engine is under a heavy load. If not, a diagnostic trouble code could be set for the TP, as well as the MAP and/or MAF sensors.
- **Automatic Transmission Shift Points** The shift points are delayed if the throttle is opened wide to allow the engine speed to increase, thereby producing more power and aiding in the acceleration of the vehicle. If the throttle is barely open, the shift point occurs at the minimum speed designed for the vehicle.
- **Target Idle Speed (Idle Control Strategy)** When the TP sensor voltage is at idle, the PCM controls idle speed using the idle air control (IAC) and/ or spark timing variation to maintain the commanded idle speed. If the TP sensor indicates that the throttle has moved off idle, fuel delivery and spark timing are programmed for acceleration. Therefore, if the throttle linkage is stuck or binding, the idle speed may not be correct.
- **Air-Conditioning Compressor Operation** The TP sensor is also used as an input sensor for air-conditioning compressor operation. If the PCM detects that the throttle is at or close to wide open, the air-conditioning compressor is disengaged.
- **Backs Up Other Sensors** The TP sensor is used as a backup to the MAP sensor and/or MAF in the event the PCM detects that one or both are not functioning correctly. The PCM then calculates fuel needs and spark timing based on the engine speed (RPM) and throttle position.

TESTING THE THROTTLE POSITION SENSOR

A TP sensor can be tested using one or more of the following tools:

- A digital voltmeter with three test leads connected in series between the sensor and the wiring harness connector or back probing using T-pins or other recommended tool that will not cause harm to the connector or wiring
- A scan tool or a specific tool recommended by the vehicle manufacturer
- An oscilloscope

Use jumper wires, T-pins to back-probe the wires, or a breakout box to gain electrical access to the wiring to the TP sensor. ● **SEE FIGURE 71–13**.

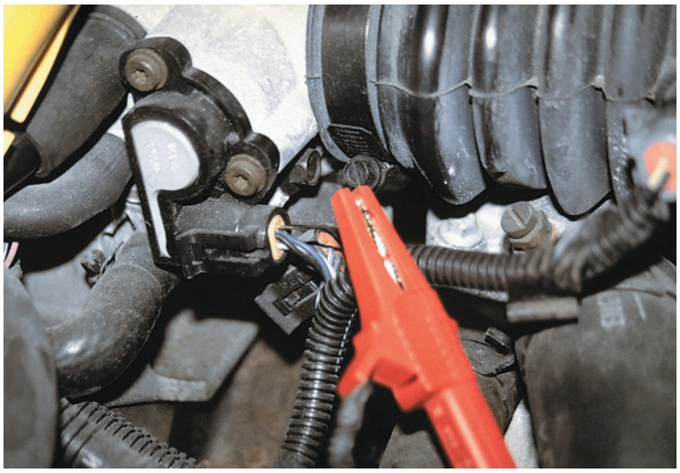

FIGURE 71–13 A meter lead connected to a T-pin that was gently pushed along the signal wire of the TP sensor until the point of the pin touched the metal terminal inside the plastic connector.

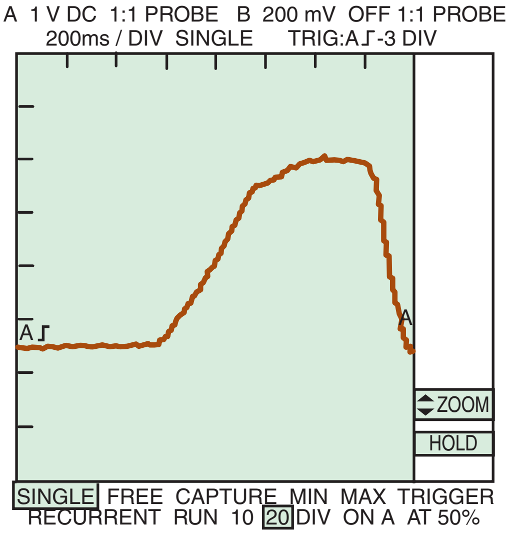

FIGURE 71–14 A typical waveform of a TP sensor signal as recorded on a DSO when the accelerator pedal was depressed with the ignition switch on (engine off). Clean transitions and the lack of any glitches in this waveform indicate a good sensor.

NOTE: The procedure that follows is the usual method used by many manufacturers. Always refer to service information for the exact recommended procedure and specifications for the vehicle being tested.

The procedure for testing the sensor using a digital multimeter is as follows:

1. Turn the ignition switch on (engine off).
2. Set the digital meter to read to DC volts and measure the voltage between the signal wire and ground (reference low) wire. The voltage should be about 0.5 volt.

NOTE: Consult the service information for exact wire colors or locations.

3. With the engine still not running (but with the ignition still on), slowly increase the throttle opening. The voltage signal from the TP sensor should also increase. Look for any "dead spots" or open circuit readings as the throttle is increased to the wide-open position. ● **SEE FIGURE 71–14** for an example of how a good TP sensor would look when tested with a digital storage oscilloscope (DSO).

NOTE: Use the accelerator pedal to depress the throttle because this applies the same forces on the TP sensor as the driver does during normal driving. Moving the throttle by hand under the hood may not accurately test the TP sensor.

4. With the voltmeter still connected, slowly return the throttle down to the idle position. The voltage from the TP sensor should also decrease evenly on the return to idle.

The TP sensor voltage at idle should be within the acceptable range as specified by the manufacturer. Some TP sensors can be adjusted by loosening their retaining screws and moving the sensor in relation to the throttle opening. This movement changes the output voltage of the sensor.

TECH TIP

Check Power and Ground before Condemning a Bad Sensor

Most engine sensors use a 5-volt reference and a ground. If the 5 volts to the sensor is too high (shorted to voltage) or too low (high resistance), the sensor output will be **skewed** or out of range. Before replacing the sensor that did not read correctly, measure both the 5-volt reference and ground. To measure the ground, simply turn the ignition on (engine off) and touch one test lead of a DMM set to read DC volts to the sensor ground and the other to the negative terminal of the battery. Any reading higher than 0.2 volt (200 mV) represents a poor ground. ● **SEE FIGURES 71–15 AND 71–16.**

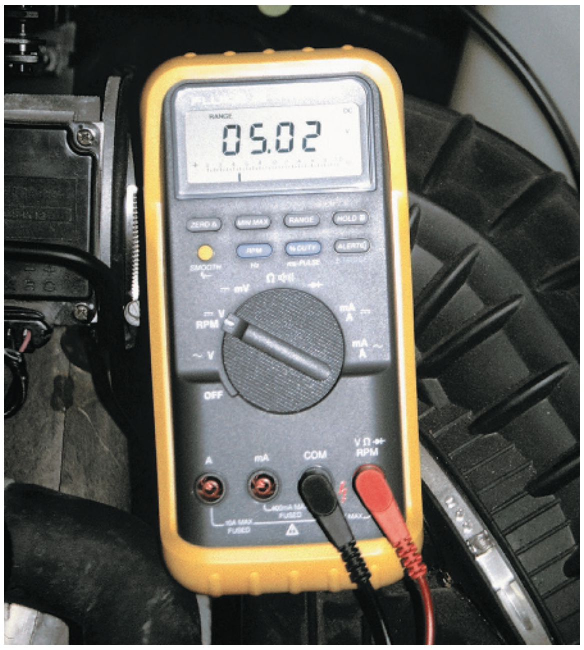

FIGURE 71–15 Checking the 5-volt reference from the computer being applied to the TP sensor with the ignition switch on (engine off).

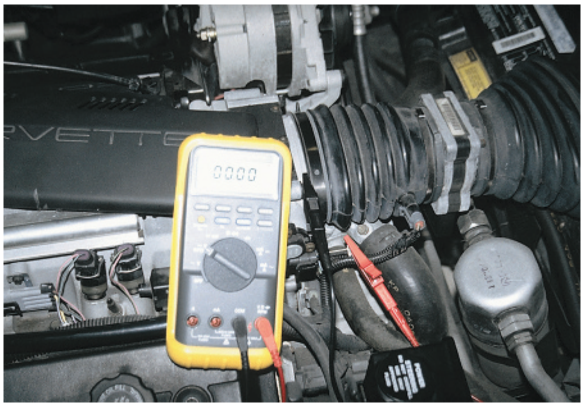

FIGURE 71–16 Checking the voltage drop between the TP sensor ground and a good engine ground with the ignition on (engine off). A reading of greater than 0.2 volt (200 mV) represents a bad computer ground.

All TP sensors should also provide a smooth transition voltage reading from idle to WOT and back to idle. Replace the TP sensor if erratic voltage readings are obtained or if the correct setting at idle cannot be obtained.

TESTING THE TP SENSOR USING A SCAN TOOL A scan tool can be used to check for proper operation of the throttle position sensor using the following steps:

STEP 1 With the key on, engine off, the TP sensor voltage display should be about 0.5 volt, but can vary from as low as 0.3 volt to as high as 1.2 volts.

STEP 2 Check the scan tool display for the percentage of throttle opening. The reading should be zero and gradually increase in percentage as the throttle is depressed.

STEP 3 The idle air control (IAC) counts should increase as the throttle is opened and decrease as the throttle is closed. Start the engine and observe the IAC counts as the throttle is depressed.

STEP 4 Start the engine and observe the TP sensor reading. Use a wedge or thin object to increase the throttle opening slightly. The throttle percentage reading should increase. Shut off and restart the engine. If the percentage of throttle opening returns to 0%, the PCM determines that the increased throttle opening is now the new minimum and resets the idle position of the TP sensor. Remove the wedge and cycle the ignition key. The throttle position sensor should again read zero percentage.

NOTE: Some engine computers are not capable of resetting the throttle position sensor.

TP SENSOR DIAGNOSTIC TROUBLE CODES The diagnostic trouble codes (DTCs) associated with the throttle position sensor include the following:

DIAGNOSTIC TROUBLE CODE	DESCRIPTION	POSSIBLE CAUSES
P0122	TP sensor low voltage	■ TP sensor internally shorted-to-ground ■ TP sensor wiring shorted-to-ground ■ TP sensor or wiring open
P0123	TP sensor high voltage	■ TP sensor internally shorted to 5-volt reference ■ TP sensor ground open ■ TP sensor wiring shorted-to-voltage
P0121	TP sensor signal does not agree with MAP	■ Defective TP sensor ■ Incorrect vehicle-speed (VS) sensor signal ■ MAP sensor out-of-calibration or defective

REVIEW QUESTIONS

1. How does a typical NTC temperature sensor work?
2. What is the difference between a stepped and a non-stepped ECT circuit?
3. What does the PCM do with the TP sensor signal voltage?
4. What is the procedure to follow when checking the 5-volt reference and TP sensor ground?
5. How can a TP sensor be diagnosed using a scan tool?

CHAPTER QUIZ

1. When checking the ECT sensor with a scan tool, about what temperature should be displayed if the connector is removed from the sensor with the key on, engine off?
   a. 284°F (140°C)
   b. 230°F (110°C)
   c. 120°F (50°C)
   d. −40°F (−40°C)
2. What happens to the voltage measured at the ECT sensor when the thermostat opens?
   a. Increases slightly
   b. Increases about 1 volt
   c. Decreases slightly
   d. Decreases about 1 volt

3. Two technicians are discussing a stepped ECT circuit. Technician A says that the sensor used for a stepped circuit is different than one used in a non-stepped circuit. Technician B says that a stepped ECT circuit uses different internal resistance inside the PCM. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
4. When testing an ECT sensor on a vehicle, a digital multimeter can be used and the signal wires back probed. What setting should the technician use to test the sensor?
   - **a.** AC volts
   - **b.** DC volts
   - **c.** Ohms
   - **d.** Hz (hertz)
5. A typical IAT or ECT sensor reads about 3,000 ohms when tested using a DMM. This resistance represents a temperature of about __________.
   - **a.** −40°F (−40°C)
   - **b.** 70°F (20°C)
   - **c.** 120°F (50°C)
   - **d.** 284°F (140°C)
6. Typical TP sensor voltage at idle is about __________.
   - **a.** 2.50 to 2.80 volts
   - **b.** 0.5 volt or 10% of WOT TP sensor voltage
   - **c.** 1.5 to 2.8 volts
   - **d.** 13.5 to 15.0 volts
7. A TP sensor is what type of sensor?
   - **a.** Rheostat
   - **b.** Voltage generating
   - **c.** Potentiometer
   - **d.** Piezoelectric
8. If the transmission fluid temperature (TFT) sensor indicates cold automatic transmission fluid temperature, what would the PCM do to the shifts?
   - **a.** Normal shifts and normal operation of the torque converter clutch
   - **b.** Disable torque converter clutch; normal shift points
   - **c.** Delayed shift points and torque converter clutch disabled
   - **d.** Normal shifts but overdrive will be disabled
9. Which sensor does the TP sensor back up if the PCM determines that a failure has occurred?
   - **a.** Oxygen sensor
   - **b.** MAF sensor
   - **c.** MAP sensor
   - **d.** Either b or c
10. Which wire on a TP sensor should be back-probed to check the voltage signal to the PCM?
    - **a.** 5-volt reference (Vref)
    - **b.** Signal
    - **c.** Ground
    - **d.** Meter should be connected between the 5-volt reference and the ground

MAP AND MAF SENSORS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss the variations in pressure that can occur within an engine.
- Describe principles of pressure sensors.
- Discuss how MAP sensors work.
- Discuss the PCM uses of the MAP sensor.
- Describe how the BARO sensor is used to test altitude.
- List the methods that can be used to test MAP sensors.
- Discuss MAF sensor types.
- Discuss the PCM uses for the MAF sensor.
- List the methods that can be used to test MAF sensors.
- List the methods that can be used to test MAF sensor contamination.

KEY TERMS:

Barometric manifold absolute pressure (BMAP) sensor 858 • Barometric pressure (BARO) sensor 858 • False air 862 • Manifold absolute pressure (MAP) sensor 855 • Mass airflow (MAF) sensor 860 • Piezoresistivity 856 • Pressure differential 854 • Speed density 857 • Tap test 862 • Vacuum 854

AIR PRESSURE

HIGH AND LOW PRESSURE Think of an internal combustion engine as a big air pump. As the pistons move up and down in the cylinders, they pump in air and fuel for combustion and pump out exhaust gases. They do this by creating a difference in air pressure. The air outside an engine has weight and exerts pressure, as does the air inside an engine.

As a piston moves down on an intake stroke with the intake valve open, it creates a larger area inside the cylinder for the air to fill. This lowers the air pressure within the engine. Because the pressure inside the engine is lower than the pressure outside, air flows into the engine to fill the low-pressure area and equalize the pressure.

The low pressure within the engine is called **vacuum** and is measured in inches of Mercury, abbreviated in. Hg. Vacuum causes the higher-pressure air on the outside to flow into the low-pressure area inside the cylinder. The difference in pressure between the two areas is called a **pressure differential**. ● **SEE FIGURE 72–1**.

PRESSURE SENSORS

PRINCIPLES Intake manifold pressure changes with changing throttle positions. At wide-open throttle, manifold pressure is almost the same as atmospheric pressure. On deceleration or at idle, manifold pressure is below atmospheric pressure, thus creating a vacuum. In cases where turbo- or supercharging is used, under part- or full-load condition, intake manifold pressure rises above atmospheric pressure. Also, oxygen content and barometric pressure change with differences in altitude, and the computer must be able to compensate by making changes in the flow of fuel entering the engine. To provide the computer with changing airflow information, a fuel-injection system may use the following:

- Manifold absolute pressure (MAP) sensor
- Manifold absolute pressure sensor plus barometric absolute pressure (BARO) sensor
- Barometric and manifold absolute pressure (BMAP) sensors combined

FIGURE 72–1 (a) As an engine is accelerated under a load, the engine vacuum drops. This drop in vacuum is actually an increase in absolute pressure in the intake manifold. A MAP sensor senses all pressures greater than that of a perfect vacuum. (b) The relationship between absolute pressure, vacuum, and gauge pressure.

The **manifold absolute pressure (MAP) sensor** may be a ceramic capacitor diaphragm, an aneroid bellows, or a piezoresistive crystal. It has a sealed vacuum reference input on one side; the other side is connected (vented) to the intake manifold. This sensor housing also contains signal conditioning circuitry. ● **SEE FIGURE 72–2**. Pressure changes in the manifold cause the sensor to deflect, varying its analog or digital return signal to the computer. As the air pressure increases, the MAP sensor generates a higher voltage or frequency return signal to the computer.

MANIFOLD ABSOLUTE PRESSURE SENSORS

CONSTRUCTION The manifold absolute pressure sensor is used by the engine computer to sense engine load. The typical MAP sensor consists of a ceramic or silicon wafer sealed on one side with a perfect vacuum and exposed to intake manifold vacuum on the other side. As the engine vacuum changes, the pressure difference on the wafer changes the output voltage or frequency of the MAP sensor.

A manifold absolute pressure sensor is used on many engines for the PCM to determine the load on the engine. The relationship among barometer pressure, engine vacuum, and MAP sensor voltage includes the following:

- Absolute pressure is equal to barometric pressure minus intake manifold vacuum.
- A decrease in manifold vacuum means an increase in manifold pressure.
- The MAP sensor compares manifold vacuum to a perfect vacuum.
- Barometric pressure minus MAP sensor reading equals intake manifold vacuum. Normal engine vacuum is 17–21 inch Hg.
- Supercharged and turbocharged engines require a MAP sensor that is calibrated for pressures above atmospheric, as well as for vacuum. ● **SEE FIGURE 72–3**.

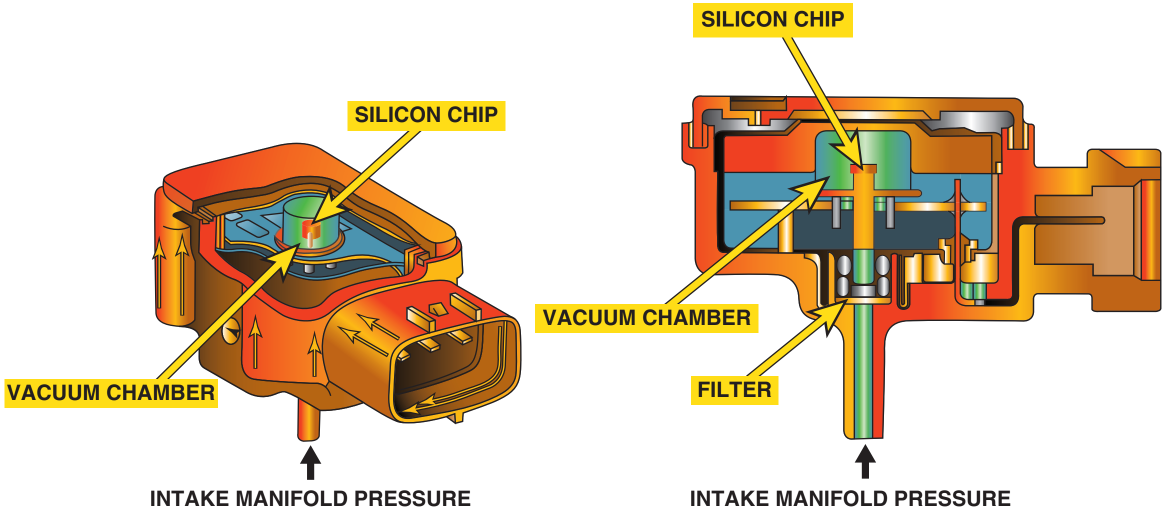

FIGURE 72–2 A MAP sensor compares the absolute pressure in the intake manifold to a perfect vacuum. The deflection of the silicon chip is converted to a an absolute pressure reading by the electronics in the sensor itself.

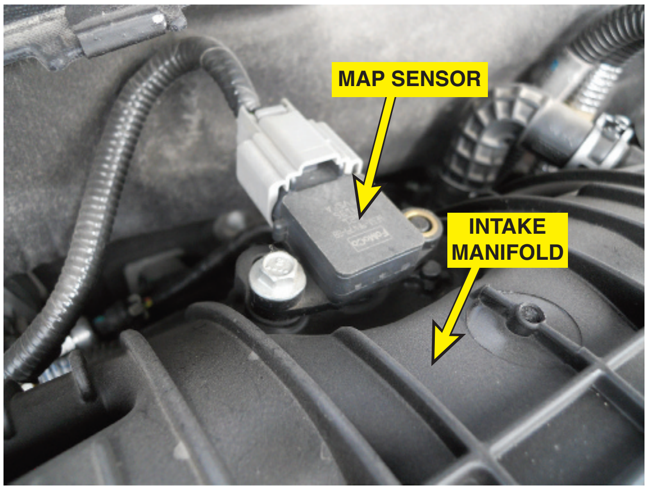

FIGURE 72–3 A typical MAP sensor installed in the intake manifold.

SILICON-DIAPHRAGM STRAIN GAUGE MAP SENSOR This is the most commonly used design for a MAP sensor and the output is a DC analog (variable) voltage. One side of a silicon wafer is exposed to engine vacuum and the other side is exposed to a perfect vacuum.

There are four resistors attached to the silicon wafer, which changes in resistance when strain is applied to the wafer. This change in resistance due to strain is called **piezoresistivity**. The resistors are electrically connected to a Wheatstone bridge circuit and then to a differential amplifier, which creates a voltage in proportion to the vacuum applied.

A typical General Motors MAP sensor voltage varies from 0.88 to 1.62 at engine idle.

- 17 inch Hg is equal to about 1.62 volts
- 21 inch Hg is equal to about 0.88 volts

Therefore, a good reading should be about 1.0 volt from the MAP sensor on a sound engine at idle speed. See the following chart that shows engine load, engine vacuum, and MAP. ● **SEE CHART 72–1**.

ENGINE LOAD	MANIFOLD VACUUM	MANIFOLD ABSOLUTE PRESSURE	MAP SENSOR VOLT SIGNAL
Heavy (WOT)	Low (almost 0 inch Hg)	High (almost atmospheric)	High (4.6–4.8 V)
Light (idle)	High (17–21 inch Hg)	Low (lower than atmospheric)	Low (0.8–1.6 V)

CHART 72–1

Engine load and how it is related to engine vacuum, and MAP sensor reading.

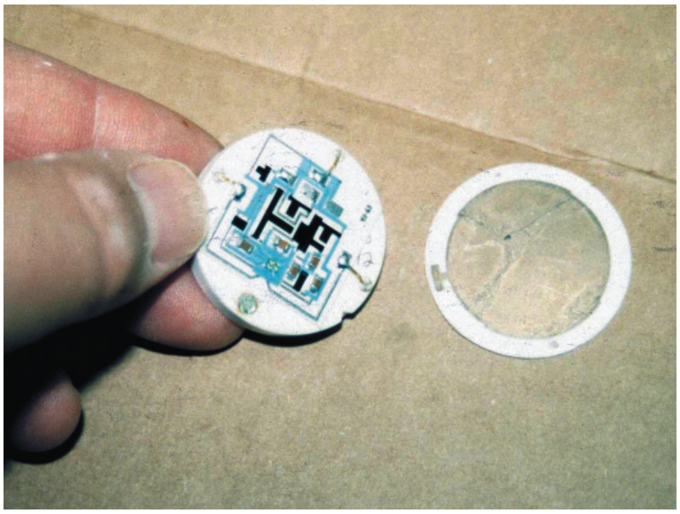

FIGURE 72–4 Shown is the electronic circuit inside a ceramic disc MAP sensor used on many Chrysler engines. The black areas are carbon resistors that are applied to the ceramic, and lasers are used to cut lines into these resistors during testing to achieve the proper operating calibration.

CERAMIC DISC MAP SENSOR The ceramic disc MAP sensor is used by Chrysler and it converts manifold pressure into a capacitance discharge. The discharge controls the amount of voltage delivered by the sensor to the PCM. The output is the same as the previously used strain gauge/Wheatstone bridge design and is interchangeable. ● **SEE FIGURE 72–4**. Also ● **SEE CHART 72–2**.

TECH TIP

If It's Green, It's a Signal Wire

Ford-built vehicles usually use a green wire as the signal wire back to the computer from the sensors. It may not be a solid green, but if there is green somewhere on the wire, then it is the signal wire. The other wires are the power and ground wires to the sensor.

PCM USES OF THE MAP SENSOR

SPEED DENSITY Engines that do not use an airflow meter or sensor rely on calculating the amount of air entering the engine by using the MAP sensor and engine speed as the major factors. The method of calculating the amount of fuel needed by the engine is called speed density.

The PCM uses the MAP sensor to determine the following:

- **The load on the engine.** The MAP sensor is used on a **speed density**–type fuel-injection system to determine the load on the engine, and therefore the amount of fuel needed. On engines equipped with a mass air flow (MAF) sensor, the MAP is used as a backup to the MAF, for diagnosis of other sensors, and systems such as the EGR system.
- **Altitude, fuel, and spark control calculations.** At key on, the MAP sensor determines the altitude (acts as a BARO sensor) and adjusts the fuel delivery and spark timing accordingly.
    - If the altitude is high, generally over 5,000 feet (1,500 meters), the PCM will reduce fuel delivery and advance the ignition timing.
    - The altitude is also reset when the engine is accelerated to wide-open throttle and the MAP sensor is used to reset the altitude reading. ● **SEE FIGURE 72–5.**

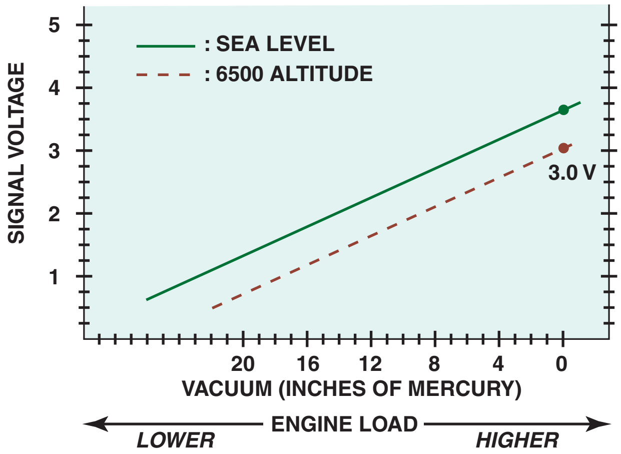

FIGURE 72–5 Altitude affects the MAP sensor voltage.

- **EGR system operation.** As part of the OBD-II standards, the exhaust gas recirculation (EGR) system must be checked for proper operation. One method used by many vehicle manufacturers is to command the EGR valve on and then watch the MAP sensor signal. The opening of the EGR pintle should decrease engine vacuum. If the MAP sensor does not react with the specified drop in manifold vacuum (increase in manifold pressure), an EGR flow rate problem diagnostic trouble code is set.
- **Detect deceleration (vacuum increases).** The engine vacuum rises when the accelerator is released, which changes the MAP sensor voltage. When deceleration is detected by the PCM, fuel is either stopped or greatly reduced to improve exhaust emissions.
- **Monitor engine condition.** As an engine wears, the intake manifold vacuum usually decreases. The PCM is programmed to detect the gradual change in vacuum and is able to keep the air–fuel mixture in the correct range. If the PCM were not capable of making adjustments for engine wear, the lower vacuum could be interpreted as increased load on the engine, resulting in too much fuel being injected, thereby reducing fuel economy and increasing exhaust emissions.
- **Load detection for returnless-type fuel injection.** On fuel delivery systems that do not use a return line back to the fuel tank, the engine load calculation for the fuel needed is determined by the signals from the MAP sensor.
- **Altitude and MAP sensor values.** On an engine equipped with a speed density–type fuel injection, the MAP sensor is the most important sensor needed to determine injection pulse width. Changes in altitude change the air density as well as weather conditions. Barometric pressure and altitude are inversely related:
    - As altitude increases—barometric pressure decreases
    - As altitude decreases—barometric pressure increases

  As the ignition switch is turned from off to the start position, the PCM reads the MAP sensor value to determine atmospheric and air pressure conditions. This barometric pressure reading is updated every time the engine is started and whenever wide-open throttle is detected. The barometric pressure reading at that time is updated. ● **SEE CHART 72–3.**

TECH TIP

Use the MAP Sensor as a Vacuum Gauge

A MAP sensor measures the pressure inside the intake manifold compared with absolute zero (perfect vacuum). For example, an idling engine that has 20 inches of mercury (inch Hg) of vacuum has a lower pressure inside the intake manifold than when the engine is under a load and the vacuum is at 10 inch Hg. A decrease in engine vacuum results in an increase in manifold pressure. A normal engine should produce between 17 and 21 inch Hg at idle. Comparing the vacuum reading with the voltage reading output of the MAP sensor indicates that the reading should be between 1.62 and 0.88 volt. Therefore, a digital multimeter (DMM), scan tool, or scope can be used to measure the MAP sensor voltage and be used instead of a vacuum gauge.

NOTE: This chart was developed by testing a MAP sensor at a location about 600 feet above sea level. For best results, a chart based on your altitude should be made by applying a known vacuum, and reading the voltage of a known-good MAP sensor. Vacuum usually drops about 1 inch per 1,000 feet of altitude.

Vacuum (in. Hg)	GM (DC volts)
0	4.80
1	4.52
2	4.46
3	4.26
4	4.06
5	3.88
6	3.66
7	3.50
8	3.30
9	3.10

11	2.76
12	2.54
13	2.36
14	2.20
15	2.00
16	1.80
17	1.62
18	1.42
19	1.20
20	1.10
21	0.88
22	0.66

Altitude and MAP Sensor Voltage

ALTITUDE	MAP SENSOR VOLTAGE (KEY ON, ENGINE OFF)
Sea level	4.6 – 4.8 V
2,500 ft (760 m)	4.0 V
5,000 ft (1,520 m)	3.7 V
7,500 ft (2,300 m)	3.35 V
10,000 ft (3,050 m)	3.05 V
12,500 ft (3,800 m)	2.80 V
15,000 ft (4,600 m)	2.45 V

CHART 72–3

Comparison between MAP sensor voltage and altitude.

BAROMETRIC PRESSURE SENSOR

TERMINOLOGY A **barometric pressure (BARO) sensor** is similar in design, but senses more subtle changes in barometric absolute pressure (atmospheric air pressure). It is vented directly to the atmosphere. The **barometric manifold absolute pressure (BMAP) sensor** is actually a combination of a BARO and MAP sensor in the same housing. The BMAP sensor has individual circuits to measure barometric and manifold pressure. This input not only allows the computer to adjust for changes in atmospheric pressure due to weather, but also is the primary sensor used to determine altitude.

NOTE: A MAP sensor and a BARO sensor are usually the same sensor, but the MAP sensor is connected to the manifold and a BARO sensor is open to the atmosphere. The MAP sensor is capable of reading barometric pressure just as the ignition switch is turned to the on position before the engine starts. See the Ford/BARO altitude chart for an example of how altitude affects intake manifold pressure. ● **SEE CHART 72–4**.

TESTING THE MAP SENSOR

Most pressure sensors operate on 5 volts from the computer and return a signal (voltage or frequency) based on the pressure (vacuum) applied to the sensor. If a MAP sensor is being tested, make certain that the vacuum hose and hose fittings are sound and making a good, tight connection to a manifold vacuum source on the engine.

Three different types of test instruments can be used to test a pressure sensor:

1. A digital voltmeter with three test leads connected in series between the sensor and the wiring harness connector or back-probe the terminals.
2. A scope connected to the sensor output, power, and ground.
3. A scan tool or a specific tool recommended by the vehicle manufacturer.

Ford MAP/BARO Altitude Chart

ALTITUDE (FEET)	VOLTS (V)
0	1.59
1,000	1.56
2,000	1.53
3,000	1.50
4,000	1.47
5,000	1.44

7,000	1.39

CHART 72–4

Comparison between Ford MAP/BARO sensor voltage and altitude.

CASE STUDY

The Case of the No-Start Lexus

The owner of a Lexus IS250 had the car towed to a shop as a no-start. The technician discovered that the "check engine" light would not come on even with key on, engine off (KOEO). A scan tool would not communicate either. Checking the resources on www.iatn.net, the technician read of a similar case where the fuel pressure sensor was shorted, which disabled all serial data communications. The technician disconnected the fuel pressure sensor located on the backside of the engine and the communications were restored and the engine started. The fuel pressure sensor was replaced and returned to the happy owner.

Summary:

Complaint—The vehicle owner stated that the engine would not start.
Cause—A shorted fuel pressure sensor was found as per a previous similar case.
Correction—The fuel pressure sensor was replaced and this corrected the serial data fault that caused the no-start condition.

NOTE: Always check service information for the exact testing procedures and specifications for the vehicle being tested.

TESTING THE MAP SENSOR USING A DMM OR SCOPE Use jumper wires, T-pins to back-probe the connector, or a breakout box to gain electrical access to the wiring to the pressure sensor. Most pressure sensors use three wires:

1. A 5-volt wire from the computer
2. A variable-signal wire back to the computer
3. A ground or reference low wire

The procedure for testing the sensor is as follows:

1. Turn the ignition on (engine off)
2. Measure the voltage (or frequency) of the sensor output
3. Using a hand-operated vacuum pump (or other variable vacuum source), apply vacuum to the sensor

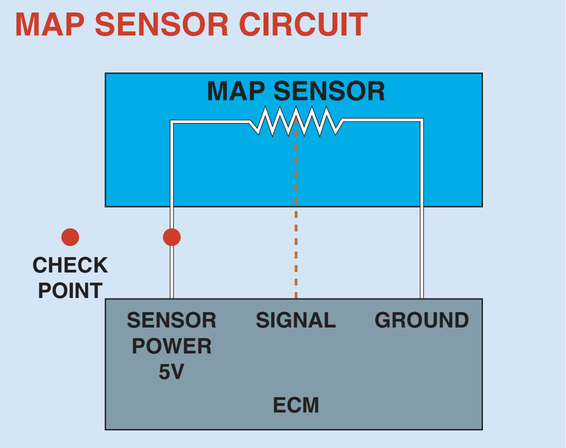

FIGURE 72–6 When checking a MAP sensor, first verify that the sensor is receiving a 5-volt reference voltage and then check for the output (signal) voltage.

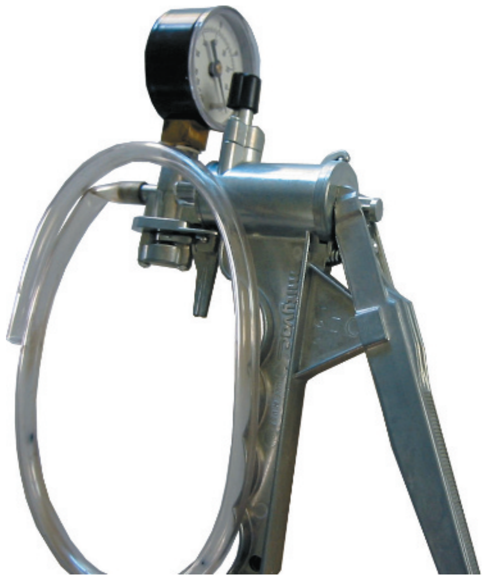

FIGURE 72–7 A typical hand-operated vacuum pump.

A good pressure sensor should change voltage in relation to the applied vacuum. If the signal does not change or the values are out of range according to the manufacturers' specifications, the sensor must be replaced. ● **SEE FIGURE 72–6**.

TESTING THE MAP SENSOR USING A SCAN TOOL A scan tool can be used to test a MAP sensor by monitoring the injector pulse width (in milliseconds) when vacuum is being applied to the MAP sensor using a hand-operated vacuum pump. ● **SEE FIGURE 72–7**.

STEP 1 Apply about 20 inch Hg of vacuum to the MAP sensor and start the engine.

STEP 2 Observe the injector pulse width. On a warm engine, the injector pulse width will normally be 1.5 to 3.5 milliseconds.

STEP 3 Slowly reduce the vacuum to the MAP sensor and observe the pulse width. A lower vacuum to the MAP sensor indicates a heavier load on the engine and the injector pulse width should increase.

NOTE: If 23 inch Hg or more vacuum is applied to the MAP sensor with the engine running, this high vacuum will often stall the engine. The engine stalls because the high vacuum is interpreted by the PCM to indicate that the engine is being

TECH TIP

Visual Check of the MAP Sensor

A defective vacuum hose to a MAP sensor can cause a variety of driveability problems including poor fuel economy, hesitation, stalling, and rough idle. A small air leak (vacuum leak) around the sensor can cause these symptoms and often set a trouble code in the vehicle computer.

When checking the MAP sensor, if anything comes out of the sensor itself, it should be replaced. This includes water, gasoline, or any other substance.

decelerated, which shuts off the fuel. During engine deceleration, the PCM shuts off the fuel injectors to reduce exhaust emissions and increase fuel economy.

MAP/BARO DIAGNOSTIC TROUBLE CODES The diagnostic trouble codes (DTCs) associated with the MAP and BARO sensors include

DIAGNOSTIC TROUBLE CODE	DESCRIPTION	POSSIBLE CAUSES
P0106	BARO sensor out-of-range at key on	■ MAP sensor fault ■ MAP sensor O-ring damaged or missing
P0107	MAP sensor low voltage	■ MAP sensor fault ■ MAP sensor signal circuit shorted-to-ground ■ MAP sensor 5-volt supply circuit open
P0108	Map sensor high voltage	■ MAP sensor fault ■ MAP sensor O-ring damaged or missing ■ MAP sensor signal circuit shorted-to-voltage

MASS AIRFLOW SENSOR TYPES

PURPOSE AND FUNCTION The purpose and function of mass air flow sensors is to measure the amount of air entering the engine.

There are several types of mass airflow sensors.

HOT FILM SENSOR The hot film sensor uses a temperature-sensing resistor (thermistor) to measure the temperature of the incoming air. Through the electronics within the sensor, a conductive film is kept at a temperature 70°C above the temperature of the incoming air. ● **SEE FIGURE 72–8.**

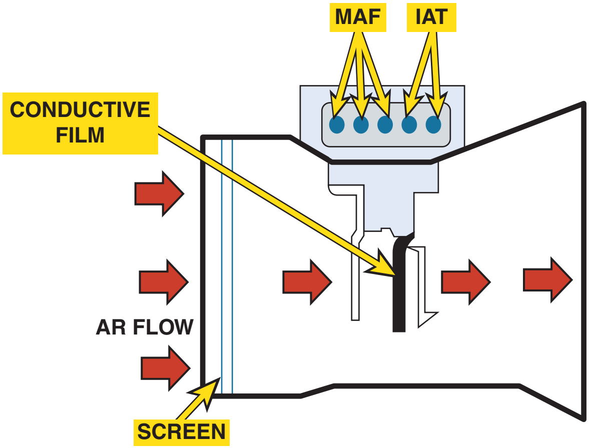

FIGURE 72–8 This five-wire mass air flow sensor consists of a metal foil sensing unit, an intake air temperature (IAT) sensor, and the electronic module.

Because the amount and density of the air both tend to contribute to the cooling effect as the air passes through the sensor, this type of sensor can actually produce an output based on the *mass* of the airflow. *Mass equals volume times density*. For example, cold air is denser than warm air so a small amount of cold air may have the same mass as a larger amount of warm air. Therefore, a mass airflow sensor is designed to measure the mass, not the volume, of the air entering the engine.

The output of this type of sensor is usually a frequency based on the amount of air entering the sensor. The more air that enters the sensor, the more the hot film is cooled. The electronics inside the sensor, therefore, increase the current flow through the hot film to maintain the 70°C temperature differential between the air temperature and the temperature of the hot film. This change in current flow is converted to a frequency output that the computer can use as a measurement of airflow. Most of these types of sensors are referred to as **mass airflow (MAF) sensors** because, unlike the air vane sensor, the MAF sensor takes into account relative humidity, altitude, and temperature of the air. The denser the air, the greater the cooling effect on the hot film sensor and the greater the amount of fuel required for proper combustion.

HOT WIRE SENSOR The hot wire sensor is similar to the hot film type, but uses a hot wire to sense the mass airflow instead of the hot film. Like the hot film sensor, the hot wire sensor uses a temperature-sensing resistor (thermistor) to measure the temperature of the air entering the sensor. ● **SEE FIGURE 72–9.** The electronic circuitry within the sensor keeps the temperature of the wire at 70°C above the temperature of the incoming air.

Both designs operate in essentially the same way. A resistor wire or screen installed in the path of intake airflow is heated to a constant temperature by electric current provided by the computer. Air flowing past the screen or wire cools it. The degree of cooling varies with air velocity, temperature, density, and humidity. These factors combine to indicate the mass of air entering the engine. As the screen or wire cools, more current is required to maintain the specified temperature. As the screen or wire heats up, less current is required. The operating principle can be summarized as follows:

- More intake air volume = cooler sensor, more current.
- Less intake air volume = warmer sensor, less current.

The computer constantly monitors the change in current and translates it into a voltage signal that is used to determine injector pulse width.

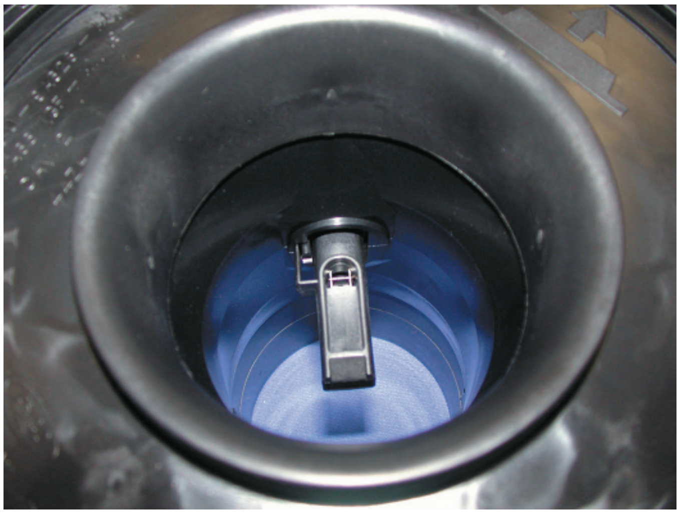

FIGURE 72–9 The sensing wire in a typical hot wire mass air flow sensor.

BURN-OFF CIRCUIT Some MAF sensors use a burn-off circuit to keep the sensing wire clean of dust and dirt. A high current is passed through the sensing wire for a short time, but long enough to cause the wire to glow due to the heat. The burn-off circuit is turned on when the ignition switch is switched off after the engine has been operating long enough to achieve normal operating temperature.

CASE STUDY

The Dirty MAF Sensor Story

The owner of a Buick Park Avenue equipped with a 3,800 V-6 engine complained that the engine would hesitate during acceleration, showed lack of power, and seemed to surge or miss at times. A visual inspection found everything to be like new, including a new air filter. There were no stored diagnostic trouble codes (DTCs). A look at the scan data showed airflow to be within the recommended 3 to 7 grams per second. A check of the frequency output showed the problem.

Idle frequency = 2.177 kHz (2,177 Hz)

Normal frequency at idle speed should be 2.37 to 2.52 kHz. Cleaning the hot wire of the MAF sensor restored proper operation. The sensor wire was covered with what looked like fine fibers, possibly from the replacement air filter.

Summary:

Complaint—Customer stated that the engine hesitated when accelerating.
Cause—Tests confirmed that the MAF sensor was operating correctly but the frequency output at idle was not within the normal range.
Correction—Cleaning the MAF sensor restored proper operation of the sensor and the engine now accelerates normally.

FREQUENTLY ASKED QUESTION

What Is Meant by a "High-Authority Sensor"?

A high-authority sensor is a sensor that has a major influence over the amount of fuel being delivered to the engine. For example, at engine start-up, the engine coolant temperature (ECT) sensor is a high-authority sensor and the oxygen sensor (O2S) is a low-authority sensor. However, as the engine reaches operating temperature, the oxygen sensor becomes a high-authority sensor and can greatly affect the amount of fuel being supplied to the engine. See the following chart:

High-Authority Sensors	Low-Authority Sensors
ECT (especially when the engine starts and is warming up)	IAT (intake air temperature) sensors modify and back up the ECT
O2S (after the engine reaches closed-loop operation)	TFT (transmission fluid temperature)
MAP	PRNDL (shift position sensor)
MAF	KS (knock sensor)
TP (high authority during acceleration and deceleration)	EFT (engine fuel temperature)

PCM USES FOR AIRFLOW SENSORS

The PCM uses the information from the airflow sensor for the following purposes:

- Airflow sensors are used mostly to determine the amount of fuel needed and base pulse-width numbers. The greater the mass of the incoming air, the longer the injectors are pulsed on.
- Airflow sensors back up the TP sensor in the event of a loss of signal or an inaccurate throttle position sensor signal. If the MAF sensor fails, then the PCM will calculate the fuel delivery needs of the engine based on throttle position and engine speed (RPM).

TESTING MASS AIRFLOW SENSORS

VISUAL INSPECTION Start the testing of a MAF sensor by performing a thorough visual inspection. Look at all the hoses that direct and send air, especially between the MAF sensor and the throttle body. Also check the electrical connector for the following:

- Corrosion
- Terminals that are bent or pushed out of the plastic connector
- Frayed wiring

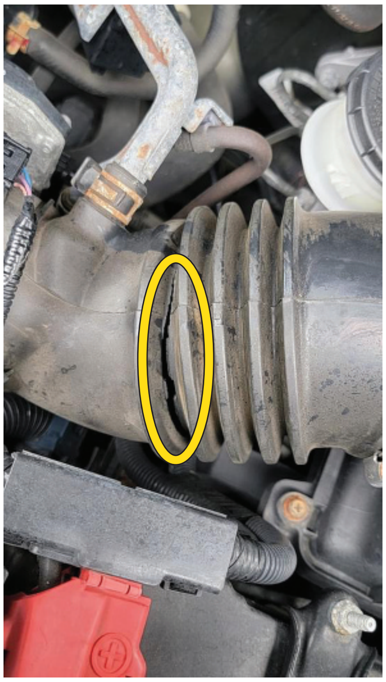

FIGURE 72–10 Carefully check the hose between the MAF sensor and the throttle plate for cracks or splits that could create extra (false) air into the engine that is not measured by the MAF sensor.

FREQUENTLY ASKED QUESTION

What Is False Air?

Airflow sensors and mass airflow (MAF) sensors are designed to measure *all* the air entering the engine. If an air inlet hose was loose or had a hole, extra air could enter the engine without being measured. This extra air is often called **false air**. ● **SEE FIGURE 72–10**.

NOTE: If the engine runs well in reverse, yet runs terrible in any forward gear, carefully look at the inlet hose for air leaks that would open when the engine torque moves the engine slightly on its mounts.

TAP TEST With the engine running at idle speed, *gently* tap the MAF sensor with the fingers of an open hand. If the engine stumbles or stalls, the MAF sensor is defective. This test is commonly called the **tap test**.

DMM AND DSO TEST OF A MAF SENSOR A digital multimeter can be used to measure the frequency (Hz) output of the sensor and compare the reading with specifications.

The frequency output and engine speed in RPM can also be plotted on a graph to check to see if the frequency and RPM are proportional, resulting in a straight line on the graph.

A digital storage oscilloscope (DSO) can be used to monitor the operation of a MAF sensor. Connect the test leads to the signal wire and the sensor ground and following the scope instructions look for a consistent pattern that changes in frequency as the engine speed is increased. ● **SEE FIGURE 72–11**.

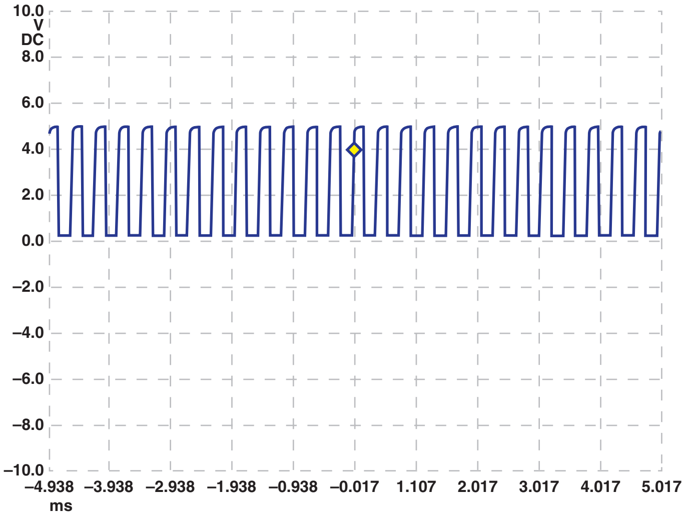

FIGURE 72–11 A scope display showing a normal Chevrolet Equinox MAF sensor at idle speed, the frequency is 2,600 hertz (2.6 kHz).

MAF SENSOR CONTAMINATION

Dirt, oil, silicon, or even spider webs can coat the sensing wire. Because it tends to insulate the sensing wire at low airflow rates, a contaminated sensor often overestimates the amount of air entering the engine at idle, and therefore causes the fuel system to go rich. At higher engine speeds near wide-open throttle (WOT), the contamination can cause the sensor to underestimate the amount of air entering the engine. As a result, the fuel system will go lean, causing spark knock and lack of power concerns. To check for contamination, check the fuel trim numbers.

If the fuel trim is negative (removing fuel) at idle, yet is positive (adding fuel) at higher engine speeds, a contaminated MAF sensor is a likely cause. Other tests for a contaminated MAF sensor are the following:

- At WOT, the grams per second, as read on a scan tool, should exceed 100.
- At WOT, the voltage, as read on a digital voltmeter, should exceed 4 volts for an analog sensor.
- At WOT, the frequency, as read on a meter or scan tool, should exceed 7 kHz for a digital sensor.

If the readings do not exceed these values, then the MAF sensor is contaminated.

MAF-RELATED DIAGNOSTIC TROUBLE CODES The diagnostic trouble codes (DTCs) associated with the mass airflow and air vane sensors are as follows:

DIAGNOSTIC TROUBLE CODE	DESCRIPTION	POSSIBLE CAUSES
P0100	Mass or volume airflow circuit problems	■ Open or short in mass airflow circuit ■ Defective MAF sensor
P0101	Mass airflow circuit range problems	■ Defective MAF sensor (check for false air)
P0102	Mass airflow circuit low output	■ Defective MAF sensor ■ MAF sensor circuit open or shorted-to-ground ■ Open 12-volt supply voltage circuit
P0103	Mass airflow circuit high output	■ Defective MAF sensor ■ MAF sensor circuit shorted-to-voltage

TECH TIP

The Unplug It Test

If a sensor is defective yet produces a signal to the computer, the computer will often accept the reading and make the required changes in fuel delivery and spark advance. If, however, the sensor is not reading correctly, the computer will process this wrong information and perform an action assuming that information being supplied is accurate. "If in doubt, take it out."

If the engine operates better with a sensor unplugged, then suspect that the sensor is defective. A sensor that is not supplying the correct information is said to be *skewed*. The computer will not set a diagnostic trouble code for this condition because the computer can often not detect that the sensor is supplying wrong information.

REVIEW QUESTIONS

1. What is the relationship between atmospheric pressure and engine vacuum?
2. What are three uses of a MAP sensor by the PCM?
3. What change in the signal will occur if engine speed is increased?
4. How is a MAF sensor tested?
5. What is the purpose of a MAF sensor?

CHAPTER QUIZ

1. As the load on an engine increases, the manifold vacuum decreases and the manifold absolute pressure ___________.
   - **a.** increases
   - **b.** decreases
   - **c.** changes with barometric pressure only (altitude or weather)
   - **d.** remains constant (absolute)
2. A typical MAP sensor compares the vacuum in the intake manifold to ___________.
   - **a.** atmospheric pressure
   - **b.** a perfect vacuum
   - **c.** barometric pressure
   - **d.** the value of the IAT sensor
3. Which statement is false?
   - **a.** Absolute pressure is equal to barometric pressure plus intake manifold vacuum.
   - **b.** A decrease in manifold vacuum means an increase in manifold pressure.
   - **c.** The MAP sensor compares manifold vacuum to a perfect vacuum.
   - **d.** Barometric pressure minus the MAP sensor reading equals intake manifold vacuum.
4. A MAP sensor can be tested using ___________.
   - **a.** a scope
   - **b.** a scan tool
   - **c.** a DMM
   - **d.** Any of these
5. Which is not a purpose or function of the MAP sensor?
   - **a.** Measures the load on the engine
   - **b.** Measures engine speed
   - **c.** Calculates fuel delivery based on altitude
   - **d.** Helps diagnose the EGR system
6. The MAF sensor is used mostly to determine the amount of what to deliver to the engine?
   - **a.** Vacuum correction
   - **b.** Idle air
   - **c.** Spark advance
   - **d.** Fuel
7. The typical MAF reading on a scan tool with the engine at idle speed and normal operating temperature is ___________.
   - **a.** 1 to 3 grams per second
   - **b.** 3 to 7 grams per second
   - **c.** 8 to 12 grams per second
   - **d.** 14 to 24 grams per second

8. Two technicians are diagnosing a poorly running engine. There are no diagnostic trouble codes. When the MAF sensor is unplugged, the engine runs better. Technician A says that this means that the MAF is supplying incorrect airflow information to the PCM. Technician B says that this indicates that the PCM is defective. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B

9. If the MAF sensor fails, the PCM uses what to calculate fuel delivery needs?
   a. MAP and throttle position
   b. RPM and throttle position
   c. Throttle position and transmission RPM
   d. RPM alone

10. Air that enters the engine without passing through the airflow sensor is called ___________.
   a. bypass air
   b. dirty air
   c. false air
   d. measured air

Chapter 73

OXYGEN SENSORS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss how O2S sensors work.
- Discuss PCM uses of the oxygen sensor.
- Discuss oxygen sensor diagnosis.
- Discuss post-catalytic converter O2S testing.
- Explain the operation of wide-band oxygen sensors.
- Describe dual cell planar wide-band sensor operation.
- Discuss dual cell diagnosis.
- Describe single cell wide-band oxygen sensors.
- Interpret oxygen sensor-related diagnostic trouble codes.

KEY TERMS:

Air–fuel ratio sensor 878 • Ambient side electrode 866 • Closed loop 868 • Cup design 866 • Dual cell 875 • Exhaust side electrode 866 • False lean 870 • False rich 870 • Finger design 866 • Fuel trim 868 • HO2S 867 • Light-off time (LOT) 874 • Nernst cell 874 • Open loop 868 • Oxygen sensors (O2S) 865 • Planar 874 • Pump cell 875 • Reference 875 • Reference electrode 866 • RTV 873 • Signal electrode 866 • Single cell 878 • Thimble design 866 • Wide-band oxygen sensors 873 • Zirconia 865 • ZrO2 865

OXYGEN SENSORS

PURPOSE AND FUNCTION Automotive computer systems use a sensor in the exhaust system to measure the oxygen content of the exhaust. These sensors are called **oxygen sensors (O2S)**. The oxygen sensor is installed in the exhaust manifold or located downstream from the manifold in the exhaust pipe. ● **SEE FIGURE 73–1**.

The oxygen sensor is directly in the path of the exhaust gas stream where it monitors oxygen levels in both the exhaust stream and the ambient air. A **zirconia** oxygen sensor is made of **zirconium dioxide (ZrO2)**, an electrically conductive material capable of generating a small voltage in the presence of oxygen.

NARROW BAND A conventional zirconia oxygen sensor (O2S) is only able to detect if the exhaust is richer or leaner than 14.7:1. A conventional oxygen sensor is therefore referred to as the following:

- *Two-step sensor*, which is either rich or lean
- *Narrow-band sensor*, which informs the PCM whether the exhaust is rich or lean only

The voltage value where a zirconia oxygen sensor switches from rich to lean or from lean to rich is 0.45 V (450 mV).

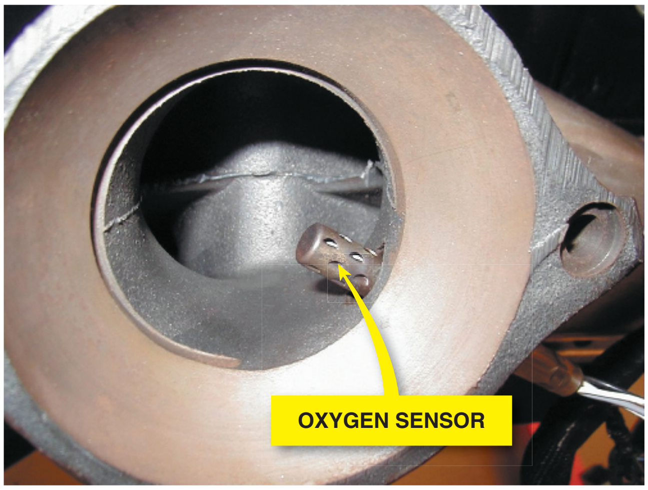

FIGURE 73–1 Many oxygen sensors are located in the exhaust manifold near its outlet so that the sensor can detect the air–fuel mixture in the exhaust stream for all cylinders that feed into the manifold.

- Above 0.45 V = rich
- Below 0.45 V = lean

● **SEE FIGURE 73–2**.

(a) (b)

FIGURE 73–2 (a) When the exhaust is lean, the output of a zirconia oxygen sensor is below 450 mV. (b) When the exhaust is rich, the output of a zirconia oxygen sensor is above 450 mV.

CONSTRUCTION A typical zirconia oxygen sensor has the sensing element in the shape of a thimble; therefore, it is often referred to as one of the following:

- **Thimble design**
- **Cup design**
- **Finger design**
- ● **SEE FIGURE 73–3**.

A typical zirconia oxygen sensor has a heater inside the thimble and does not touch the inside of the sensor. The sensor is similar to a battery that has two electrodes and an electrolyte. The electrolyte is solid and is the zirconia (zirconium dioxide). There are also two porous platinum electrodes, which have the following functions:

- **Exhaust side electrode** is exposed to the exhaust stream.
- **Ambient side electrode** is exposed to outside (ambient) air and is the **signal electrode**, also called the **reference electrode**. ● **SEE FIGURE 73–4**.

The electrolyte (zirconia) is able to conduct electrons as follows:

- If the exhaust is rich, O_2 from the reference (inner) electrode wants to flow to the exhaust side electrode, which results in the generation of a voltage.
- If the exhaust is lean, O_2 flow is not needed. As a result, there is little if any electron movement and, therefore, no voltage is produced.

PLATINUM ELECTRODES
CUP TYPE HEATED OXYGEN SENSOR

FIGURE 73–3 Most conventional zirconia oxygen sensors and some wide-band oxygen sensors use the cup (finger) type of design.

OPERATION Exhaust from the engine passes through the end of the sensor where the gases contact the outer side of the thimble. Atmospheric air enters through the other end of the sensor or through the wire of the sensor and contacts the inner side of the thimble. The inner and outer surfaces of the thimble are plated with platinum. The inner surface becomes a negative

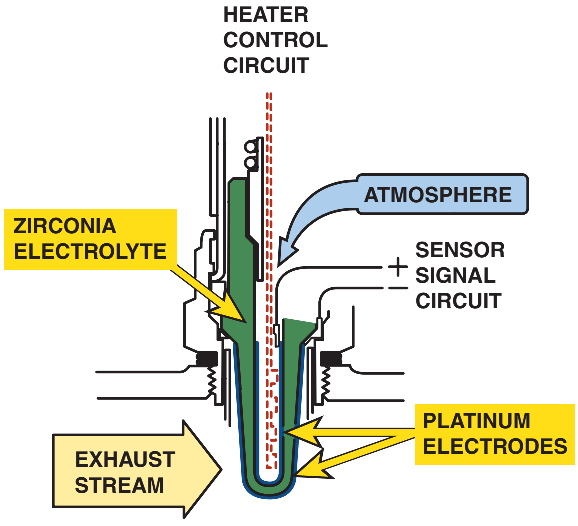

FIGURE 73–4 A typical heated zirconia oxygen sensor, showing the sensor signal circuit that uses the outer (exhaust) electrode as the negative and the ambient air side electrode as the positive.

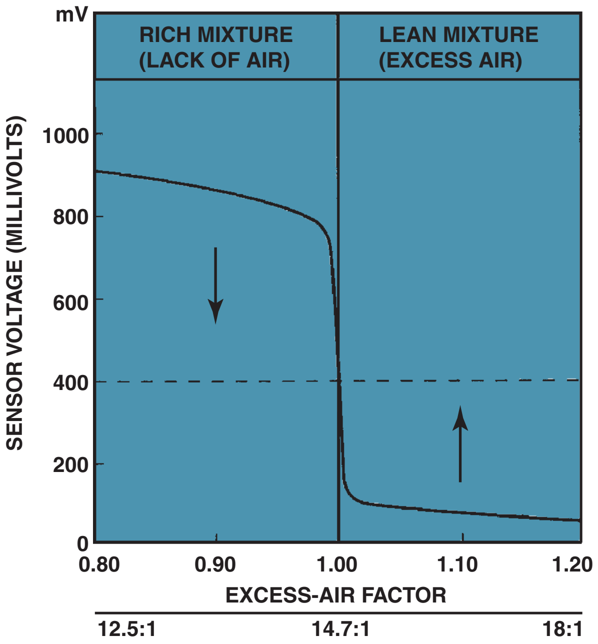

FIGURE 73–5 The oxygen sensor provides a quick response at the stoichiometric air–fuel ratio of 14.7:1.

electrode and the outer surface is a positive electrode. The atmosphere contains a relatively constant 21% of oxygen. Exhaust gases created by burning a rich air–fuel mixture contain little oxygen. Exhaust gases from burning a lean air–fuel mixture contain more oxygen.

Negatively charged oxygen ions are drawn to the thimble where they collect on both the inner and outer surfaces.

Because the oxygen present in the atmosphere exceeds that in the exhaust gases, the air side of the thimble draws more negative oxygen ions than the exhaust side. The difference between the two sides creates an electrical potential, or voltage. When the concentration of oxygen on the exhaust side of the thimble is low, a high voltage (0.60 to 1.0 V) is generated between the electrodes. As the oxygen concentration on the exhaust side increases, the voltage generated drops low (0.0 to 0.3 V).

An O2S does not send a voltage signal until its tip reaches a temperature of about 572°F (300°C). Also, oxygen sensors provide their fastest response to mixture changes at about 1,472°F (800°C). When the engine starts and the O2S is cold, the PCM operates the engine in the open-loop mode, drawing on prerecorded data in the PROM for fuel control on a cold engine, or when O2S output is not within certain limits.

If the exhaust contains very little oxygen, the PCM assumes that the intake charge is rich (too much fuel) and reduces fuel delivery. However, when the oxygen level is high, the PCM assumes that the intake charge is lean (not enough fuel) and increases fuel delivery. ● **SEE FIGURE 73–5.**

There are several different designs of oxygen sensors, including the following:

- **One-wire oxygen sensor.** The single wire of the one-wire oxygen sensor is the O2S signal wire. The ground for the O2S is through the shell and threads of the sensor and through the exhaust manifold.
- **Two-wire oxygen sensor.** The two-wire sensor has a signal wire and a ground wire for the O2S.
- **Three-wire oxygen sensor.** The three-wire sensor design uses an electric resistance heater to help get the O2S up to temperature more quickly and to help keep the sensor at operating temperature even at idle speeds. The three wires include the O2S signal, the power, and ground for the heater.
- **Four-wire oxygen sensor.** The four-wire sensor is a **heated O2S (HO2S)** that uses an O2S signal wire and signal ground. The other two wires are the power and ground for the heater.

HEATER CIRCUITS The heater circuit on conventional oxygen sensors requires 0.8 to 2.0 amperes and keeps the sensor at about 600°F (315°C).

A wide-band oxygen sensor operates at a higher temperature than a conventional HO2S, from 1,200°F to 1,400°F (650°C to 760°C). The amount of electrical current needed for a wide-band oxygen sensor is about 8 to 10 amperes.

CASE STUDY

The Chevrolet Pickup Truck Story

The owner of a Chevrolet pickup truck complained that the engine ran terribly. It would hesitate and surge, yet there were no diagnostic trouble codes (DTCs). After hours of troubleshooting, the technician discovered while talking to the owner that the problem started after the transmission had been repaired. However, the transmission shop said that the problem was an engine problem and not related to the transmission.

A thorough visual inspection revealed that the front and rear oxygen sensor connectors had been switched. The PCM was trying to compensate for an air-fuel mixture condition that did not exist. Reversing the O2S connectors restored proper operation of the truck.

Summary:

Complaint—Vehicle owner complained that the pickup truck ran terribly.
Cause—During a previous repair, the upstream and downstream oxygen sensor connectors were reversed.
Correction—The connectors were moved to their correct locations, which restored proper engine operation.

FIGURE 73–6 Number and label designations for oxygen sensors. Bank 1 is the bank where cylinder 1 is located.

FREQUENTLY ASKED QUESTION

Where Is HO2S1?

Oxygen sensors are numbered according to their location in the engine. On a V-type engine, heated oxygen sensor number 1 (HO2S1) is located in the exhaust system upstream of the catalytic converter on the side of the engine where cylinder 1 is located. ● **SEE FIGURE 73–6**.

PCM USES OF THE OXYGEN SENSOR

FUEL CONTROL The amount of fuel delivered to an engine is determined by the powertrain control module (PCM) based on inputs from the engine coolant temperature (ECT), throttle position (TP) sensor, and others until the oxygen sensor is capable of supplying a usable signal. When the PCM alone is determining the amount of fuel needed, it is called **open-loop** operation. As soon as the oxygen sensor (O2S) is capable of supplying rich and lean signals, PCM adjustments can be made to fine-tune the correct air–fuel mixture. This checking and adjusting of the PCM is called **closed-loop** operation.

The upstream oxygen sensors are among the high-authority sensors used for fuel control while operating in closed loop. Before the oxygen sensors are hot enough to give accurate exhaust oxygen information to the PCM, fuel control is determined by other sensors and the anticipated injector pulse width determined by those sensors. After the control system achieves closed-loop status, the oxygen sensor provides feedback to actual exhaust gas oxygen content.

FUEL TRIM The **fuel trim** numbers are determined from the signals by the oxygen sensor(s). If the engine has been operating too lean, short-term and long-term fuel time programming inside the PCM can cause an increase in the commanded injector pulse width to bring the air–fuel mixture back into the proper range. Fuel trim can be negative (subtracting fuel) or positive (adding fuel).

OXYGEN SENSOR DIAGNOSIS

PCM SYSTEM TESTS The oxygen sensors are used for diagnosis of other systems and components. For example, the exhaust gas recirculation (EGR) system is tested by the PCM, by commanding the EGR valve to open during the test. Some PCMs determine whether enough exhaust gas flows into the engine by looking at the oxygen sensor response (fuel trim numbers). The upstream and downstream oxygen sensors are also used to determine the efficiency of the catalytic converter. Therefore, if a fault occurs with an oxygen sensor, the PCM may not be able to test other systems. ● **SEE FIGURE 73–7**.

VISUAL INSPECTION Whenever an oxygen sensor is replaced, the old sensor should be carefully inspected to help determine the cause of the failure. This is an important step because if the

CASE STUDY

The Oxygen Sensor Is Lying to You

A technician was trying to solve a driveability problem with an older V-6 passenger car. The car idled roughly, hesitated, and accelerated poorly. A thorough visual inspection did not indicate problems and there were no diagnostic trouble codes stored.

The technician checked the oxygen sensor activity using a DMM. The voltage stayed above 600 mV most of the time. If the technician removed a large vacuum hose, the oxygen sensor voltage would temporarily drop to below 450 mV and then return to a reading of over 600 mV. Remember:

- High O2S readings = rich exhaust (low O_2 content in the exhaust)
- Low O2S readings = lean exhaust (high O_2 content in the exhaust)

As part of a thorough visual inspection, the technician removed and inspected the spark plugs. All the spark plugs were white, indicating a lean mixture, not the rich mixture that the oxygen sensor was indicating. The high O2S reading signaled the PCM to reduce the amount of fuel, resulting in an excessively lean operation.

After replacing the oxygen sensor, the engine ran great. But what killed the oxygen sensor? The technician finally learned from the owner that the head gasket had been replaced over a year ago. The silicate and phosphate additives in the antifreeze coolant had coated the oxygen sensor. Because the oxygen sensor was coated, the oxygen content of the exhaust could not be detected, resulting in a false rich signal from the oxygen sensor.

Summary:

Complaint—Vehicle owner complained that the car equipped with a V-6 engine ran terribly.
Cause—The oxygen sensor was contaminated by the additives in the coolant caused by a previously repaired head gasket failure.
Correction—Replacing the oxygen sensors restored proper engine operation.

cause of the failure is not discovered, it could lead to another sensor failure.

Inspection may reveal the following:

1. Black sooty deposits usually indicate a rich air–fuel mixture.
2. White chalky deposits are characteristic of silica contamination. Usual causes for this type of sensor failure include silica deposits in the fuel or a technician having used the wrong type of silicone sealant during the servicing of the engine.
3. White sandy or gritty deposits are characteristic of antifreeze (ethylene glycol) contamination. A defective cylinder head or intake manifold gasket could be the cause, or a cracked cylinder head or engine block. Antifreeze may also cause the oxygen sensor to become green as a result of the dye used in antifreeze.

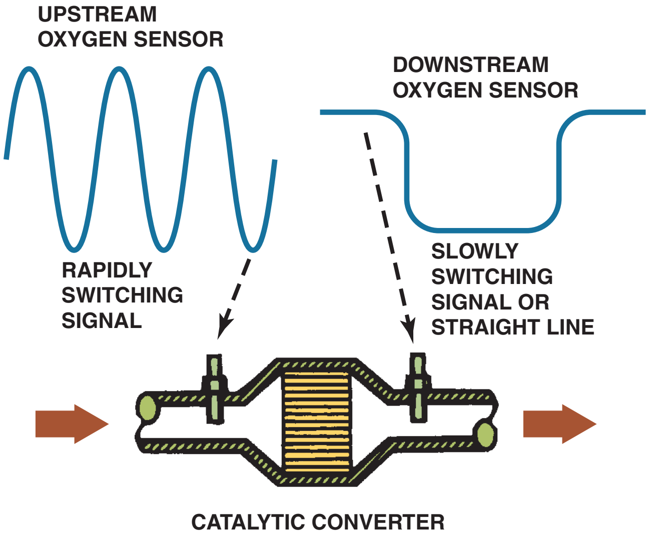

FIGURE 73–7 The OBD-II catalytic converter monitor compares the signals of the upstream and downstream oxygen sensor to determine converter efficiency.

4. Dark brown deposits indicate excessive oil consumption. Possible causes include a defective positive crankcase ventilation (PCV) system or a mechanical engine problem, such as defective valve stem seals or piston rings.

DIGITAL VOLTMETER TESTING The oxygen sensor can be checked for proper operation using a digital high-impedance voltmeter.

1. With the engine off, connect the red lead of the meter to the oxygen sensor signal wire and the black meter lead to a good engine ground. ● **SEE FIGURE 73–8**.
2. Start the engine and allow it to reach closed-loop operation.
3. In closed-loop operation, the oxygen sensor voltage should be constantly changing as the fuel mixture is being controlled.

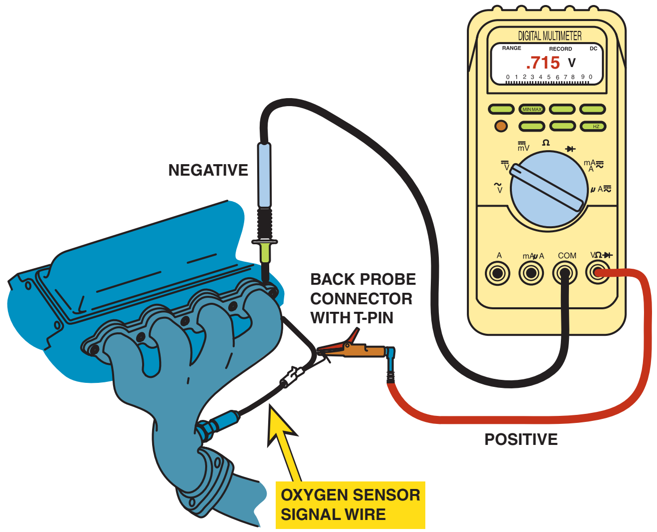

FIGURE 73–8 Testing an oxygen sensor using a DMM set on DC volts. With the engine operating in closed loop, the oxygen voltage should read over 800 mV and lower than 200 mV and be constantly fluctuating.

TECH TIP

Do Not Solder Oxygen Sensor Wires

Oxygen sensors must have outside oxygen to compare with the oxygen content in the exhaust. Most oxygen sensors breathe through the signal wire and, if soldered, would block the flow of outside air to the sensor. If a replacement oxygen sensor is used, always use the factory replacement, using the original connectors or a crimp-and-seal connector that will seal out any moisture and still allow air to flow through the connector.

The results should be interpreted as follows:

- If the oxygen sensor fails to respond, and its voltage remains at about 450 mV, the sensor may be defective and require replacement. Before replacing the oxygen sensor, check the manufacturer's recommended procedures.
- If the oxygen sensor reads high all the time (above 550 mV), the fuel system could be supplying too rich a fuel mixture or the oxygen sensor may be contaminated. An oxygen sensor reading that is high could be due to other things besides a rich air–fuel mixture. When the O2S reads temporarily drop to below 450 mV and besides a rich mixture, it is often called a **false rich** indication.

False rich indications (high O2S readings) can be attributed to the following:

- Contaminated O2S due to additives in the engine coolant or due to silicon poisoning
- A stuck open EGR valve (especially at idle)
- A spark plug wire too close to the oxygen sensor signal wire, which can induce a higher than normal voltage in the signal wire, thereby indicating to the PCM a false rich condition
- A loose oxygen sensor ground connection, which can cause a higher than normal voltage and a false rich signal
- A break or contamination of the wiring and its connectors, which could prevent reference oxygen from reaching the oxygen sensor, resulting in a false rich indication. (All oxygen sensors require an oxygen supply inside the sensor itself for reference to be able to sense exhaust gas oxygen.)

If the oxygen sensor voltage remains low (below 350 mV), the oxygen sensor itself could be bad or the fuel system could be supplying too lean a fuel mixture. Check for a vacuum leak or partially clogged fuel injector(s). Before replacing the oxygen sensor, check the manufacturer's recommended procedures. If an oxygen sensor reads low as a result of a factor besides a lean mixture, it is often called a **false lean** indication.

False lean indications (low O2S readings) can be attributed to the following:

1. **Ignition misfires.** An ignition misfire due to a defective spark plug wire, fouled spark plug, and so forth, causes no burned air and fuel to be exhausted past the O2S. The O2S "sees" the oxygen (not the unburned gasoline) and the O2S voltage is low.
2. **Exhaust leak in front of the O2S.** An exhaust leak between the engine and the oxygen sensor causes outside oxygen to be drawn into the exhaust and past the O2S. This oxygen is "read" by the O2S and produces a lower than normal voltage. The PCM interprets the lower than normal voltage signal from the O2S as meaning that the air–fuel mixture is lean. The PCM will cause the fuel system to deliver a richer air–fuel mixture.
3. **Spark plug misfire.** The PCM does not know that the extra oxygen going past the oxygen sensor is not due to a lean air–fuel mixture. The PCM commands a richer mixture, which could cause the spark plugs to foul, increasing the rate of misfiring.

MIN/MAX TESTING A digital meter set on DC volts can be used to record the minimum and maximum voltage with the engine running. A good oxygen sensor should be able to produce a value of less than 300 mV and a maximum voltage above 800 mV. ● **SEE FIGURE 73–9**.

Replace any oxygen sensor that fails to go above 700 mV or lower than 300 mV. ● **SEE CHART 73–1**.

FREQUENTLY ASKED QUESTION

Why Does the Oxygen Sensor Voltage Read 5 Volts on Many Chrysler Vehicles?

Many Chrysler vehicles apply a 5-volt reference to the signal wire of the oxygen sensor. The purpose of this voltage is to allow the PCM to detect if the oxygen sensor signal circuit is open or grounded.

- If the voltage on the signal wire is 4.5 volts or more, the PCM assumes that the sensor is open.
- If the voltage on the signal wire is zero, the PCM assumes that the sensor is shorted-to-ground.

If either condition exists, the PCM can set a diagnostic trouble code (DTC).

TECH TIP

The Key On, Engine Off Oxygen Sensor Test

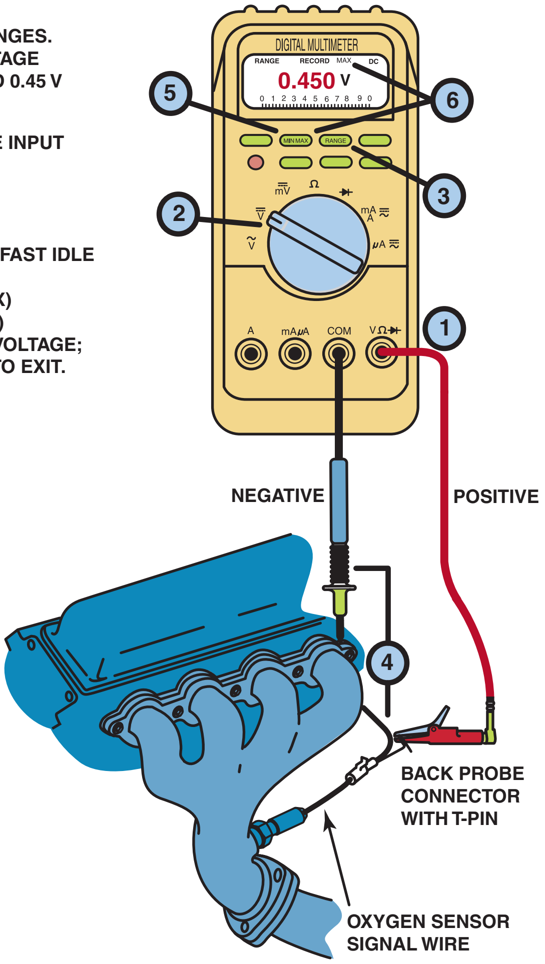
This test works on General Motors vehicles and may work on others if the PCM applies a bias voltage to the oxygen sensors. Zirconia oxygen sensors become more electrically conductive as they get hot. To perform this test, be sure that the vehicle has not run for several hours.

STEP 1 Connect a scan tool and get the display ready to show oxygen sensor data.

STEP 2 Key the engine on *without* starting the engine. The heater in the oxygen sensor will start heating the sensor.

STEP 3 Observe the voltage of the oxygen sensor. The applied bias voltage of 450 mV should slowly decrease for all oxygen sensors as they become more electrically conductive as the bias voltage is flowing to ground.

STEP 4 A good oxygen sensor should indicate a voltage of less than 100 mV after three minutes. Any sensor that displays a higher than usual voltage or seems to stay higher longer than the others could be defective or skewed high.



WATCH ANALOG POINTER SWEEP AS O2 VOLTAGE CHANGES. DEPENDING ON THE DRIVING CONDITIONS, THE O2 VOLTAGE RISES AND FALLS, BUT IT USUALLY AVERAGES AROUND 0.45 V

1. SHUT THE ENGINE OFF AND INSERT TEST LEAD IN THE INPUT TERMINALS SHOWN.
2. SET THE ROTARY SWITCH TO VOLTS DC.
3. MANUALLY SELECT THE 4 V RANGE
4. CONNECT THE TEST LEADS AS SHOWN.
5. START THE ENGINE. IF THE O2 SENSOR IS UNHEATED, FAST IDLE THE ENGINE FOR A FEW MINUTES.
6. PRESS MIN / MAX BUTTON TO DISPLAY MAXIMUM (MAX) 02 VOLTAGE; PRESS AGAIN TO DISPLAY MINIMUM (MIN) VOLTAGE; PRESS AGAIN TO DISPLAY AVERAGE (AVG) VOLTAGE; PRESS AND HOLD DOWN MIN / MAX FOR 2 SECONDS TO EXIT.

FIGURE 73–9 Using a digital multimeter to test an oxygen sensor using the MIN/MAX record function of the meter.

MIN/MAX OXYGEN SENSOR TEST CHART

MINIMUM VOLTAGE	MAXIMUM VOLTAGE	AVERAGE VOLTAGE	TEST RESULTS
Below 200 mV	Above 800 mV	400–500 mV	Oxygen sensor is okay.
Above 200 mV	Any reading	400–500 mV	Oxygen sensor is defective.
Any reading	Below 800 mV	400–500 mV	Oxygen sensor is defective.
Below 200 mV	Above 800 mV	Below 400 mV	System is operating lean.*
Below 200 mV	Below 800 mV	Below 400 mV	System is operating lean. (Add propane to the intake air to see if the oxygen sensor reacts. If not, the sensor is defective.)
Below 200 mV	Above 800 mV	Above 500 mV	System is operating rich.
Above 200 mV	Above 800 mV	Above 500 mV	System is operating rich. (Remove a vacuum hose to see if the oxygen sensor reacts. If not, the sensor is defective.)

CHART 73–1

The test results of using a digital meter set to read minimum and maximum values while testing a narrow-band oxygen sensor. *Check for an exhaust leak upstream from the O2S or ignition misfire that can cause a false lean indication before further diagnosis.

SCAN TOOL TESTING A good oxygen sensor should sense the oxygen content and change voltage outputs rapidly. How fast an oxygen sensor switches from high (above 450 mV) to low (below 350 mV) is measured as frequency, or the number of times the voltage switches per second.

NOTE: On a fuel-injected engine at 2000 engine RPM, 1 to 5 Hz (one to five switches per second) is normal.

Using a scan tool, observe the oxygen sensor voltages with the engine running at 2000 RPM. Look for numbers higher than 800 mV and lower than 200 mV.

If the frequency of switching is low, the oxygen sensor may be contaminated, or the fuel delivery system is delivering a constant rich or lean air–fuel mixture. If the frequency of switching is higher than 5 Hz, look for misfire conditions.

1. Connect the scan tool and start the engine.
2. Operate the engine at a fast idle (2,500 RPM) for two minutes to allow time for the oxygen sensor to warm to operating temperature.
3. Observe the oxygen sensor activity on the scan tool to verify closed-loop operation. Select the "snapshot" mode, hold the engine speed steady, and start recording.
4. Play back snapshot and place a mark beside each range of oxygen sensor voltage for each frame of the snapshot.

A good oxygen sensor and PCM should result in the most snapshot values at both ends (0 to 300 mV and 600 to 1,000 mV). If most of the readings are in the middle, the oxygen sensor is not working correctly.

SCOPE TESTING A scope can also be used to test an oxygen sensor. Connect the scope to the signal wire and ground for the sensor (if it is so equipped). ● **SEE FIGURE 73–10**.

With the engine operating in closed loop, the voltage signal of the sensor should be constantly changing. ● **SEE FIGURE 73–11**.

Check for rapid switching from rich to lean and lean to rich and change between once every two seconds and five times per second (0.5 to 5.0 Hz).

NOTE: General Motors warns not to base the diagnosis of an oxygen sensor problem solely on its scope pattern. The varying voltage output of an oxygen sensor can easily be mistaken for a fault in the sensor itself, rather than a fault in the fuel delivery system.

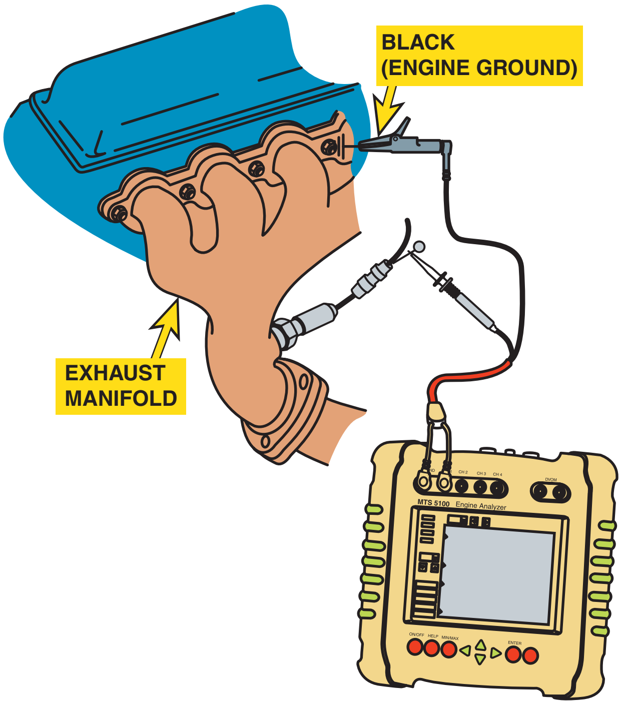


FIGURE 73–10 Connecting a handheld digital storage oscilloscope to an oxygen sensor signal wire. Check the instructions for the scope as some require the use of a filter to be installed in the test lead to reduce electromagnetic interference that can affect the oxygen sensor waveform.

POST-CATALYTIC CONVERTER OXYGEN SENSOR TESTING

The oxygen sensor located behind the catalytic converter is used on OBD-II vehicles to monitor converter efficiency. A changing air–fuel mixture is required for the most efficient operation of the converter. If the converter is working correctly, the oxygen content after the converter should be fairly constant. ● **SEE FIGURE 73–12**.

The post-catalytic converter oxygen sensor also is used to modify the amount of fuel delivered to the engine to allow the converter to work efficiently. If, for example, the rear oxygen sensor voltage stayed high, the PCM will try to increase the amount of oxygen entering the converter by leaning the air–fuel mixture

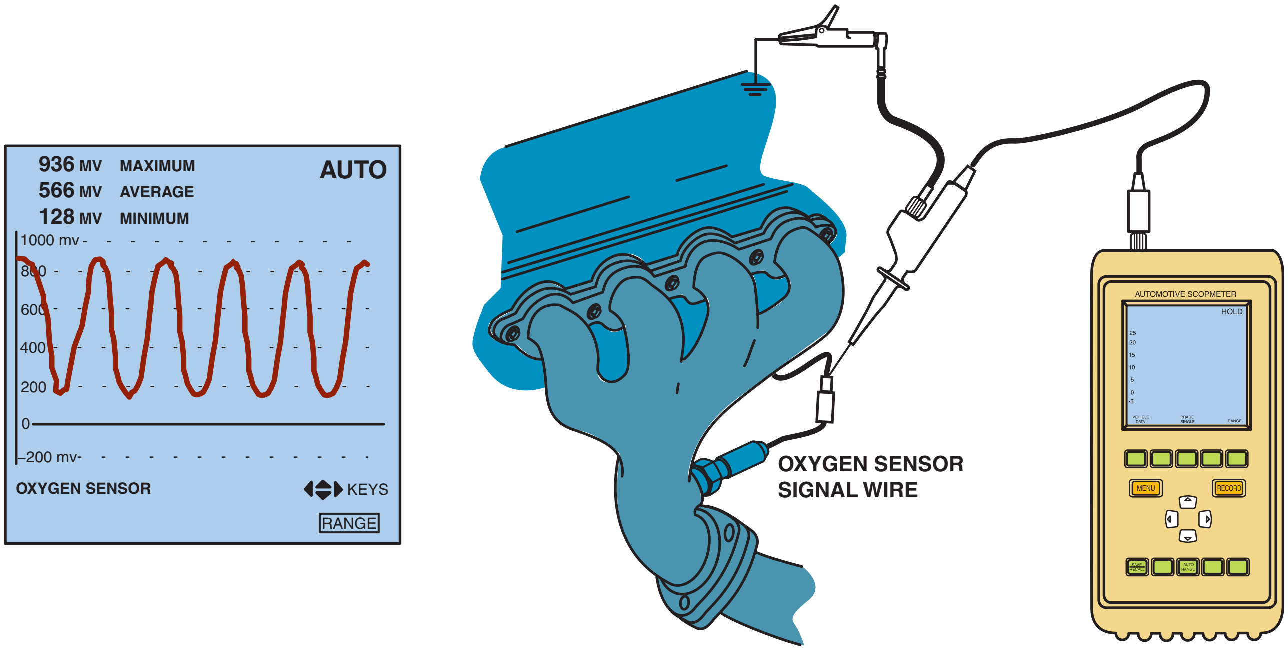

FIGURE 73–11 The waveform of a good oxygen sensor as displayed on a digital storage oscilloscope (DSO). Note that the maximum reading is above 800 mV and the minimum reading is less than 200 mV.

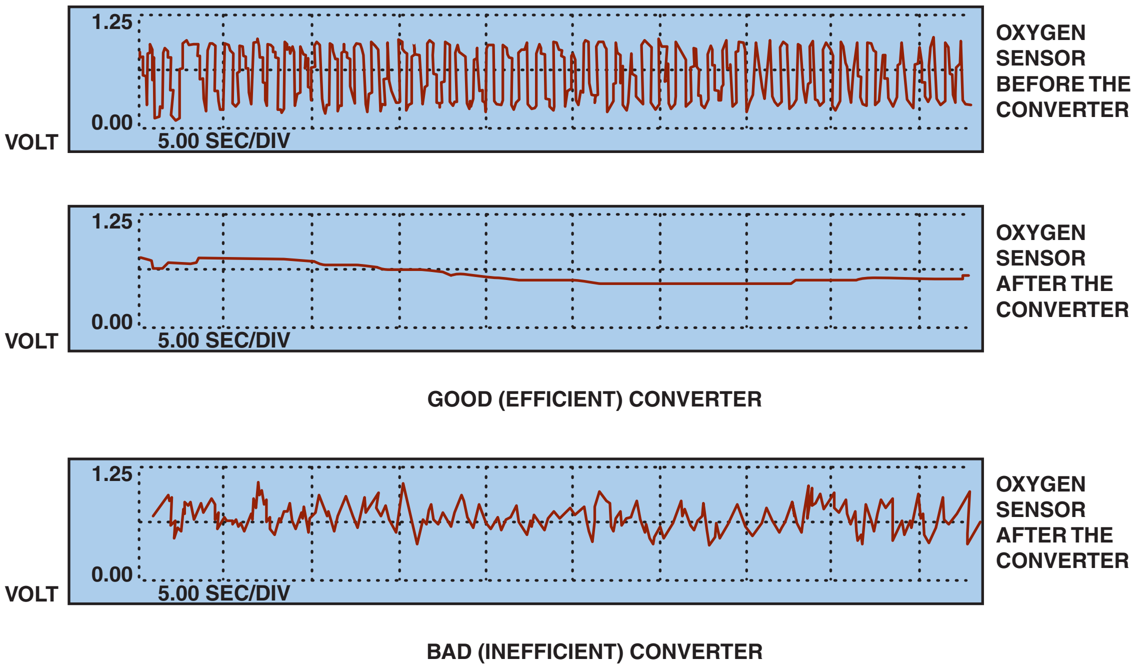

FIGURE 73–12 The post-catalytic converter oxygen sensor should display very little activity if the catalytic converter is efficient.

TECH TIP

The Propane Oxygen Sensor Test

Adding propane to the air inlet of a running engine is an excellent way to check if the oxygen sensor is able to react to changes in air–fuel mixture. Follow these steps in performing the propane trick:

1. Connect a digital storage oscilloscope to the oxygen sensor signal wire.
2. Start and operate the engine until it reaches operating temperature and is in closed-loop fuel control.
3. While watching the scope display, add some propane to the air inlet. The scope display should read full rich (over 800 mV).
4. Shut off the propane. The waveform should drop to less than 200 mV (0.2 V).
5. Quickly add some propane while the oxygen sensor is reading low and watch for a rapid transition to rich. The transition should occur in less than 100 milliseconds (ms).

FREQUENTLY ASKED QUESTION

How Could Using Silicone Sealer on a Valve Cover Gasket Affect the Oxygen Sensor?

The wrong type of silicone **room temperature vulcanization (RTV)** sealer on a valve cover gasket gives off harmful silica fumes during the curing process. These fumes enter the crankcase area by way of the oil drainback holes in the cylinder head, as well as through pushrod openings and other passages in the engine. During engine operation, these fumes are drawn into the intake manifold through the positive crankcase ventilation (PCV) system and are burned in the engine. The harmful silica then exits through the exhaust system, where the contamination affects the oxygen sensor.

NOTE: Be careful not to spray any silicone lubricant near the engine vacuum, which might draw the fumes into the engine and cause silica damage to the oxygen sensor.

to the engine. This process is often called the target upstream fuel trim. Therefore, instead of the PCM commanding a target air–fuel mixture of 14.7:1, the new target may specify an air–fuel ratio of 14.9:1 or slightly leaner than normal to help provide a little extra oxygen for use by the catalytic converter. This target air–fuel ratio or fuel trim is displayed on scan tools.

WIDE-BAND OXYGEN SENSORS

TERMINOLOGY **Wide-band oxygen sensors** have been used since 1992 on some Hondas. Today, they are used by most vehicle manufacturers to ensure that the exhaust emissions can meet the current standard. Wide-band oxygen sensors have various names, depending on the vehicle and/or oxygen sensor manufacturer, including the following:

- Wide-band oxygen sensor
- Broadband oxygen sensor
- Wide-range oxygen sensor
- Air–fuel ratio (AFR) sensor
- Wide-range air–fuel (WRAF) sensor
- Lean-air fuel (LAF) sensor
- Air–fuel (AF) sensor

Wide-band oxygen sensors are also manufactured in dual cell and single cell designs.

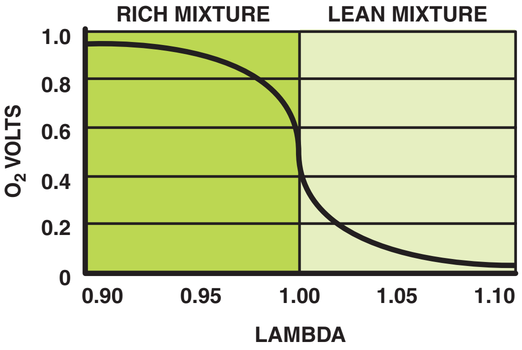

FIGURE 73–13 A conventional zirconia oxygen sensor can only reset to exhaust mixtures that are richer or leaner than 14.7:1 (lambda 1.00).

FIGURE 73–14 A planar design zirconia oxygen sensor places all of the elements together, which allows the sensor to reach operating temperature quickly.

INTRODUCTION A conventional zirconia oxygen sensor reacts to an air–fuel mixture that is either richer or leaner than 14.7:1. This means that the sensor cannot be used to detect the exact air–fuel mixture. ● **SEE FIGURE 73–13**.

The need for more stringent exhaust emission standards, such as the national low emission vehicle (NLEV), plus the ultra low emission vehicle (ULEV) and the super ultra low emission vehicle (SULEV) require more accurate fuel control than can be provided by a traditional oxygen sensor.

PURPOSE AND FUNCTION A wide-band oxygen sensor is capable of supplying air–fuel ratio information to the PCM over a much broader range. Compared with a conventional zirconia oxygen sensor, the wide-band oxygen sensor has the following features:

1. The ability to detect exhaust air–fuel ratio from as rich as 10:1 to as lean as 23:1 in some cases
2. Cold start activity within as little as 10 seconds

PLANAR DESIGN In 1998, Bosch introduced a wide-band oxygen sensor that is flat and thin (1.5 mm or 0.006 inch), known as a planar design and not in the shape of a thimble as previously constructed. Now several manufacturers produce a similar **planar** design wide-band oxygen sensor. Its thin design makes it easier to heat than older styles of oxygen sensors and, as a result, it can achieve closed loop in less than 10 seconds. This fast heating, called **light-off time (LOT)**, helps improve fuel economy and reduces cold-start exhaust emissions. The type of construction is not noticed by the technician, nor does it affect the testing procedures.

A conventional oxygen sensor can also be constructed using a planar design instead of the thimble-type design. A planar design has the following features:

- The elements including the zirconia electrolyte and the two electrodes and heater are stacked together in a flat-type design.
- It allows faster warm-up because the heater is in direct contact with the other elements.
- Planar oxygen sensors are the most commonly used. Some planar designs are used as a conventional narrow-band oxygen sensor.

The sandwich-type designs of the planar style of oxygen sensor have the same elements and operate the same, but are stacked in the following way from the exhaust side to the ambient air side:

Exhaust stream
Outer electrode
Zirconia (Zr_2) (electrolyte)
Inner electrode (reference or signal)
Outside (ambient) air
Heater

● **SEE FIGURE 73–14**.

Another name for a conventional oxygen sensor is a **Nernst cell**, named for Walther Nernst, 1864–1941, a German physicist known for his work in electrochemistry.

FREQUENTLY ASKED QUESTION

How Quickly Can a Wide-Band Oxygen Sensor Achieve Closed Loop?

In a Toyota Highlander hybrid electric vehicle, the operation of the gasoline engine is delayed for a short time when the vehicle is first driven. During this time of electric operation, the oxygen sensor heaters are turned on in readiness for the gasoline engine starting. The gasoline engine often achieves closed-loop operation during *cranking* because the oxygen sensors are fully warm and ready to go at the same time the engine is started. Having the gasoline engine achieve closed loop quickly, allows it to meet the stringent SULEV standards.

DUAL CELL PLANAR WIDE-BAND SENSOR OPERATION

CONSTRUCTION In a conventional zirconia oxygen sensor, a bias or reference voltage can be applied to the two platinum electrodes, and then oxygen ions can be forced (pumped) from the ambient reference air side to the exhaust side of the sensor.

If the polarity is reversed, the oxygen ion can be forced to travel in the opposite direction.

A **dual cell** planar-type wide-band oxygen sensor is made like a conventional planar O2S, or Nernst cell. Above the Nernst cell is another zirconia layer with two electrodes, called the **pump cell**. The two cells share a common ground, called the **reference**.

There are two internal chambers:

- The air reference chamber is exposed to ambient air.
- The diffusion chamber is exposed to the exhaust gases.

Platinum electrodes are on both sides of the zirconia electrolyte elements, which separate the air reference chamber and the exhaust exposed diffusion chamber.

OPERATION The basic principle of operation of a typical wide-band oxygen sensor is that it uses a positive or negative voltage signal to keep a balance between two sensors. Oxygen sensors do not measure the quantity of free oxygen in the exhaust. Instead, oxygen sensors produce a voltage that is based on the ion flow between the platinum electrodes of the sensor to maintain a stoichiometric balance.

For example,

- If there is a lean exhaust, there is oxygen in the exhaust and the ion flow from the ambient side to the exhaust side is low.
- If there is rich exhaust, the ion flow is increased to help maintain balance between the ambient air side and the exhaust side of the sensor.

The PCM can apply a small current to the pump cell electrodes, which causes oxygen ions through the zirconia into or out of the diffusion chamber. The PCM pumps O_2 ions in and out of the diffusion chamber to bring the voltage back to 0.45 V, using the pump cell.

The operation of a wide-band oxygen sensor is best described by looking at what occurs when the exhaust is stoichiometric, rich, and lean. ● **SEE FIGURE 73–15**.

STOICHIOMETRIC

- When the exhaust is at stoichiometric (14.7:1 air–fuel ratio), the voltage of the Nernst cell is 450 mV (0.45 V).
- The voltage between the diffusion chamber and the air reference chamber changes from 0.45 V. This voltage will be:
  - Higher if the exhaust is rich
  - Lower if the exhaust is lean

The reference voltage remains constant, usually at 2.5 V, but can vary depending on the year, make, and model of vehicle and the type of sensor. Typical reference voltages include the following:

- 2.2 V
- 2.5 V
- 2.7 V
- 3.3 V
- 3.6 V

RICH EXHAUST When the exhaust is rich, the voltage between the common (reference) electrode and the Nernst cell electrode that is exposed to ambient air is higher than 0.45 V. The PCM applies a negative current in milliamperes to the pump cell electrode to bring the circuit back into balance. ● **SEE FIGURE 73–16**.

LEAN EXHAUST When the exhaust is lean, the voltage between the common (reference) electrode and the Nernst cell electrode is lower than 0.45 V. The PCM applies a positive current in milliamperes to the pump cell to bring the circuit back into balance. ● **SEE FIGURE 73–17**.

DUAL CELL DIAGNOSIS

SCAN TOOL DIAGNOSIS Most service information specifies that a scan tool be used to check the wide-band oxygen sensor because the PCM performs tests of the unit and can identify faults. However, even wide-band oxygen sensors can be fooled if there is an exhaust manifold leak or other fault, which could lead to false or inaccurate readings. If the oxygen sensor reading is false, the PCM will command an incorrect

A comparison showing what a factory scan tool and a generic OBD-II scan tool might display at various air–fuel ratios.

amount of fuel. The scan data shown on a generic (global) OBD-II scan tool will often be different than the reading on the factory scan tool. ● **SEE CHART 73–2** for an example of a Toyota wide-band oxygen sensor being tested using a factory scan tool and a generic OBD-II scan tool.

SCAN TOOL DATA (PID) The following information will be displayed as a scan tool when looking at data for a wide-band oxygen sensor:

H02S1 = ______mA ÷	If the current is positive, this means that the PCM is pumping current in the diffusion gap due to a rich exhaust. If the current is negative, the PCM is pumping current out of the diffusion gap due to a lean exhaust.
Air–fuel ratio = ______	Usually expressed in lambda. One means that the exhaust is at stoichiometric (14.7:1 air–fuel ratio) and numbers higher than one indicate a lean exhaust and numbers lower than one indicate a rich exhaust.

DIGITAL METER TESTING When testing a wide-band oxygen sensor for proper operation, perform the following steps:

STEP 1 Check service information and determine the circuit and connector terminal identification.

STEP 2 Measure the calibration resistor. While the value of this resistor can vary widely depending on the type of sensor, the calibrating resistor should still be checked for opens and shorts.

NOTE: The calibration resistor is usually located within the connector itself.

- If open, the ohmmeter will read OL (infinity ohms).
- If shorted, the ohmmeter will read zero or close to zero.

STEP 3 Measure the heater circuit for proper resistance or current flow.

STEP 4 Measure the reference voltage relative to ground. This can vary but is generally 2.4 to 2.6 V.

STEP 5 Using jumper wires, connect an ammeter and measure the current in the pump cell control wire.

RICH EXHAUST When the exhaust is rich (lambda less than 1.00), the Nernst cell voltage will move higher than 0.45 V. The PCM will pump oxygen from the exhaust into the diffusion gap by applying a negative voltage to the pump cell.

LEAN EXHAUST When the exhaust is lean (lambda higher than 1.00), the Nernst cell voltage will move lower than 0.45 V. The PCM will pump oxygen out of the diffusion gap by applying a positive voltage to the pump cell.

Pump cell is used to pump oxygen into the diffusion gap when the exhaust is rich. The pump cell applies a negative voltage to do this.

- Positive current = lean exhaust
- Negative current = rich exhaust

● **SEE FIGURE 73–18.**

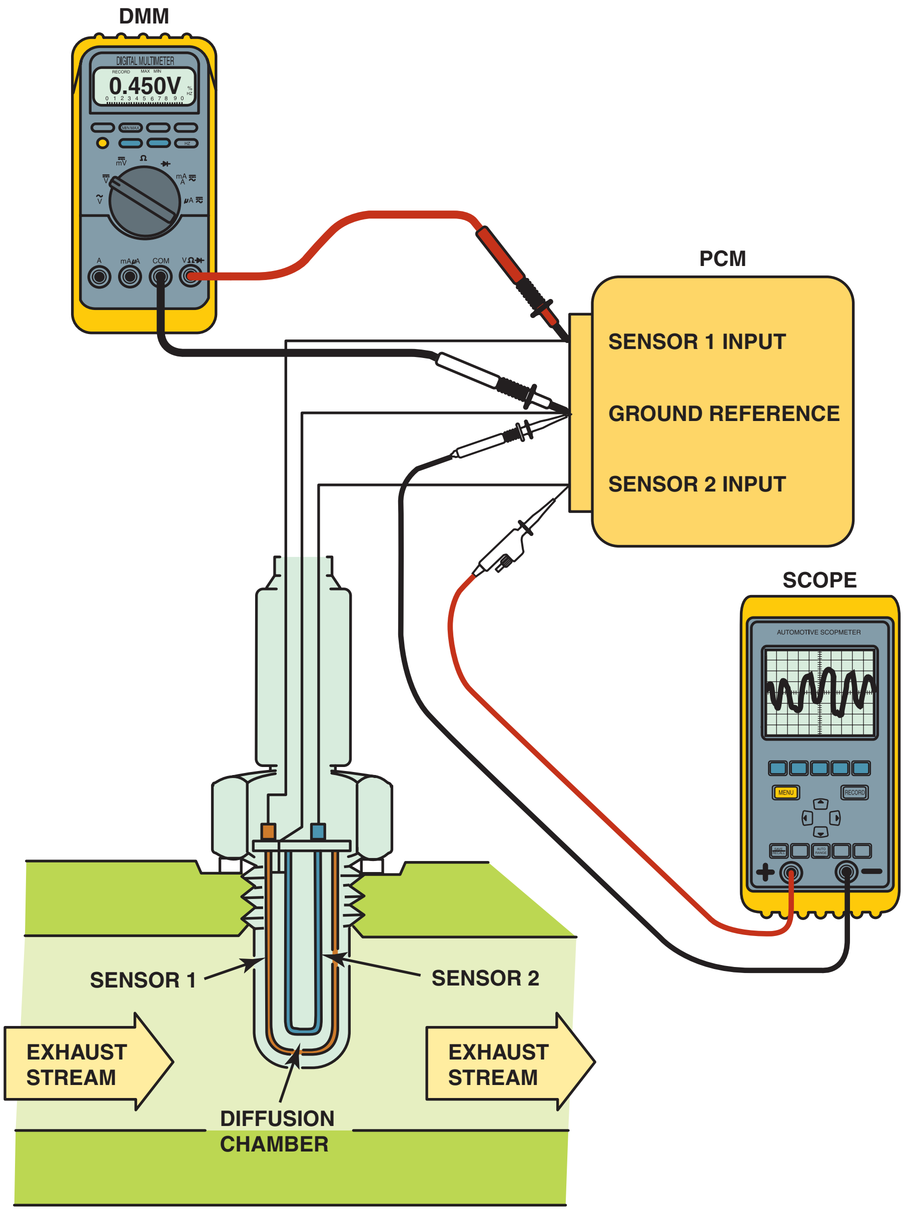

FIGURE 73–18 Testing a dual cell wide-band oxygen sensor can be done using a voltmeter or a scope. The meter reading is attached to the Nernst cell and should read stoichiometric (450 mV) at all times. The scope is showing activity to the pump cell with commands from the PCM to keep the Nernst cell at 14.7:1 air–fuel ratio.

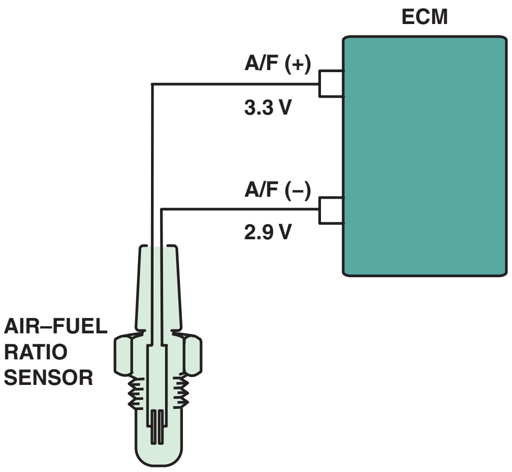

FIGURE 73–19 A single cell wide-band oxygen sensor has four wires with two for the heater and two for the sensor itself. The voltage applied to the sensor is 0.4 V (3.3 − 2.9 = 0.4) across the two leads of the sensor.

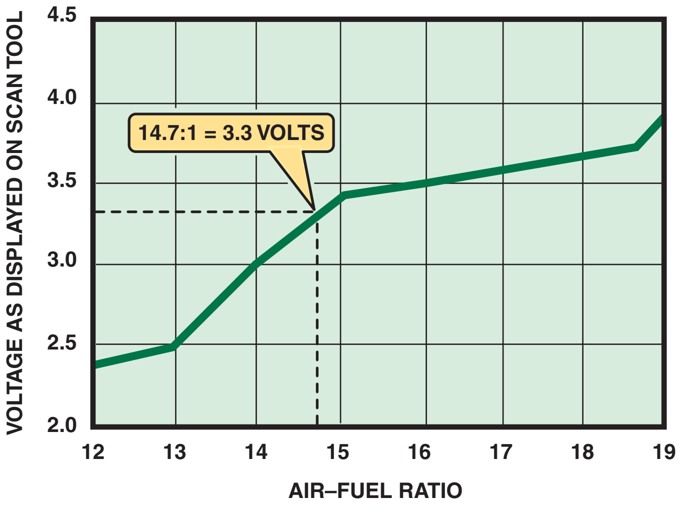

FIGURE 73–20 A scan tool can display various voltages but will often show 3.3 V because the PCM is controlling the sensor through applying a low current to the sensor to achieve balance.

SINGLE CELL WIDE-BAND OXYGEN SENSORS

CONSTRUCTION A typical **single cell** wide-band oxygen sensor looks similar to a conventional four-wire zirconia oxygen sensor. The typical single cell wide-band oxygen sensor, usually called an **air–fuel ratio sensor**, has the following construction features:

- It can be made using the cup or planar design.
- Oxygen (O_2) is pumped into the diffusion layer similar to the operation of a dual cell wide-band oxygen sensor. ● **SEE FIGURE 73–19**.
- Current flow reverses positive and negative.
- There are two cell wires and two heater wires (power and ground).
- The heater usually requires 6 amperes and the ground side is pulse-width modulated.

MILLIAMMETER TESTING The PCM controls the single cell wide-band oxygen sensor by maintaining a voltage difference of 300 mV (0.3 V) between the two sensor leads. The PCM keeps the voltage difference constant under all operating conditions by increasing or decreasing current between the element of the cell:

- Zero (0 mA) represents lambda or stoichiometric air–fuel ratio of 14.7:1
- +10 mA indicates a lean condition
- −10 mA indicates a rich condition

SCAN TOOL TESTING A scan tool will display a voltage reading but can vary depending on the type and maker of scan tool. ● **SEE FIGURE 73–20**.

OXYGEN SENSOR–RELATED DIAGNOSTIC TROUBLE CODES

Diagnostic trouble codes (DTCs) associated with the oxygen sensor include the following:

Diagnostic Trouble Codes	Description	Possible Causes
P0131	Upstream HO2S grounded	■ Exhaust leak upstream of HO2S (bank 1) ■ Extremely lean air–fuel mixture ■ HO2S defective or contaminated ■ HO2S signal wire shorted-to-ground
P0132	Upstream HO2S shorted	■ Upstream HO2S (bank 1) shorted ■ Defective HO2S ■ Fuel-contaminated HO2S
P0133	Upstream HO2S slow response	■ Open or short in heater circuit ■ Defective or fuel-contaminated HO2S ■ EGR or fuel system fault

REVIEW QUESTIONS

1. How does an oxygen sensor detect oxygen levels in the exhaust?
2. What is the difference between open-loop and closed-loop engine operation?
3. What are three ways oxygen sensors can be tested?
4. How can the oxygen sensor be fooled and provide the wrong information to the PCM?
5. What is the purpose of a wide-band oxygen sensor?

CHAPTER QUIZ

1. The voltage output of a zirconia oxygen sensor when the exhaust stream is lean (excess oxygen) is __________.
   a. relatively high (close to 1 volt)
   b. about in the middle of the voltage range
   c. relatively low (close to 0 volt)
   d. Either a or b, depending on atmospheric pressure
2. What does the PCM do with the input from the oxygen sensor(s)?
   a. Shifts the automatic transmission
   b. Controls fuel injector pulse width
   c. Helps determine the condition of the catalytic converter
   d. Both b and c
3. The post-catalytic converter oxygen sensor voltage is not going above 800 mV but instead is staying at a low voltage level. What is the most likely cause?
   a. Normal catalytic converter operation
   b. The catalytic converter is not working
   c. The catalytic converter is clogged
   d. The PCM has failed
4. A wide-band oxygen sensor can detect which of the following?
   a. The ability to detect exhaust air–fuel ratio from as rich as 10:1 to as lean as 23:1 in some cases
   b. Cold start activity within as little as 10 seconds
   c. Helps meet the national low emission vehicle (NLEV), ultra-low emission vehicle (ULEV) and the super ultra-low emission vehicle (SULEV)
   d. All of the above
5. A dual cell wide-band oxygen sensor uses __________.
   a. two internal chambers
   b. an air reference chamber
   c. a diffusion chamber
   d. All of the above
6. What is used to test a dual cell wide-band oxygen sensor?
   a. Scan tool
   b. Digital meter
   c. Either a or b
   d. Neither a nor b
7. A single cell wide-band oxygen sensor uses how many wires?
   a. One
   b. Two
   c. Three
   d. Four
8. A wide-band oxygen sensor is capable of detecting the air–fuel mixture in the exhaust from __________ (rich) to __________ (lean).
   a. 12:1; 15:1
   b. 13:1; 16.7:1
   c. 10:1; 23:1
   d. 8:1; 18:1
9. A wide-band oxygen sensor needs to be heated to what operating temperature?
   a. 600°F (315°C)
   b. 800°F (427°C)
   c. 1,400°F (760°C)
   d. 2,000°F (1,093°C)
10. A P0133 DTC is being discussed. Technician A says that a defective heater circuit could be the cause. Technician B says that a contaminated sensor could be the cause. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

FUEL PUMPS, LINES, AND FILTERS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss the fuel delivery system, including fuel tanks and rollover leak protection.
- Discuss the different types of fuel lines.
- Explain the different types of electric fuel pumps.
- Describe fuel filters.
- Describe how to test fuel pumps.
- Describe how to replace fuel pumps.

KEY TERMS:

Accumulator 887 • Baffle 880 • Gerotor 885 • Hydrokinetic pump 885 • Inertia switch 882 • Onboard refueling vapor recovery (ORVR) 881 • Peripheral pump 885 • Residual or rest pressure 885 • Roller cell 885 • Rotary vane pump 885 • Side-channel pump 885 • Turbine pump 885 • Vapor lock 883 • Volatile organic compound (VOC) 884

FUEL DELIVERY SYSTEM

Creating and maintaining a correct air–fuel mixture requires a properly functioning fuel and air delivery system. Fuel delivery (and return) systems use many, if not all, of the following components to make certain that fuel is available under the right conditions to the fuel-injection system:

- Fuel storage tank, filler neck, and gas cap
- Fuel tank pressure sensor
- Fuel pump
- Fuel filter(s)
- Fuel delivery lines and fuel rail
- Fuel-pressure regulator
- Fuel return line (if equipped with a return-type fuel delivery system)

FUEL TANKS A vehicle fuel tank is made of corrosion-resistant steel or polyethylene plastic. Some models, such as sport utility vehicles (SUVs) and light trucks, may have an auxiliary fuel tank.

Tank design and capacity are a compromise between available space, filler location, fuel expansion room, and fuel movement. Some later-model tanks deliberately limit tank capacity by extending the filler tube neck into the tank low enough to prevent complete filling, or by providing for expansion room. ● **SEE FIGURE 74–1**. A vertical **baffle** in this same tank limits fuel sloshing as the vehicle moves.

Regardless of size and shape, all fuel tanks incorporate most if not all of the following features:

- Inlet or filler tube through which fuel enters the tank
- Filler cap with pressure holding and relief features
- An outlet to the fuel line leading to the fuel pump or fuel injector
- Fuel pump mounted within the tank
- Tank vent system
- Fuel pickup tube and fuel level sending unit

TANK LOCATION AND MOUNTING Most vehicles use a horizontally suspended fuel tank, usually mounted below the rear of the floor pan, just ahead of or behind the rear axle. Fuel tanks are located there so that frame rails and body components protect the tank in the event of a crash. To prevent squeaks, some models have insulated strips cemented on the top or sides of the tank wherever it contacts the underbody.

FUEL TANK PRESSURE SENSOR

FIGURE 74–1 The fuel system includes many separate parts and components, including the fuel tank, fuel pump and lines, as well as the fuel tank pressure sensor used to measure the pressure inside the fuel tanks used by the evaporative fuel control system.

Fuel inlet location depends on the tank design and filler tube placement. It is located behind a filler cap and is often a hinged door in the outer side of either rear fender panel.

Generally, a pair of metal retaining straps holds a fuel tank in place. Underbody brackets or support panels hold the strap ends using bolts. The free ends are drawn underneath the tank to hold it in place and then bolted to other support brackets or to a frame member on the opposite side of the tank.

FILLER TUBES Fuel enters the tank through a large tube extending from the tank to an opening on the outside of the vehicle. ● **SEE FIGURE 74–2**.

Effective in 1993, federal regulations require manufacturers to install a device to prevent fuel from being siphoned through the filler neck. Federal authorities recognized methanol as a poison, and methanol used in gasoline is a definite health hazard. Additionally, gasoline is a suspected carcinogen (cancer-causing agent). To prevent siphoning, manufacturers welded a filler-neck check-ball tube in fuel tanks. To drain check ball-equipped fuel tanks, a technician must disconnect the check-ball tube at the tank and attach a siphon directly to the tank. ● **SEE FIGURE 74–3**.

Onboard refueling vapor recovery (ORVR) systems have been developed to reduce evaporative emissions during refueling. ● **SEE FIGURE 74–4**. These systems add components to the filler neck and the tank. One ORVR system utilizes a tapered filler neck with a smaller diameter tube and a check valve. When fuel flows down the neck, it opens the normally closed check valve. The vapor passage to the charcoal canister

CHECK BALL
GROUND WIRE

FIGURE 74–3 A view of a typical filler tube with the fuel tank removed. Notice the ground strap used to help prevent the buildup of static electricity as the fuel flows into the plastic tank. The check ball looks like a ping-pong ball.

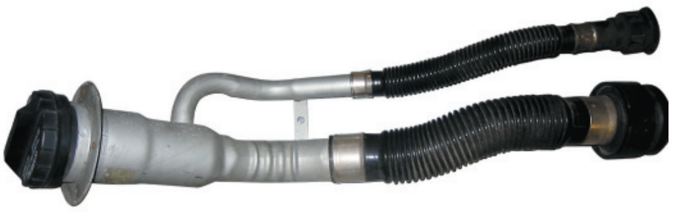

FIGURE 74–4 Vehicles equipped with onboard refueling vapor recovery usually have a reduced-size fill tube.

is opened. The decreased size neck and the opened air passage allow fuel and vapor to flow rapidly into the tank and the canister, respectively. When the fuel has reached a predetermined level, the check valve closes, and the fuel tank pressure increases. This forces the nozzle to shut off, thereby preventing the tank from being overfilled.

PRESSURE-VACUUM FILLER CAP Fuel and vapors are sealed in the tank by the safety filler cap. The safety cap must release excess pressure or excess vacuum. Either condition could cause fuel tank damage, fuel spills, and vapor escape. Typically, the cap will release if the pressure is over 1.5 to 2.0 PSI (10 to 14 kPa) or if the vacuum is 0.15 to 0.30 PSI (1 to 2 kPa).

FUEL PICKUP TUBE The fuel pickup tube is usually a part of the fuel sender assembly or the electric fuel pump assembly. Since dirt and sediment eventually gather on the bottom of a fuel tank, the fuel pickup tube is fitted with a filter sock or strainer to prevent contamination from entering the fuel lines. The woven plastic strainer also acts as a water separator by preventing water from being drawn up with the fuel. The filter sock usually is designed to filter out particles that are larger than 70 to 100 microns, or 30 microns if a gerotor-type fuel pump is used. One micron is 0.000039 inch. ● **SEE FIGURE 74–5**.

NOTE: The human eye cannot see anything smaller than about 40 microns.

The filter is made from woven Saran resin (copolymer of vinylidene chloride and vinyl chloride). The filter blocks any water that may be in the fuel tank, unless it is completely submerged in water. In that case, it will allow water through the filter. This filter should be replaced whenever the fuel pump is replaced.

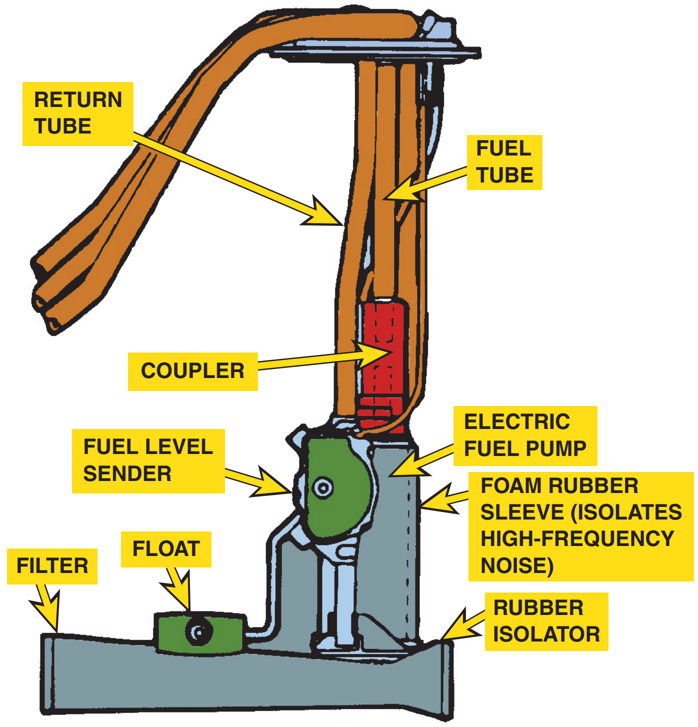

FIGURE 74–5 The fuel pickup tube is part of the fuel sender and pump assembly.

TANK VENTING REQUIREMENTS Fuel tanks must be vented to prevent a vacuum lock as fuel is drawn from the tank. As fuel is used and its level drops in the tank, the space above the fuel increases. As the air in the tank expands to fill this greater space, its pressure drops. Without a vent, the air pressure inside the tank would drop below atmospheric pressure, developing a vacuum, which prevents the flow of fuel. Under extreme pressure variance, the tank could collapse. Venting the tank allows outside air to enter as the fuel level drops, preventing a vacuum from developing.

An EVAP system vents gasoline vapors from the fuel tank directly to a charcoal-filled vapor storage canister, and uses an unvented filler cap. Many filler caps contain valves that open to relieve pressure or vacuum above specified safety levels. Systems that use completely sealed caps have separate pressure and vacuum relief valves for venting.

Because fuel tanks are not vented directly to the atmosphere, the tank must allow for fuel expansion, contraction, and overflow that can result from changes in temperature or overfilling. One way is to use a dome in the top of the tank. Many General Motors vehicles use a design that includes a vertical slosh baffle which reserves up to 12% of the total tank capacity for fuel expansion.

ROLLOVER LEAKAGE PROTECTION All vehicles have one or more devices to prevent fuel leaks in case of vehicle rollover or a collision in which fuel may spill.

Variations of the basic one-way check valve may be installed in any number of places between the fuel tank and the engine. The valve may be installed in the fuel return line, vapor vent line, or fuel tank filler cap.

In addition to the rollover protection devices, some vehicles use devices to ensure that the fuel pump shuts off when an accident occurs. Some pumps depend upon an oil pressure or an engine speed signal to continue operating; these pumps turn off whenever the engine dies.

Ford vehicles use an **inertia switch**. ● **SEE FIGURE 74–6**. The inertia switch is installed in the rear of the vehicle between the electric fuel pump and its power supply. With any sudden impact, such as a jolt from another vehicle in a parking lot, the inertia switch opens and shuts off power to the fuel pump. The switch must be reset manually by pushing a button to restore current to the pump.

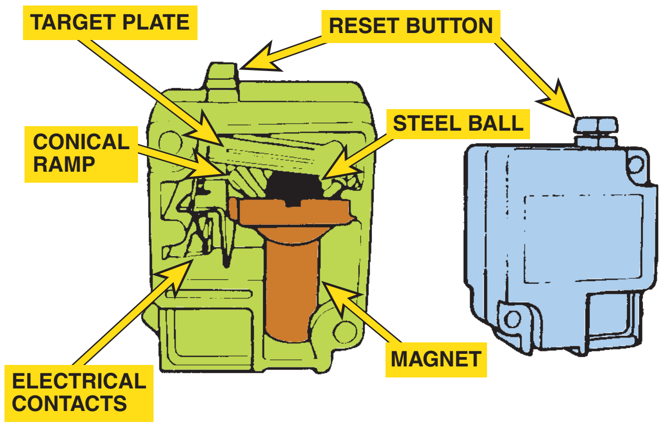

FIGURE 74–6 Ford uses an inertia switch to turn off the electric fuel pump in case of an accident.

FUEL LINES

PURPOSE AND FUNCTION Fuel and vapor lines made of steel, nylon tubing, or fuel-resistant rubber hoses connect the parts of the fuel system. Fuel lines supply fuel to the throttle body or fuel rail. They also return excess fuel and vapors to the tank. Depending on their function, fuel and vapor lines may be either rigid or flexible.

Fuel lines must remain as cool as possible. If any part of the line is located near too much heat, the gasoline passing through it vaporizes and **vapor lock** occurs. When this happens, the fuel pump supplies only vapor that passes into the injectors. Without liquid gasoline, the engine stalls and a hot restart problem develops.

The fuel delivery system supplies 10 to 15 PSI (69 to 103 kPa) or up to 35 PSI (241 kPa) to many throttle-body injection units and up to 50 PSI (345 kPa) for multiport fuel-injection systems. Fuel-injection systems retain residual or rest pressure in the lines for a half hour or longer when the engine is turned off to prevent hot engine restart problems. Higher-pressure systems such as these require special fuel lines.

RIGID LINES All fuel lines fastened to the body, frame, or engine are made of seamless steel tubing. Steel springs may be wound around the tubing at certain points to protect against impact damage.

Only steel tubing, or that recommended by the manufacturer, should be used when replacing rigid fuel lines. *Never substitute copper or aluminum tubing for steel tubing*. These materials do not withstand normal vehicle vibration and could combine with the fuel to cause a chemical reaction.

FLEXIBLE LINES Most fuel systems use synthetic rubber hose sections where flexibility is needed. Short hose sections often connect steel fuel lines to other system components. The fuel delivery hose inside diameter (ID) is generally larger (3/16 to 3/8 in. or 8 to 10 mm) than the fuel return hose ID (1/4 in. or 6 mm).

Fuel-injection systems require special-composition reinforced hoses specifically made for these higher-pressure systems. Similarly, vapor vent lines must be made of materials that resist fuel vapors. Replacement vent hoses are usually marked with the designation "EVAP" to indicate their intended use.

FUEL LINE MOUNTING Fuel supply lines from the tank to a throttle body or fuel rail are routed to follow the frame along the underbody of the vehicle. Vapor and return lines may be routed with the fuel supply line. All rigid lines are fastened to the frame rail or underbody with screws and clamps, or clips. ● **SEE FIGURE 74–7**.

FUEL-INJECTION LINES Hoses used for fuel-injection systems are made of materials with high resistance to oxidation and deterioration. Replacement hoses for injection systems should always be equivalent to original equipment manufacturer (OEM) hoses.

CAUTION: Do not use spring-type clamps on fuel-injected engines—they cannot withstand the fuel pressures involved.

FUEL-INJECTION FITTINGS AND NYLON LINES Because of their operating pressures, fuel-injection systems often use special kinds of fittings to ensure leakproof connections. Some high-pressure fittings on GM vehicles with port fuel-injection systems use O-ring seals instead of the traditional flare connections. When disconnecting such a fitting, inspect the O-ring for damage and replace it if necessary. *Always* tighten O-ring fittings to the specified torque value to prevent damage.

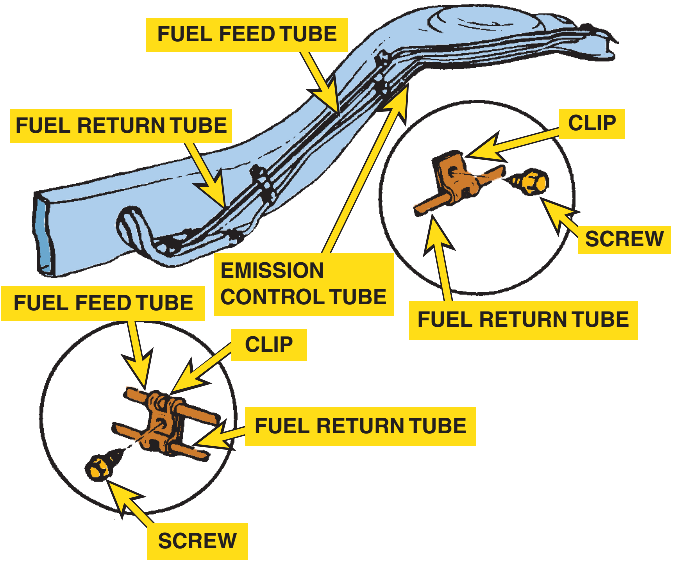

FIGURE 74–7 Fuel lines are routed along the frame or body and secured with clips.

Other manufacturers also use O-ring seals on fuel line connections. In all cases, the O-rings are made of special materials that withstand contact with gasoline and oxygenated fuel blends. Some manufacturers specify that the O-rings be replaced every time the fuel system connection is opened. When replacing one of these O-rings, a new part specifically designed for fuel system service must be used.

Ford also uses spring-lock connectors to join male and female ends of steel tubing. ● **SEE FIGURE 74–8**. The coupling is held together by a garter spring inside a circular cage. The flared end of the female fitting slips behind the spring to lock the coupling together.

General Motors has used nylon fuel lines with quick-connect fittings at the fuel tank and fuel filter since the early 1990s. Like the GM threaded couplings used with steel lines, nylon line couplings use internal O-ring seals. Unlocking the metal connectors

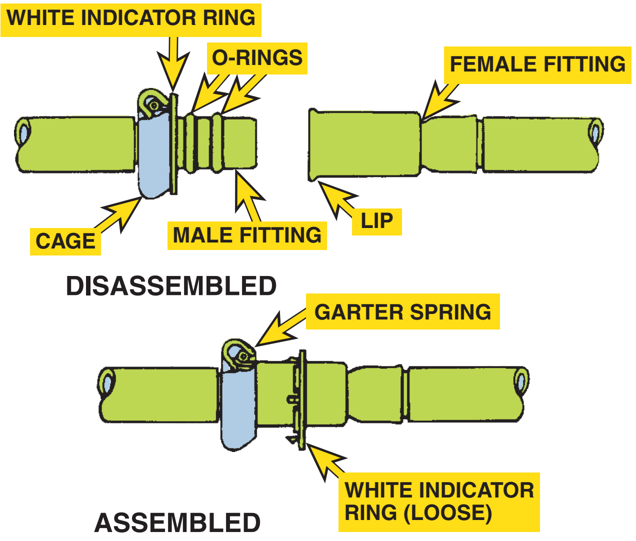

FIGURE 74–8 Some Ford metal line connections use springlocks and O-rings.

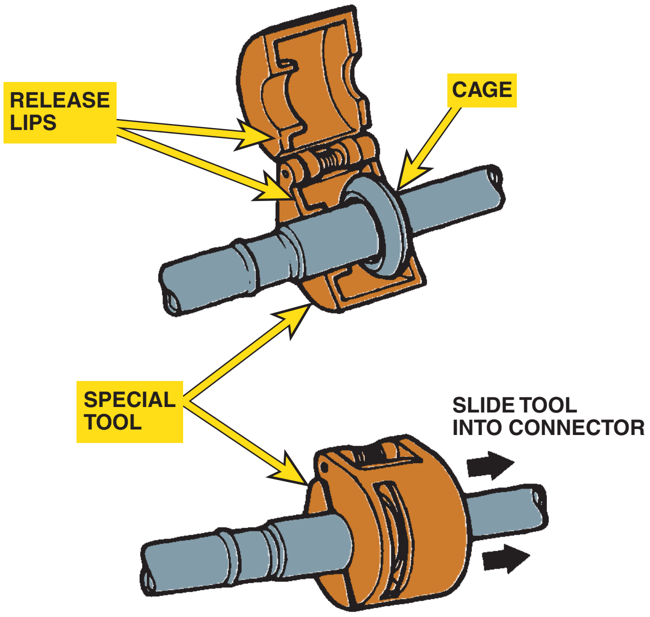

FIGURE 74–9 Ford spring-lock connectors require a special tool for disassembly.

requires a special quick-connector separator tool; plastic connectors can be released without the tool. ● **SEE FIGURES 74–9 AND 74–10.**

FREQUENTLY ASKED QUESTION

Just How Much Fuel Is Recirculated?

Approximately 80% of the available fuel-pump volume is released to the fuel tank through the fuel-pressure regulator at idle speed. For example, a passenger vehicle cruising down the road at 60 mph gets 30 mpg. With a typical return-style fuel system pumping about 30 gallons per hour from the tank, it would therefore burn 2 gallons per hour, and return about 28 gallons per hour to the tank!

FREQUENTLY ASKED QUESTION

How Can an Electric Pump Work Inside a Gas Tank and Not Cause a Fire?

Even though fuel fills the entire pump, no burnable mixture exists inside the pump because there is no air and no danger of commutator brush arcing, igniting the fuel.

FUEL LINE LAYOUT Fuel pressures have tended to become higher to prevent vapor lock, and a major portion of the fuel routed to the fuel-injection system returns to the tank by way of a fuel return line or return-type systems. This allows better control, within limits, of heat absorbed by the gasoline as it is routed through the engine compartment. Throttle-body and multiport injection systems have typically used a pressure regulator to control fuel pressure in the throttle body or fuel rail, and also allow excess fuel not used by the injectors to return to the tank. However, the warmer fuel in the tank may create problems, such as an excessive rise in fuel vapor pressures in the tank.

With late-model vehicles, there has been some concern about too much heat being sent back to the fuel tank, causing rising in-tank temperatures and increases in fuel vaporization and **volatile organic compound (VOC)** (hydrocarbon) emissions. To combat this problem, manufacturers have placed the pressure regulator back by the tank instead of under the hood on mechanical returnless systems. In this way, returned fuel is not subjected to the heat generated by the engine and the underhood environment. To prevent vapor lock in these systems, pressures have

been raised in the fuel rail, and injectors tend to have smaller openings to maintain control of the fuel spray under pressure.

Not only must the fuel be filtered and supplied under adequate pressure, but there must also be a consistent *volume* of fuel to assure smooth engine performance even under the heaviest of loads.

ELECTRIC FUEL PUMPS

LOCATION The electric fuel pump is a pusher unit. When the pump is mounted in the tank, the entire fuel supply line to the engine can be pressurized. Because the fuel, when pressurized, has a higher boiling point, it is unlikely that vapor will form to interfere with fuel flow.

Most vehicles use the impeller or turbine pumps. ● **SEE FIGURE 74–11**. All electrical pumps are driven by a small electric motor, but the turbine pump turns at higher speeds and is quieter than the others.

POSITIVE DISPLACEMENT PUMP A positive displacement pump is a design that forces everything that enters the pump to leave the pump.

In the **roller cell** or vane pump, the impeller draws fuel into the pump, and then pushes it out through the fuel line to the injection system. All designs of pumps use a variable-sized chamber to draw in fuel. When the maximum volume has been reached, the supply port closes and the discharge opens. Fuel is forced out the discharge as this volume decreases. The chambers are formed by rollers or gears in a rotor plate. Since this type of pump uses no valves to move the fuel, the fuel flows steadily through the pump housing. Since fuel flows steadily through the entire pump, including the electrical portion, the pump stays cool. Usually, only when a vehicle runs out of fuel is there a risk of pump damage.

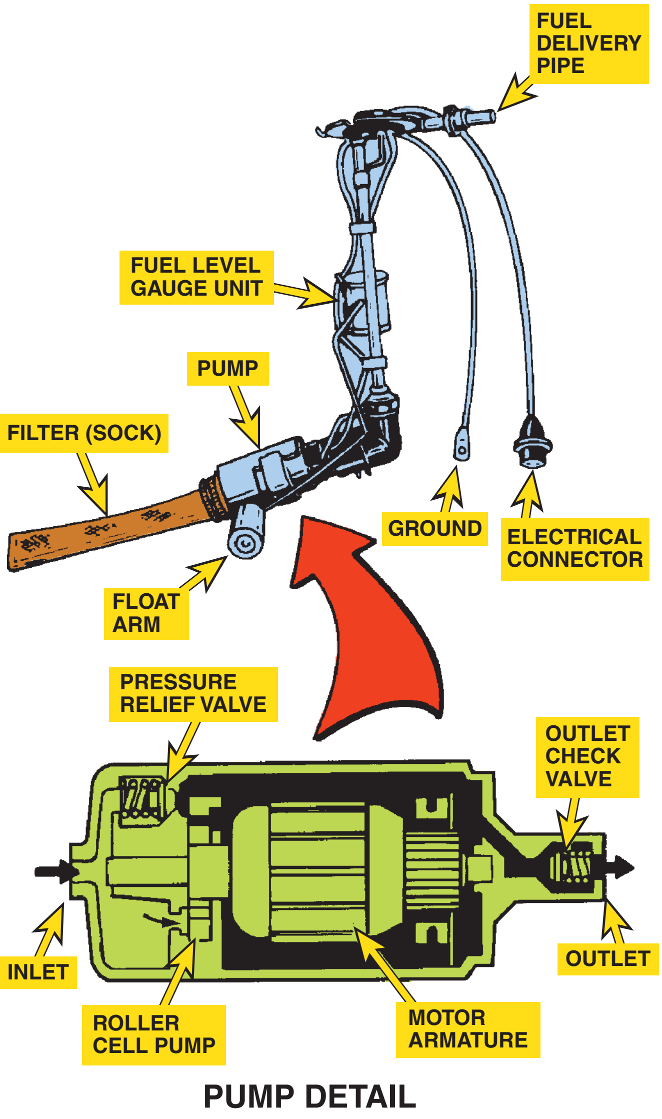

FIGURE 74–11 A roller cell-type electric fuel pump.

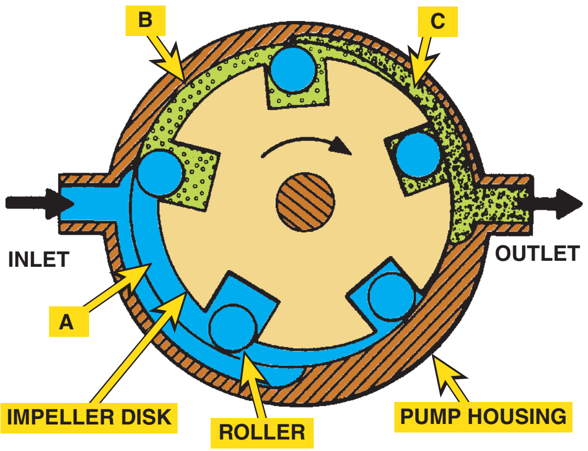

FIGURE 74–12 The pumping action of an impeller or rotary vane pump.

Most electric fuel pumps are equipped with a fuel outlet check valve that closes to maintain fuel pressure when the pump shuts off. **Residual or rest pressure** prevents vapor lock and hot-start problems on these systems.

● **FIGURE 74–12** shows the pumping action of a **rotary vane pump**. The pump consists of a central impeller disk, several rollers or vanes that ride in notches in the impeller, and a pump housing that is offset from the impeller centerline. The impeller is mounted on the end of the motor armature and spins whenever the motor is running. The rollers are free to slide in and out within the notches in the impeller to maintain sealing contact. Unpressurized fuel enters the pump, fills the spaces between the rollers, and is trapped between the impeller, the housing, and two rollers. An internal gear pump, called a **gerotor**, is another type of positive displacement pump that is often used in engine oil pumps. It uses the meshing of internal and external gear teeth to pressurize the fuel. ● **SEE FIGURE 74–13** for an example of a gerotor-type fuel pump that uses an impeller as the first stage and is used to move the fuel gerotor section where it is pressurized.

HYDROKINETIC FLOW PUMP DESIGN The word *hydro* means liquid and the term *kinetic* refers to motion, so the term **hydrokinetic pump** means that this design of pump rapidly moves the fuel to create pressure. This design of pump is a nonpositive displacement pump design.

A **turbine pump** is the most common because it tends to be less noisy. Sometimes called turbine, **peripheral**, and **side-channel**, these units use an impeller that accelerates the fuel particles before actually discharging them into a tract where they generate pressure via pulse exchange. Actual pump volume is controlled by using a different number of impeller blades, and in some cases a higher number of impellers, or different shapes along the side discharge channels. These units are fitted more toward lower operating pressures of less than 60 PSI. ● **SEE FIGURE 74–14** for an example of a two-stage turbine pump.

FUEL OUT

FIGURE 74–14 A cutaway view of a typical two-stage turbine electric fuel pump.

The turbine impeller has a staggered blade design to minimize pump harmonic noise and to separate vapor from the liquid fuel. The end cap assembly contains a pressure relief valve and a radio-frequency interference (RFI) suppression module. The check valve is usually located in the upper fuel pipe connector assembly.

After it passes through the strainer, fuel is drawn into the lower housing inlet port by the impellers. It is pressurized and delivered to the convoluted fuel tube for transfer through a check valve into the fuel feed pipe. A typical electric fuel pump used on a fuel-injection system delivers about 40 to 50 gallons per hour or 0.6 to 0.8 gallons per minute at a pressure of 70 to 90 PSI.

MODULAR FUEL SENDER ASSEMBLY The modular fuel sender consists of a fuel level sensor, a turbine pump, and a jet pump. The reservoir housing is attached to the cover containing fuel pipes and the electrical connector. Fuel is transferred from the pump to the fuel pipe through a convoluted (flexible) fuel pipe. The convoluted fuel pipe eliminates the need for rubber hoses, nylon pipes, and clamps. The reservoir dampens fuel slosh to maintain a constant fuel level available to the roller vane pump; it also reduces noise.

Some of the flow, however, is returned to the jet pump for recirculation. Excess fuel is returned to the reservoir through one of the three hollow support pipes. The hot fuel quickly mixes with the cooler fuel in the reservoir; this minimizes the possibility of vapor lock. In these modules, the reservoir is filled by the jet pump. Some of the fuel from the pump is sent through the jet pump to lift fuel from the tank into the reservoir.

ELECTRIC PUMP CONTROL CIRCUITS Fuel-pump circuits are controlled by the fuel-pump relay. Fuel-pump relays are activated initially by turning the ignition key to on, which allows the pump to pressurize the fuel system. As a safety precaution, the relay de-energizes after a few seconds unless the key is moved to the crank position. On some systems, once an ignition coil signal, or “tach” signal, is received by the engine control computer, indicating the engine is rotating, the relay remains energized even with the key released to the run position.

CHRYSLER On older Chrysler vehicles, the PCM must receive an engine speed (RPM) signal during cranking before it can energize a circuit driver inside the power module to activate an automatic shutdown (ASD) relay to power the fuel pump, ignition coil, and injectors. As a safety precaution, if the RPM signal to the logic module is interrupted, the logic module signals the power module to deactivate the ASD, turning off the pump, coil, and injectors. In some vehicles, the oil pressure switch circuit may be used as a safety circuit to activate the pump in the ignition switch run position.

FREQUENTLY ASKED QUESTION

Why Are Many Fuel-Pump Modules Spring-Loaded?

Fuel modules that contain the fuel pickup sock, fuel pump, and fuel level sensor are often spring-loaded when fitted to a plastic fuel tank. The plastic material shrinks when cold and expands when hot, so having the fuel module spring-loaded ensures that the fuel pickup sock will always be the same distance from the bottom of the tank. ● **SEE FIGURE 74–15**.

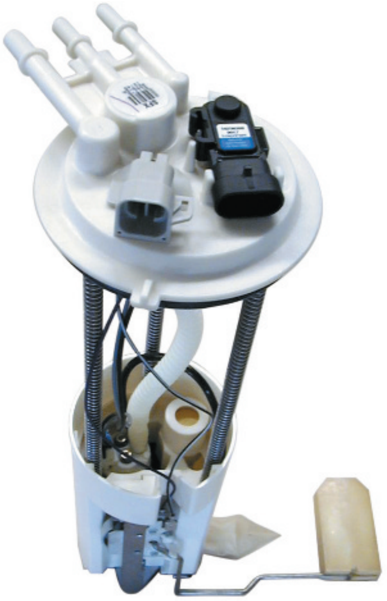

FIGURE 74–15 A typical fuel-pump module assembly, which includes the pickup strainer and fuel pump, as well as the fuel pressure sensor and fuel level sensing unit.

GENERAL MOTORS General Motors systems energize the pump with the ignition switch to initially pressurize the fuel lines, but then deactivate the pump if an RPM signal is not received within one or two seconds. The pump is reactivated as soon as engine cranking is detected. The oil pressure sending unit serves as a backup to the fuel-pump relay on some vehicles. In case of pump relay failure, the oil pressure switch will operate the fuel pump once oil pressure reaches about 4 PSI (28 kPa).

FORD Older fuel-injected Fords used an inertia switch between the fuel pump relay and fuel pump.

The inertia switch opens under a specified impact, such as a collision. When the switch opens, current to the pump shuts off because the fuel-pump relay will not energize. The switch must be reset manually by opening the trunk and depressing the reset button before current flow to the pump can be restored. ● **SEE FIGURE 74–16** for a schematic of a typical fuel system that uses an inertia switch in the power feed circuit to the electric fuel pump.

Since about 2008, the inertial switch has been replaced with a signal input from the airbag module. If the airbag is deployed, the circuit to the fuel pump is opened and the fuel pump stops.

PUMP PULSATION DAMPENING Some manufacturers use an **accumulator** in the system to reduce pressure pulses and noise. Others use a pulsator located at the outlet of the fuel pump to absorb pressure pulsations that are created by the pump. These pulsators are usually used on roller vane pumps and are a source of many internal fuel leaks. ● **SEE FIGURE 74–17**.

FUEL PUMP
DIAPHRAGM
FUEL INLET STRAINER/FILTER
FUEL FROM OUTLET OF PUMP

FIGURE 74–17 A typical fuel pulsator used mostly with roller vane-type pumps to help even out the pulsation in pressure that can cause noise.

NOTE: Some experts suggest that the pulsator be removed and replaced with a standard section of fuel line to prevent the loss of fuel pressure that results when the connections on the pulsator loosen and leak fuel back into the tank.

VARIABLE SPEED PUMPS Another way to help reduce noise, current draw, and pump wear is to reduce the speed of the pump when less than maximum output is required. Pump speed and pressure can be regulated by controlling the voltage supplied to the pump with a resistor switched into the circuit, or by using a separate fuel pump driver module to supply a pulse-width modulated (PWM) voltage to the pump. With slower pump speed and pressure, less noise is produced.

FUEL FILTERS

PURPOSE AND FUNCTIONS Despite the care generally taken in refining, storing, and delivering gasoline, some impurities get into the automotive fuel system. Fuel filters remove dirt, rust, water, and other contamination from the gasoline before it can reach the fuel injectors. Most fuel filters are designed to filter particles that are 10 to 20 microns or larger in size.

The useful life of many filters is limited, but vehicles that use a returnless-type fuel-injection system usually use filters that are part of the fuel pump assembly and do not have any specified interval. This means they should last the life of the vehicle. If fuel filters are not replaced according to the manufacturer's recommendations, they can become clogged and restrict fuel flow.

In addition to using several different types of fuel filters, a single fuel system may contain two or more filters. The inline filter is located in the line between the fuel pump and the throttle body or fuel rail. ● **SEE FIGURE 74–18**. This filter protects the system from contamination, but does not protect the fuel pump. The

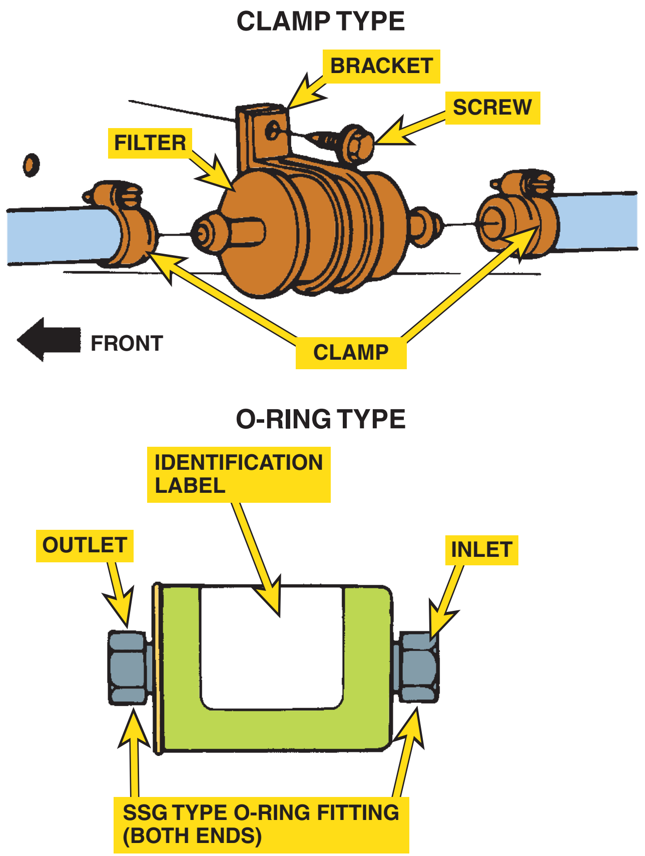

FIGURE 74–18 Inline fuel filters are usually attached to the fuel line with screw clamps or threaded connections. The fuel filter must be installed in the proper direction or a restricted fuel flow can result.

TECH TIP

Use a Headlight to Test for Power and Ground

When replacing a fuel pump, always check for proper power and ground. If the supply voltage is low due to resistance in the circuit or the ground connection is poor, the lower available voltage to the pump will result in lower pump output and could also reduce the life of the pump. While a voltage drop test can be preformed, a quick and easy test is to use a headlight connected to the circuit. If the headlight is bright, then both the power side and the ground side of the pump circuit are normal. If the headlight is dim, then more testing will be needed to find the source of the resistance in the circuit(s). ● **SEE FIGURE 74–19**.

TECH TIP

The Ear Test

No, this is not a test of your hearing, but rather using your ear to check that the electric fuel pump is operating. The electric fuel pump inside the fuel tank is often difficult to hear running, especially in a noisy shop environment. A commonly used trick to better hear the pump is to use a funnel in the fuel filter neck. ● **SEE FIGURE 74–20**.

FIGURE 74–19 A dim headlight indicates excessive resistance in fuel pump circuit.

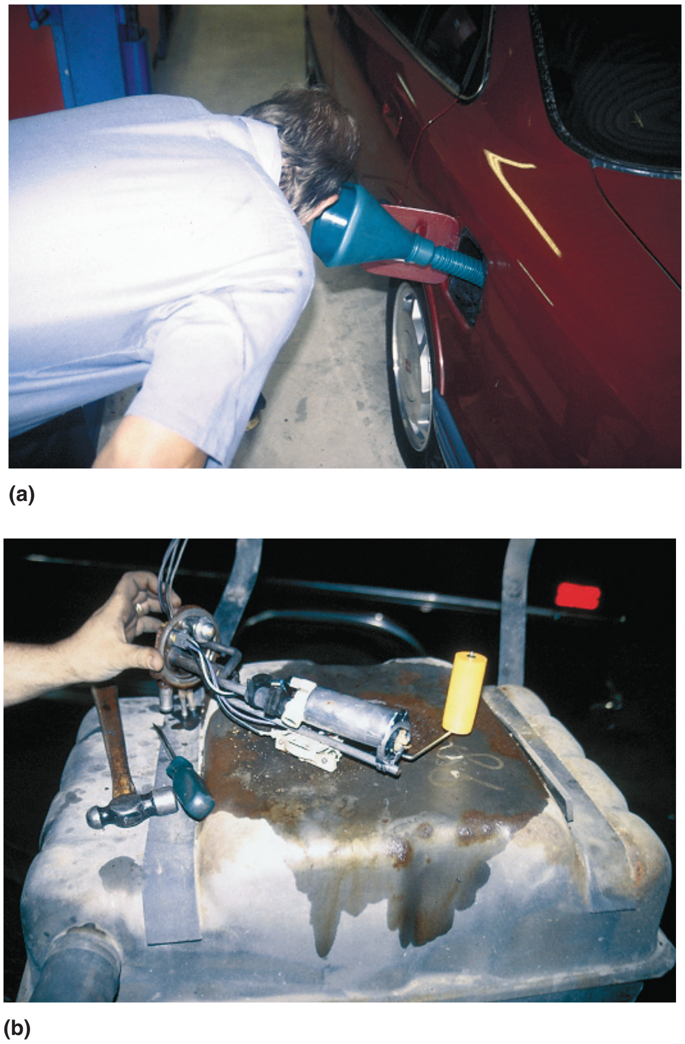

FIGURE 74–20 (a) A funnel helps in hearing if the electric fuel pump inside the gas tank is working. (b) If the pump is not running, check the wiring and current flow before going through the process of dropping the fuel tank to remove the pump.

inline filter usually is a metal or plastic container with a pleated paper element sealed inside.

Fuel filters may be mounted on a bracket on the fender panel, a shock tower, or another convenient place in the engine compartment. They may also be installed under the vehicle near the fuel tank. Fuel filters should be replaced according to the vehicle manufacturer's recommendations, which range from every 30,000 miles (48,000 km) to 100,000 miles (160,000 km) or longer. Fuel filters that are part of the fuel-pump module assemblies usually do not have any specified service interval.

FUEL-PUMP TESTING

Fuel-pump testing includes many different tests and procedures. Even though a fuel pump can pass one test, it does not mean that there is not a fuel-pump problem. For example, if the pump motor is rotating slower than normal, it may be able to produce the specified pressure, but not enough volume to meet the needs of the engine while operating under a heavy load.

TESTING FUEL-PUMP VOLUME Fuel pressure alone is not enough for proper engine operation. Sufficient fuel capacity (flow) should be at least 2 pints (1 L) every 30 seconds or 1 pint in 15 seconds. Fuel flow specifications are usually expressed in gallons per minute. A typical specification would be 0.5 gallons per minute or more. Volume testing is shown in ● **FIGURE 74–21**.

All fuel must be filtered to prevent dirt and impurities from damaging the fuel system components and/or engine. The first filter is inside the gas tank and is usually not replaceable separately but is attached to the fuel pump (if the pump is electric) and/or fuel gauge sending unit. The replaceable fuel filter is usually located between the fuel tank and the fuel rail or inlet to the fuel-injection system. Most vehicle manufacturers state in service information when to replace the fuel filter. Most newer vehicles, that use returnless-type fuel-injection systems, do not have replaceable filters as they are built into the fuel pump module assembly. (Check the vehicle manufacturers' recommendations for exact time and mileage intervals.)

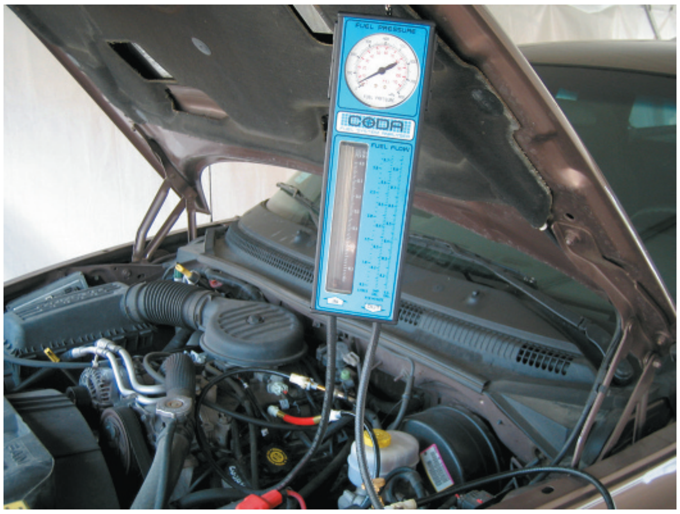

FIGURE 74–21 A fuel system tester connected in series in the fuel system so all of the fuel used flows through the meter, which displays the rate of flow and the fuel pressure.

TECH TIP

Remove the Bed to Save Time?

The electric fuel pump is easier to replace on many General Motors pickup trucks if the bed is removed. Access to the top of the fuel tank, where the access hole is located, for the removal of the fuel tank sender unit and pump is restricted by the bottom of the pickup truck bed. It would take several people (usually other technicians in the shop) to lift the truck bed from the frame after removing only a few fasteners. ● **SEE FIGURE 74–22**.

CAUTION: Be sure to clean around the fuel pump opening so that dirt or debris does not enter the tank when the fuel pump is removed.

FUEL-PUMP CURRENT DRAW TEST Another test that can and should be performed on a fuel pump is to measure the current draw in amperes. This test is most often performed by connecting a digital multimeter set to read DC amperes and test the current draw. ● **SEE FIGURE 74–23** for the hookup for vehicles equipped with a fuel-pump relay. Compare the reading to factory specifications.

FUEL-PUMP REPLACEMENT

The following recommendations should be followed whenever replacing an electric fuel pump:

- The fuel-pump strainer (sock) should be replaced with the new pump.
- If the original pump had a deflector shield, it should always be used to prevent fuel return bubbles from blocking the inlet to the pump.

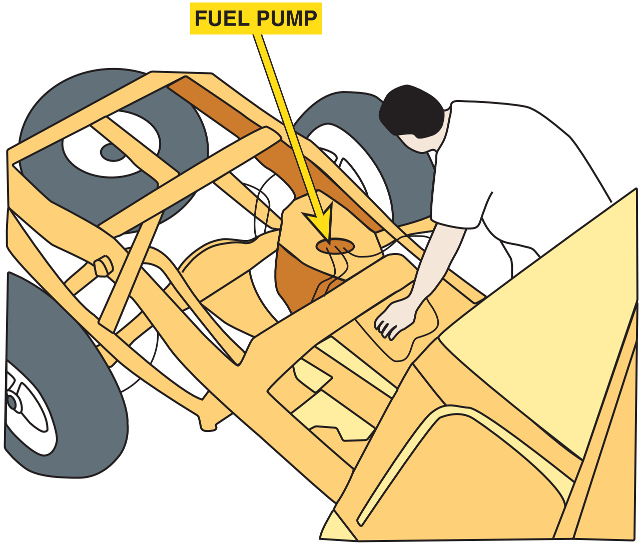

FIGURE 74–22 Removing the bed from a pickup truck makes gaining access to the fuel pump a lot easier.

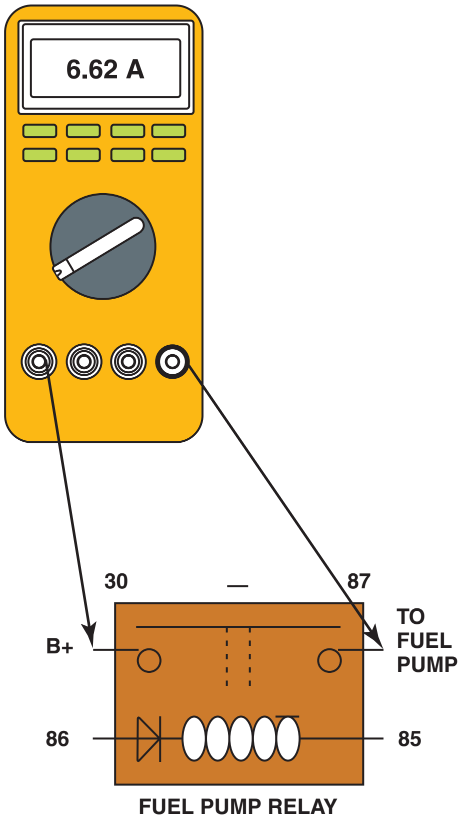

FIGURE 74–23 Hookup for testing fuel-pump current draw on any vehicle equipped with a fuel-pump relay.

- Always check the interior of the fuel tank for evidence of contamination or dirt.
- Double-check that the replacement pump is correct for the application.
- Check that the wiring and electrical connectors are clean and tight.

FUEL SUPPLY-RELATED SYMPTOM GUIDE

PROBLEM	POSSIBLE CAUSES
Pressure too high after engine start-up.	1. Defective fuel-pressure regulator
	2. Restricted fuel return line
	3. Excessive system voltage
	4. Restricted return line
	5. Wrong fuel pump
Pressure too low after engine start-up.	1. Stuck-open pressure regulator
	2. Low voltage
	3. Poor ground
	4. Plugged fuel filter
	5. Faulty inline fuel pump
	6. Faulty in-tank fuel pump
	7. Partially clogged filter sock
	8. Faulty hose coupling
	9. Leaking fuel line
	10. Wrong fuel pump
	11. Leaking pulsator
	12. Restricted accumulator
	13. Faulty pump check valves
	14. Faulty pump installation
Pressure drops off with key on/ engine off. With key off, the pressure does not hold.	1. Leaky pulsator
	2. Leaking fuel-pump coupling hose
	3. Faulty fuel pump (check valves)
	4. Faulty pressure regulator
	5. Leaking fuel injector
	6. Leaking cold-start fuel injector
	7. Faulty installation
	8. Lines leaking

REVIEW QUESTIONS

1. What are the three most commonly used pump designs?

2. What is the proper way to disconnect and connect plastic fuel line connections?

3. Where are the fuel filters located in the fuel system?

4. What accident and rollover devices are installed in a fuel delivery system?

5. What methods can be used to test a fuel pump?

CHAPTER QUIZ

1. The first fuel filter in the sock inside the fuel tank normally filters particles larger than ___________.
a. 0.001 to 0.003 inch
b. 0.010 to 0.030 inch
c. 10 to 20 microns
d. 70 to 100 microns

2. If it is tripped, which type of safety device will keep the electric fuel pump from operating?
a. Rollover valve
b. Inertia switch
c. Anti-siphoning valve
d. Check valve

3. Fuel lines are constructed from ___________.
   a. seamless steel tubing
   b. nylon plastic
   c. copper and/or aluminum tubing
   d. both a and b
4. What prevents the fuel pump inside the fuel tank from catching the gasoline on fire?
   a. Electricity is not used to power the pump
   b. No air is around the motor brushes
   c. Gasoline is hard to ignite in a closed space
   d. All of the above
5. A good fuel pump should be able to supply how much fuel per minute?
   a. 1/4 pint
   b. 1/2 pint
   c. 1 pint
   d. 0.6 to 0.8 gallons
6. Technician A says that fuel pump modules are spring-loaded so that they can be compressed to fit into the opening. Technician B says that they are spring-loaded to allow for expansion and contraction of plastic fuel tanks. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
7. Most fuel filters are designed to remove particles larger than ___________.
   a. 10 microns
   b. 20 microns
   c. 70 microns
   d. 100 microns
8. The fuel pressure is lower than specified. All of the following are possible causes *except* ___________
   a. poor ground
   b. plugged fuel filter
   c. restriction in the return line
   d. defective fuel pump
9. A fuel pump is being replaced for the third time. Technician A says that the gasoline could be contaminated. Technician B says that wiring to the pump could be corroded. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
10. After starting the engine, the fuel pressure is too high. What is the most likely cause?
    a. Poor ground
    b. Restricted accumulator
    c. Restricted return line
    d. Stuck-open pressure regulator

Chapter

75

FUEL-INJECTION PARTS AND OPERATION

LEARNING OBJECTIVES:

After studying this chapter, the reader will be able to:

- Describe how electronic fuel injection works.
- Describe types of fuel injection.
- Explain the different methods used to regulate fuel pressure.
- Discuss fuel injectors.
- Discuss fuel-injection modes of operation.
- Describe idle control systems.

KEY TERMS:

Demand delivery system (DDS) 898 • Electronic air control (EAC) 900 • Electronic returnless fuel system (ERFS) 897 • Flare 900 • Fuel rail 898 • Mechanical returnless fuel system (MRFS) 897 • Port fuel-injection 893 • Pressure control valve (PCV) 898 • Pressure vent valve (PVV) 897

ELECTRONIC FUEL INJECTION

OPERATION Electronic fuel-injection systems use the computer to control the following operation of fuel injectors and other functions based on information sent to the computer from the various sensors. Most electronic fuel-injection systems share the following:

1. Electric fuel pump (usually located inside the fuel tank)
2. Fuel-pump relay (controlled by the computer)
3. Fuel-pressure regulator (mechanically operated spring-loaded rubber diaphragm maintains proper fuel pressure)
4. Fuel-injector nozzle or nozzles which are basically 12-volt solenoids

● **SEE FIGURE 75–1**. Most electronic fuel-injection systems use the computer to control the following aspects of their operation:

1. **Pulsing the fuel injectors on and off.** The longer the injectors are held open, the greater the amount of fuel injected into the intake manifold near the intake valve.
2. **Operating the fuel-pump relay circuit.** The computer usually controls the operation of the electric fuel pump located inside (or near) the fuel tank. The computer uses signals from the ignition switch and RPM signals from the ignition module or system to energize the fuel-pump relay circuit.

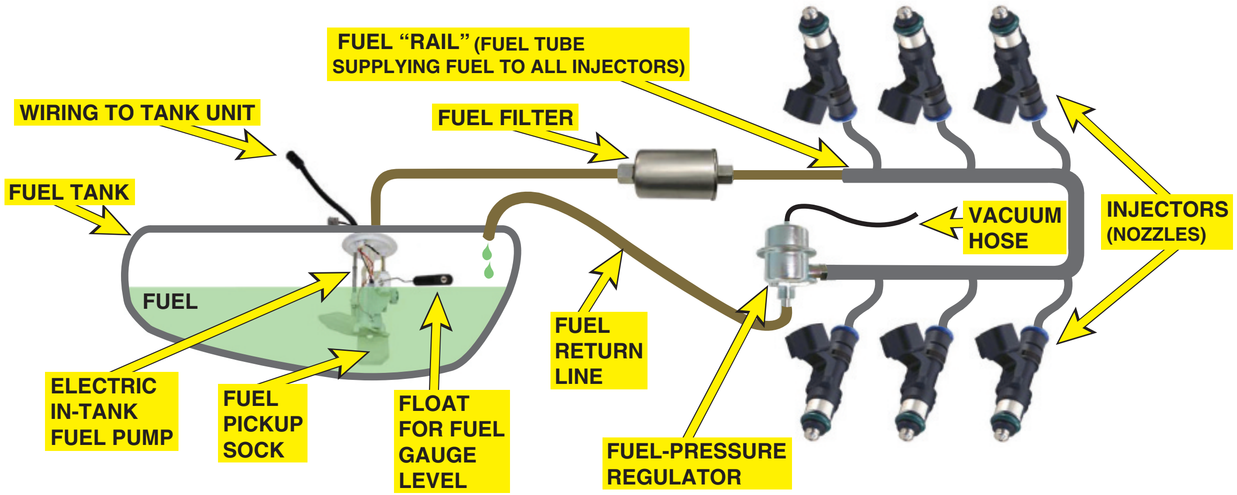
NOTE: This is a safety feature, because if the engine stalls and the tachometer (engine speed) signal is lost, the computer will shut off (de-energize) the fuel-pump relay and stop the fuel pump.

A **port fuel-injection** design uses a nozzle for each cylinder and the fuel is squirted into the intake manifold about 2 to 3 inches (70 to 100 mm) from the intake valve. ● **SEE FIGURE 75–2**.

TYPES OF FUEL INJECTION

Fuel-injection computer systems require a method for measuring the amount of air the engine is breathing in, in order to match the correct fuel delivery. There are two basic methods used:

1. Speed density
2. Mass airflow



FUEL "RAIL" (FUEL TUBE SUPPLYING FUEL TO ALL INJECTORS)

AIR ONLY
INJECTOR SPRAY PATTERN

FIGURE 75–2 A typical port fuel-injection system squirts fuel into the low pressure (vacuum) of the intake manifold, about 3 inch (70 to 100 mm) from the intake valve.

SPEED-DENSITY The speed-density method does not use an air quantity sensor, but rather calculates the amount of fuel required by the engine. The computer uses information from sensors such as the MAP and TP to calculate the needed amount of fuel.

- **MAP sensor.** The value of the intake (inlet) manifold pressure (vacuum) is a direct indication of engine load.
- **TP sensor.** The position of the throttle plate and its rate of change are used as part of the equation to calculate the proper amount of fuel to inject.
- **Temperature sensors.** Both engine coolant temperature (ECT) and intake air temperature (IAT) are used to calculate the density of the air and the need of the engine for fuel. A cold engine (low-coolant temperature) requires a richer air–fuel mixture than a warm engine.

On speed-density systems, the computer calculates the amount of air in each cylinder by using manifold pressure and engine RPM. The amount of air in each cylinder is the major factor in determining the amount of fuel needed. Other sensors provide information to modify the fuel requirements. The formula used to determine the injector pulse width (PW) in milliseconds (ms) is the following:

Injector pulse width = MAP/BARO × RPM/maximum RPM

The formula is modified by values from other sensors, including the following:

- Throttle position (TP)
- Engine coolant temperature (ECT)
- Intake air temperature (IAT)
- Oxygen sensor voltage (O2S)
- Adaptive memory

A fuel injector delivers atomized fuel into the airstream where it is instantly vaporized. All throttle body injection (TBI) systems and early multipoint (port) injection systems used the speed-density method of fuel calculation.

MASS AIRFLOW The formula used by fuel-injection systems that use a mass airflow (MAF) sensor to calculate the injection base pulse width is the following:

Injector pulse width = airflow/RPM

The formula is modified by other sensor values such as the following:

- Throttle position
- Engine coolant temperature
- Barometric pressure
- Adaptive memory

Electronic fuel-injection systems use a solenoid operated injector to spray atomized fuel in timed pulses into the manifold or near the intake valve. Injectors are sequenced and fired by the PCM and their pulse width is determined and controlled by the engine computer. ● **SEE FIGURES 75–3, 75–4, AND 75–5.**

FREQUENTLY ASKED QUESTION

How Do the Sensors Affect the Pulse Width?

The base pulse width of a fuel-injection system is primarily determined by the value of the MAF or MAP sensor and engine speed (RPM). However, the PCM relies on the input from many other sensors, such as the following, to modify the base pulse width as needed:

- **TP Sensor.** This sensor causes the PCM to command up to 500% (five times) the base pulse width if the accelerator pedal is depressed rapidly to the floor. It can also reduce the pulse width by about 70% if the throttle is rapidly closed.
- **ECT.** The value of this sensor determines the temperature of the engine coolant, helps determine the base pulse width, and can account for up to 60% of the determining factors.
- **BARO.** The BARO sensor compensates for altitude and adds up to about 10% under high-pressure conditions and subtracts as much as 50% from the base pulse width at high altitudes.
- **IAT.** The intake air temperature is used to modify the base pulse width based on the temperature of the air entering the engine. It is usually capable of adding as much as 20% if very cold air is entering the engine or reducing the pulse width by up to 20% if very hot air is entering the engine.
- **O2S.** This is one of the main modifiers to the base pulse width and can add or subtract up to about 20% to 25% or more, depending on the oxygen sensor activity.

FUEL-PRESSURE REGULATOR

PURPOSE AND FUNCTION The pressure regulator and fuel pump work together to maintain the required pressure drop at the injector tips. The fuel-pressure regulator typically consists of a spring-loaded, diaphragm-operated valve in a metal housing.

Fuel-pressure regulators on fuel-return-type fuel-injection systems are installed on the return (downstream) side of the injectors at the end of the fuel rail, or are built into or mounted upon the throttle-body housing. Downstream regulation minimizes fuel-pressure pulsations caused by pressure drop across the injectors as the nozzles open. It also ensures positive fuel pressure at the injectors at all times and holds residual pressure in the lines when the engine is off. On

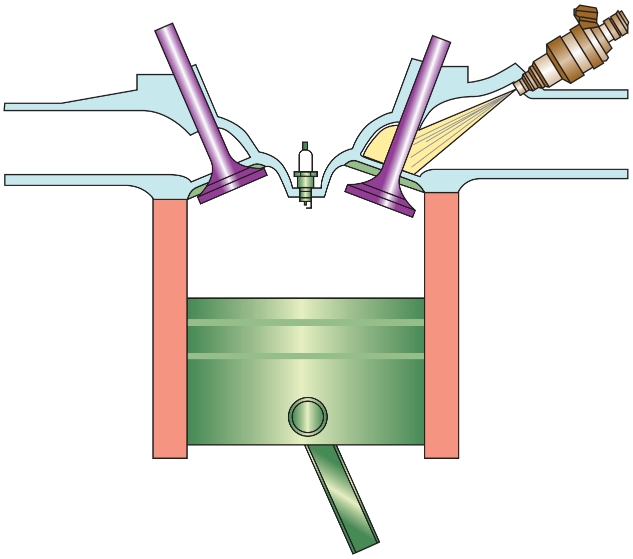

FIGURE 75–5 Port fuel injectors spray atomized fuel into the intake manifold about 3 inches (75 mm) from the intake valve.

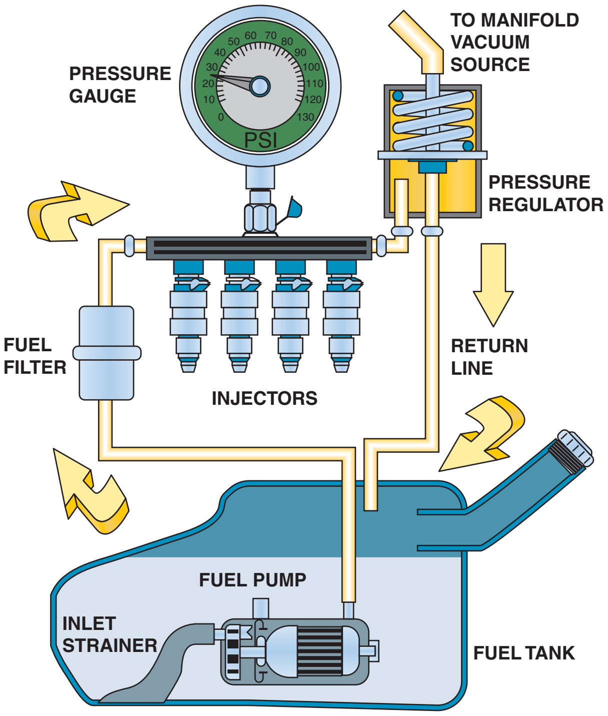

FIGURE 75–6 A typical port fuel-injected system showing a vacuum-controlled fuel-pressure regulator.

mechanical returnless systems, the regulator is located back at the tank with the fuel filter.

OPERATION In order for excess fuel (about 80% to 90% of the fuel delivered) to return to the tank, fuel pressure must overcome spring pressure on the spring-loaded diaphragm to uncover the return line to the tank. This happens when system pressure exceeds operating requirements. With TBI, the regulator is close to the injector tip, so the regulator senses essentially the same air pressure as the injector.

The pressure regulator used in a port fuel-injection system has an intake-manifold vacuum line connection on the regulator vacuum chamber. This allows fuel pressure to be modulated by a combination of spring pressure and manifold vacuum acting on the diaphragm. ● **SEE FIGURES 75–6 AND 75–7.**

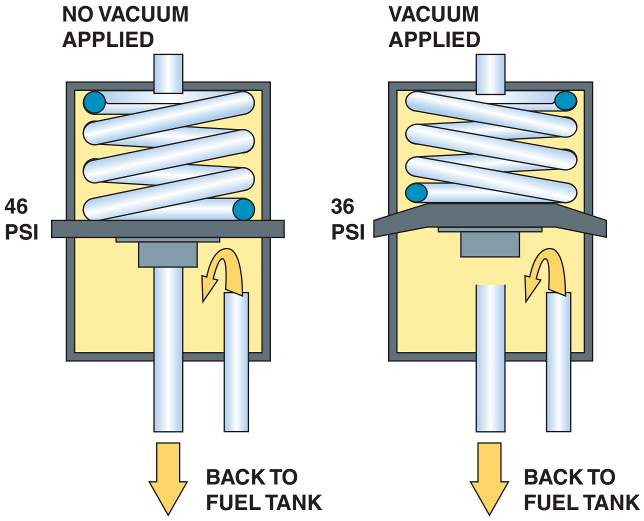

FIGURE 75–7 A typical fuel-pressure regulator that has a spring that exerts 46 pounds of force against the fuel. If 20 inches of vacuum are applied above the spring, the vacuum reduces the force exerted by the spring on the fuel, allowing the fuel to return to the tank at a lower pressure.

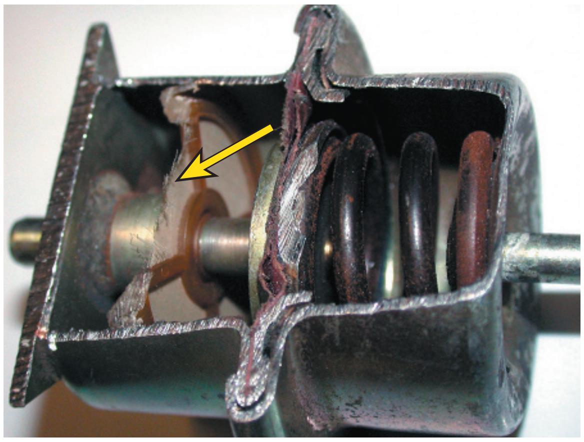

FIGURE 75–8 A lack of fuel flow could be due to a restricted fuel-pressure regulator. Notice the fine screen filter. If this filter were to become clogged, higher than normal fuel pressure would occur.

TECH TIP

Don't Forget the Regulator

Some fuel-pressure regulators contain a 10 micron filter. If this filter becomes clogged, a lack of fuel flow would result. ● **SEE FIGURE 75–8.**

In both TBI and port fuel-injection systems, the regulator shuts off the return line when the fuel pump is not running. This maintains pressure at the injectors for easy restarting after hot soak as well as reducing vapor lock.

Port fuel-injection systems generally operate with pressures at the injector of about 30 to 55 PSI (207 to 379 kPa).

VACUUM-BIASED FUEL-PRESSURE REGULATOR The primary reason why many port fuel-injected systems use a vacuum-controlled fuel-pressure regulator is to ensure that there is a constant pressure drop across the injectors. In a throttle-body fuel-injection system, the injector squirts into the atmospheric pressure regardless of the load on the engine. In a port fuel-injected engine, however, the pressure inside the intake manifold changes as the load on the engine increases.

ENGINE OPERATING CONDITION	INTAKE-MANIFOLD VACUUM	FUEL PRESSURE
Idle or cruise	High	Lower
Heavy load	Low	Higher

The computer can best calculate injector pulse width based on all sensors if the pressure drop across the injector is the same under all operating conditions. A vacuum-controlled fuel-pressure regulator allows the equal pressure drop by reducing the force exerted by the regulator spring at high vacuum (low-load condition), yet allowing the full force of the regulator spring to be exerted when the vacuum is low (high-engine-load condition).

ELECTRONIC RETURNLESS FUEL SYSTEM This system is unique because it does not use a mechanical valve to regulate rail pressure. Fuel pressure at the rail is sensed by a pressure transducer, which sends a low-level signal to a controller. The controller contains logic to calculate a signal to the pump power driver. The power driver contains a high-current transistor that controls the pump speed using pulse width modulation (PWM). This system is called the **electronic returnless fuel system (ERFS)**. ● **SEE FIGURE 75–9**. This transducer can be differentially referenced to manifold pressure for closed-loop feedback, correcting and maintaining the output of the pump to a desired rail setting. This system is capable of continuously varying rail pressure as a result of engine vacuum, engine fuel demand, and fuel temperature (as sensed by an external temperature transducer, if necessary). A **pressure vent valve (PVV)** is employed at the tank to relieve overpressure due to thermal expansion of fuel. In addition, a supply-side bleed, by means of an in-tank reservoir using a supply-side jet pump, is necessary for proper pump operation.

MECHANICAL RETURNLESS FUEL SYSTEM The first production returnless systems employed the **mechanical returnless fuel system (MRFS)** approach. This system has a bypass regulator to control rail pressure that is located in close proximity to the fuel tank. Fuel is sent by the in-tank pump to a chassis-mounted inline filter with excess fuel returning to the tank through a short return line. ● **SEE FIGURE 75–10**. The inline filter may be mounted directly to the tank, thereby eliminating the shortened return line. Supply pressure is regulated on the downstream side of the inline filter to accommodate changing restrictions throughout the filter's service life. This system is limited to constant rail pressure (*CRP) system calibrations, whereas with ERFS, the pressure transducer can be referenced to atmospheric pressure for CRP systems or differentially referenced to intake-manifold pressure for constant differential injector pressure (**CIP) systems.

NOTE: *CRP is referenced to atmospheric pressure, has lower operating pressure, and is desirable for calibrations using speed/air density sensing. **CIP is referenced to manifold pressure, varies rail pressure, and is desirable in engines that use mass airflow sensing.

DEMAND DELIVERY SYSTEM (DDS) Given the experience with both ERFS and MRFS, a need was recognized to develop new returnless technologies that could combine the speed control and constant injector pressure attributes of ERFS together with the cost savings, simplicity, and reliability of MRFS. This

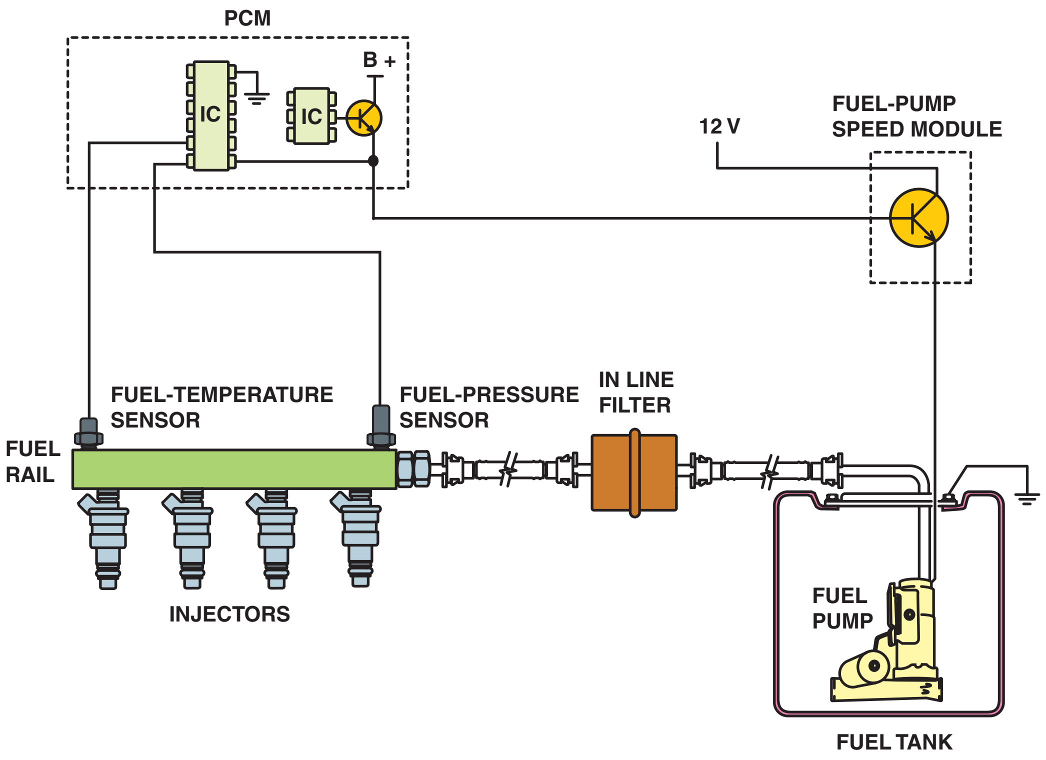

FIGURE 75–9 The fuel-pressure sensor and fuel-temperature sensor are often constructed together in one assembly to help give the PCM the needed data to control the fuel-pump speed.

new technology also needed to address pulsation dampening/hammering and fuel transient response. Therefore, the **demand delivery system (DDS)** technology was developed. A different form of demand pressure regulator has been applied to the fuel rail. It mounts at the head or port entry and regulates the pressure downstream at the injectors by admitting the precise quantity of fuel into the rail as consumed by the engine. Having demand regulation at the rail improves pressure response to flow transients and provides rail pulsation dampening. A fuel pump and a low-cost, high-performance bypass regulator are used within the appropriate fuel sender. ● **SEE FIGURE 75–11**. They supply a pressure somewhat higher than the required rail set pressure to accommodate dynamic line and filter pressure losses. Electronic pump speed control is accomplished using a smart regulator as an integral flow sensor. A **pressure control valve (PCV)** may also be used and can readily reconfigure an existing design fuel sender into a returnless sender.

FREQUENTLY ASKED QUESTION

Why Are Some Fuel Rails Rectangular Shaped?

A port fuel-injection system uses a pipe or tubes to deliver fuel from the fuel line to the intended fuel injectors. This pipe or tube is called the **fuel rail**. Some vehicle manufacturers construct the fuel rail in a rectangular cross section. ● **SEE FIGURE 75–12**. The sides of the fuel rail are able to move in and out slightly, thereby acting as a fuel pulsator evening out the pressure pulses created by the opening and closing of the injectors to reduce underhood noise. A round cross-sectional fuel rail is not able to deform and, as a result, some manufacturers have had to use a separate dampener.

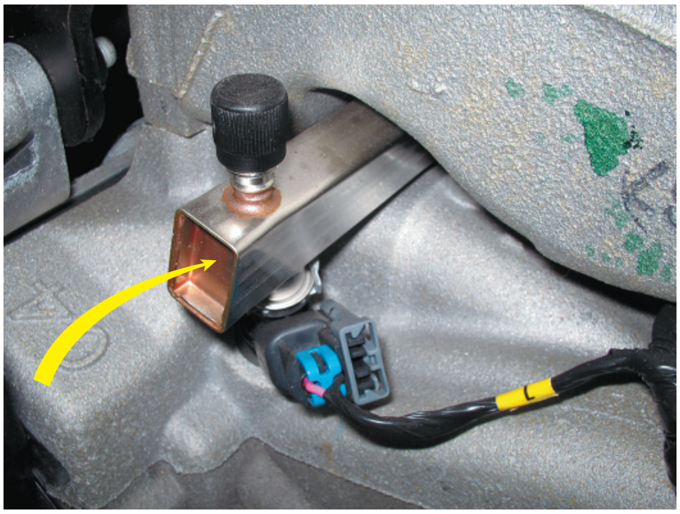

FIGURE 75–12 A rectangular-shaped fuel rail is used to help dampen fuel system pulsations and noise caused by the injectors opening and closing.

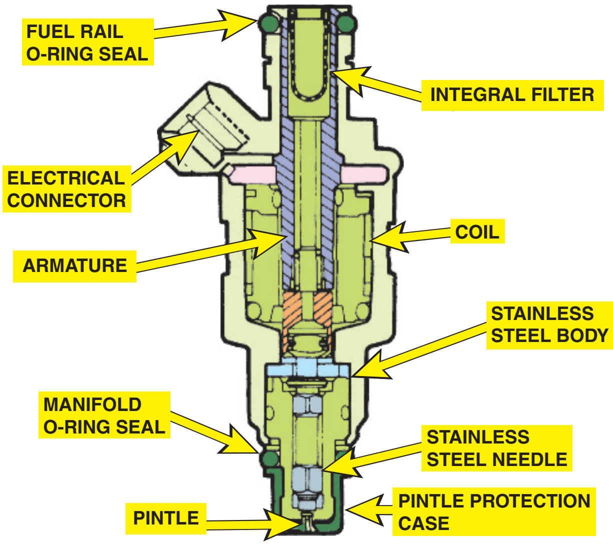

FIGURE 75–13 A multiport fuel injector. Notice that the fuel flows straight through and does not come in contact with the coil windings.

FUEL INJECTORS

EFI systems use 12-volt solenoid-operated injectors. ● **SEE FIGURE 75–13**. This electromagnetic device contains an armature and a spring-loaded needle valve or ball valve assembly. When the computer energizes the solenoid, voltage is applied to the solenoid coil until the current reaches a specified level. This permits a quick pull-in of the armature during turn-on. The armature is pulled off of its seat against spring force, allowing fuel to flow through the inlet filter screen to the spray nozzle, where it is sprayed in a pattern that varies with application. ● **SEE FIGURE 75–14**. The injector opens the same amount each time it is energized, so the amount of fuel injected depends on the length of time the injector remains open. By angling the director hole plates, the injector sprays fuel more directly at the intake valves, which further atomizes and vaporizes the fuel before it enters the combustion chamber. PFI injectors typically are a top-feed design in which fuel enters the top of the injector and passes through its entire length to keep it cool before being injected.

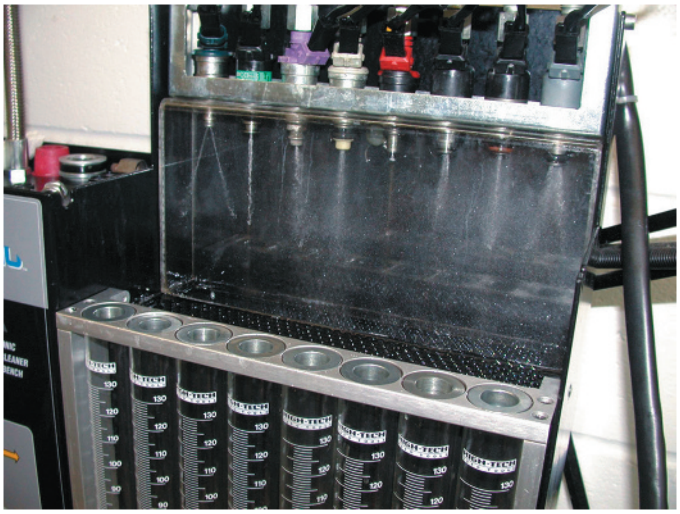

FIGURE 75–14 Each of the eight injectors shown are producing a correct spray pattern for the applications. While all throttle-body injectors spray a conical pattern, most port fuel injections do not.

FUEL-INJECTION MODES OF OPERATION

STARTING MODE When the ignition is turned to the start (on) position, the engine cranks and the PCM energizes the fuel-pump relay. The PCM also pulses the injectors on, basing the pulse width on engine speed and engine coolant temperature. The colder the engine is, the greater the pulse width. Cranking mode air–fuel ratio varies from about 1.5:1 at −40°F (−40°C) to 14.7:1 at 200°F (93°C).

CLEAR FLOOD MODE If the engine becomes flooded with too much fuel, the driver can depress the accelerator pedal to greater than 80% to enter the clear flood mode. When the PCM detects that the engine speed is low (usually below 600 RPM) and the throttle-position (TP) sensor voltage is high (WOT), the injector pulse width is greatly reduced or even shut off entirely, depending on the vehicle.

OPEN-LOOP MODE Open-loop operation occurs during warm-up before the oxygen sensor can supply accurate information to the PCM. The PCM determines injector pulse width based on values from the MAF, MAP, TP, ECT, and IAT sensors.

CLOSED-LOOP MODE Closed-loop operation is used to modify the base injector pulse width as determined by feedback from the oxygen sensor to achieve proper fuel control.

ACCELERATION ENRICHMENT MODE During acceleration, the throttle-position (TP) voltage increases, indicating that a richer air–fuel mixture is required. The PCM then supplies a longer injector pulse width and may even supply extra pulses to supply the needed fuel for acceleration.

DECELERATION ENLEANMENT MODE When the engine decelerates, a leaner air–fuel mixture is required to help reduce emissions and to prevent deceleration backfire. If the deceleration is rapid, the injector may be shut off entirely for a short time and then pulsed on enough to keep the engine running.

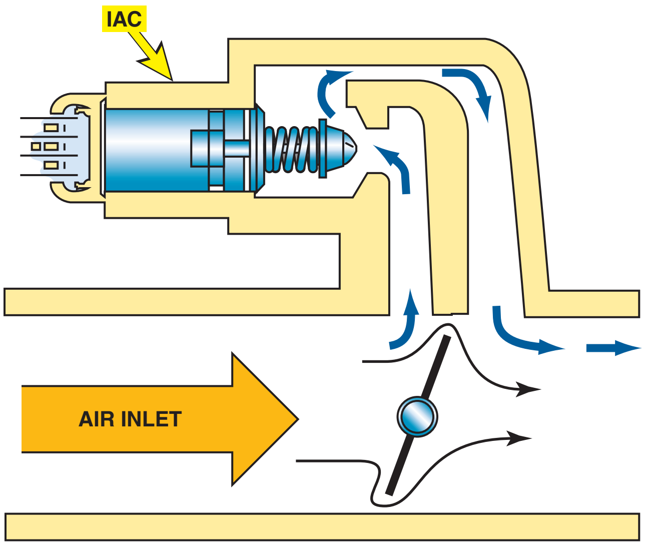

FIGURE 75–15 The small arrows indicate the air bypassing the throttle plate in the closed throttle position. This air is called minimum air. The air flowing through the IAC is the airflow that determines the idle speed.

FUEL SHUTOFF MODE Besides shutting off fuel entirely during periods of rapid deceleration, PCM also shuts off the injector when the ignition is turned off to prevent the engine from continuing to run.

IDLE CONTROL

PURPOSE AND FUNCTION Before electronic throttle control (ETC) systems, the idle speed was controlled by using an air bypass control unit. ● **SEE FIGURE 75–15**. This air bypass or regulator provides needed additional airflow, and thus more fuel. The engine needs more power when cold to maintain its normal idle speed to overcome the increased friction from cold lubricating oil. It does this by opening an intake air passage to let more air into the engine just as depressing the accelerator pedal would open the throttle valve, allowing more air into the engine. The system is calibrated to maintain engine idle speed at a specified value regardless of engine temperature.

Most PFI systems use an idle air control (IAC) motor to regulate idle bypass air. The IAC is computer-controlled, and is either a solenoid-operated valve or a stepper motor that regulates the airflow around the throttle. The idle air control valve is also called an **electronic air control (EAC)** valve.

When the engine stops, most IAC units will retract outward to get ready for the next engine start. When the engine starts, the engine speed is high to provide for proper operation when the engine is cold. Then, as the engine gets warmer, the computer reduces engine idle speed gradually by reducing the number of counts or steps commanded by the IAC.

When the engine is warm and restarted, the idle speed should momentarily increase, then decrease to normal idle speed. This increase and then decrease in engine speed is often called an engine **flare**. If the engine speed does not flare, then the IAC may not be working (it may be stuck in one position).

STEPPER MOTOR OPERATION A digital output is used to control stepper motors. Stepper motors are direct-current motors that move in fixed steps or increments from de-energized (no voltage) to fully energized (full voltage). A stepper motor often has as many as 120 steps of motion.

A common use for stepper motors is as an idle air control (IAC) valve, which controls engine idle speeds and prevents stalls due to changes in engine load. When used as an IAC, the stepper motor is usually a reversible DC motor that moves in increments, or steps. The motor moves a shaft back and forth to operate a conical valve. When the conical valve is moved back, more air bypasses the throttle plates and enters the engine, increasing idle speed. As the conical valve moves inward, the idle speed decreases.

When using a stepper motor that is controlled by the PCM, it is very easy for the PCM to keep track of the position of the stepper motor. By counting the number of steps that have been sent to the stepper motor, the PCM can determine the relative position of the stepper motor. While the PCM does not actually receive a feedback signal from the stepper motor, it does know how many steps forward or backward the motor should have moved.

A typical stepper motor uses a permanent magnet and two electromagnets. Each of the two electromagnetic windings is controlled by the computer. The computer pulses the windings and changes the polarity of the windings to cause the armature of the stepper motor to rotate 90 degrees at a time. Each 90-degree pulse is recorded by the computer as a "count" or "step"; therefore, the name given to this type of motor. ● **SEE FIGURE 75–16**.

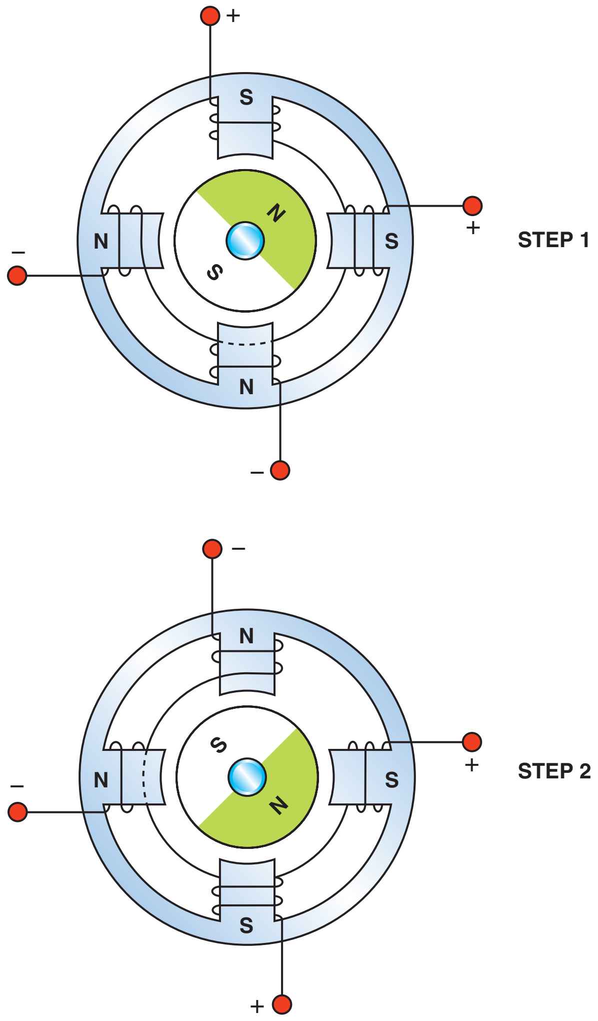

FIGURE 75–16 Most stepper motors use four wires, which are pulsed by the computer to rotate the armature in steps.

ELECTRONIC THROTTLE CONTROL SYSTEM The idle speed on newer vehicles is controlled by the electric throttle control (ETC) system. Using an ETC system on an engine has many advantages over a conventional method that uses a mechanical cable between the accelerator pedal and the throttle valve.

The major components of an ETC system include the following:

- Accelerator pedal position (APP) sensor
- ETC actuator motor and spring
- Throttle position (TP) sensor
- Electronic control unit

See Chapter 77 for more details on ETC systems.

REVIEW QUESTIONS

1. What are the two basic methods used for measuring the amount of air the engine is breathing in, in order to match the correct fuel delivery?
2. What is the purpose of the vacuum-controlled (biased) fuel-pressure regulator?
3. How many sensors are used to determine the base pulse width on a speed-density system?
4. How many sensors are used to determine the base pulse width on a mass airflow system?
5. What are the three types of returnless fuel-injection systems?

CHAPTER QUIZ

1. Technician A says that the fuel-pump relay is usually controlled by the PCM. Technician B says that the injector sprays fuel above the throttle plate. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. Why are some fuel rails rectangular in shape?
   a. Increases fuel pressure
   b. Helps keep air out of the injectors
   c. Reduces noise
   d. Increases the speed of the fuel through the fuel rail
3. Which fuel-injection system uses the MAP sensor as the primary sensor to determine the base pulse width?
   a. Speed density
   b. Mass airflow
   c. Demand delivery
   d. Mechanical returnless
4. Why is a vacuum line attached to a fuel-pressure regulator on many fuel-injected engines?
   a. To draw fuel back into the intake manifold through the vacuum hose
   b. To create an equal pressure drop across the injectors
   c. To raise the fuel pressure at idle
   d. To lower the fuel pressure under heavy engine load conditions to help improve fuel economy
5. Which sensor has the greatest influence on injector pulse width besides the MAF sensor?
   a. IAT
   b. BARO
   c. ECT
   d. TP
6. Technician A says that the port fuel-injection injectors operate using 5 volts from the computer. Technician B says that electronic fuel injectors use 12 volts to operate. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
7. Which type of electronic fuel-injection system uses a fuel-temperature and/or fuel-pressure sensor?
   a. All port fuel-injected engines
   b. TBI units only
   c. Electronic returnless systems
   d. Demand delivery systems
8. Which of these is NOT a mode of operation for electronic fuel injection?
   a. Clear flood
   b. Open loop
   c. Closed loop
   d. Mid loop
9. Where is the fuel-pressure regulator located on a vacuum biased port fuel-injection system?
   a. In the tank
   b. At the inlet of the fuel rail
   c. At the outlet of the fuel rail
   d. Near or on the fuel filter
10. What type of device is used to control idle speed?
   a. ETC system
   b. Stepper motor
   c. Either a or b
   d. Neither a nor b

Chapter

76

GASOLINE DIRECT-INJECTION SYSTEMS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain how a direct fuel-injection system works.
- Describe the direct-injection fuel delivery system.
- Describe modes of operation.
- Discuss GDI piston designs.
- Discuss port/direct injection systems.
- Discuss engine start systems.
- Discuss GDI service issues.

KEY TERMS:

Gasoline direct-injection (GDI) 902 • Homogeneous mode 904 • Spark ignition direct injection (SIDI) 902 • Stratified mode 904

DIRECT FUEL INJECTION

PORT INJECTION VS. DIRECT INJECTION Unlike a port fuel-injection system, a GDI system varies the fuel pressure to achieve greater fuel delivery using a very short pulse time, which is usually less than one millisecond.

- Port Fuel Injection–Constant fuel pressure but variable injector pulse-width.
- GDI–Almost constant injector pulse-width with varying fuel pressure.

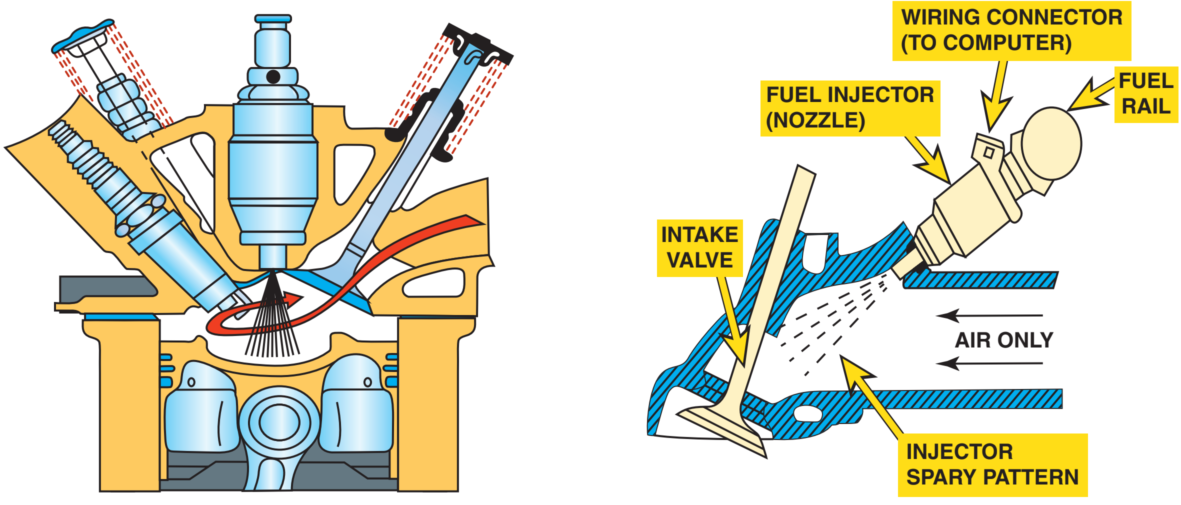
In a port fuel injection system, the fuel is squirted into the intake manifold or in the intake port upstream from the intake valve. The atomized fuel then mixes with the air entering the cylinder on the way to the combustion chamber.

In a **gasoline direct-injection (GDI)** system the fuel is squirted directly into the combustion chamber. ● **SEE FIGURE 76–1**. General Motors refers to GDI as a **spark ignition direct injection (SIDI)** system.

PARTS AND OPERATION A direct-injection system sprays high-pressure fuel, up to 2,900 PSI, into the combustion chamber as the piston approaches the top of the compression stroke. With the combination of high-pressure swirl injectors and modified combustion chamber, almost instantaneous vaporization occurs. This combined with a higher compression ratio allows a direct-injected engine to operate using a leaner-than-normal air–fuel ratio, which results in improved fuel economy with higher power output and reduced exhaust emissions. ● **SEE FIGURE 76–2**.

ADVANTAGES OF GASOLINE DIRECT INJECTION The use of direct injection compared with port fuel injection has many advantages including the following:

- Improved fuel economy due to reduced pumping losses and heat loss
- Allows a higher compression ratio for higher engine efficiency
- Allows the use of lower-octane gasoline
- The volumetric efficiency is higher
- Less need for extra fuel for acceleration
- Improved cold starting and throttle response
- Allows the use of greater percentage of EGR to reduce exhaust emissions
- Up to 25% improvement in fuel economy
- 12% to 15% reduction in exhaust emissions



Direct injection into cylinder

Injection upstream near the valve

FIGURE 76–1 A comparison of a port fuel injection system (right) to a gasoline direct injection (GDI) system on the left.

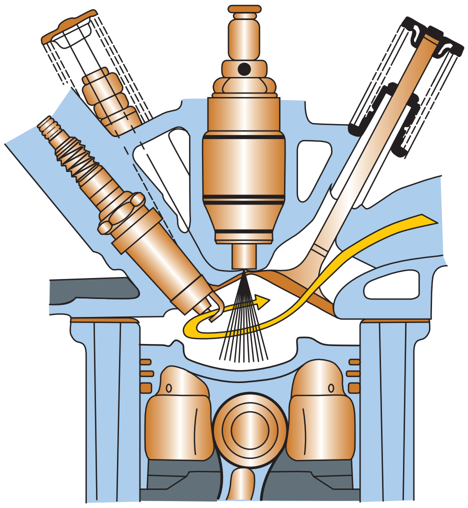


FIGURE 76–2 A gasoline direct-injection system injects fuel under high pressure directly into the combustion chamber.

DISADVANTAGES OF GASOLINE DIRECT INJECTION

- Higher cost due to high-pressure pump and injectors
- More components compared with port fuel injection
- Due to the high compression, a NO$_x$ storage catalyst is sometimes required to meet emission standards, especially in Europe. ● **SEE FIGURE 76–3**.
- Uses up to six operating modes depending on engine load and speed, which requires more calculations to be performed by the Powertrain Control module (PCM).

DIRECT-INJECTION FUEL DELIVERY SYSTEM

LOW-PRESSURE SUPPLY PUMP The fuel pump in the fuel tank supplies fuel to the high-pressure fuel pump at a pressure of approximately 60 PSI. The fuel filter is located in the fuel tank and is part of the fuel pump assembly. It is not usually serviceable as a separate component; the engine control module (ECM) controls the output of the high-pressure pump, which has a range between 500 PSI (3,440 kPa) and 2,900 PSI (15,200 kPa) during engine operation. ● **SEE FIGURES 76–3 AND 76–4**.

HIGH-PRESSURE PUMP In a General Motors system, the engine control module (ECM) controls the output of the high-pressure pump, which has a range between 500 PSI (3,440 kPa) and 2,900 PSI (15,200 kPa) during engine operation. The high-pressure fuel pump connects to the pump in the fuel tank through the low-pressure fuel line. The pump consists of a single-barrel piston pump, which is driven by the engine camshaft. The pump plunger rides on a three-lobed cam on the camshaft. The high-pressure pump is cooled and lubricated by the fuel itself. ● **SEE FIGURE 76–5**.

FUEL RAIL The fuel rail stores the fuel from the high-pressure pump and stores high-pressure fuel for use to each injector. All injectors get the same pressure fuel from the fuel rail.

FUEL PRESSURE REGULATOR An electric pressure-control valve is installed between the pump inlet and outlet valves. The fuel rail pressure sensor connects to the PCM with three wires:

- 5-volt reference
- ground
- signal

The sensor signal provides an analog signal to the PCM that varies in voltage as fuel rail pressure changes. Low pressure results in a low-voltage signal and high pressure results in a high-voltage signal.

The PCM uses internal drivers to control the power feed and ground for the pressure control valve. When both PCM drivers are deactivated, the inlet valve is held open by spring pressure. This causes the high-pressure fuel pump to default to low-pressure mode. The fuel from the high-pressure fuel pump flows through a line to the fuel rail and injectors. The actual operating pressure can vary from as low as 500 PSI (3,440 kPa) at idle to over 2,000 PSI (13,800 kPa) during high speed or heavy load conditions. ● **SEE FIGURE 76–6**.

GDI FUEL INJECTORS Each high-pressure fuel injector assembly is an electrically magnetic injector mounted in the cylinder head. In the GDI system, the PCM controls each fuel injector with 50 to 90 volts (usually 60 to 70 volts), depending on the system, which is created by a boost capacitor in the PCM. During the high-voltage boost phase, the capacitor is discharged through an injector, allowing for initial injector opening. The injector is then held open with 12 volts. The high-pressure fuel injector has a small slit or six precision-machined holes that generate the desired spray

pattern. The injector also has an extended tip to allow for cooling from a water jacket in the cylinder head.

● **SEE CHART 76–1** for an overview of the differences between a port fuel-injection system and a GDI system.

MODES OF OPERATION

The two basic modes of operation include the following:

1. **Stratified mode**. In this mode of operation, the air–fuel mixture is richer around the spark plug than it is in the rest of the cylinder.
2. **Homogeneous mode**. In this mode of operation, the air–fuel mixture is the same throughout the cylinder.

There are variations of these modes that can be used to fine-tune the air–fuel mixture inside the cylinder. For example, Bosch, a supplier to many vehicle manufacturers, uses the following six modes of operation:

- **Homogeneous mode.** In this mode, the injector is pulsed one time to create an even air–fuel mixture in the cylinder. The injection occurs during the intake stroke. This mode is used during high-speed and/or high-torque conditions.
- **Homogeneous lean mode.** Similar to the homogeneous mode except that the overall air–fuel mixture is slightly lean

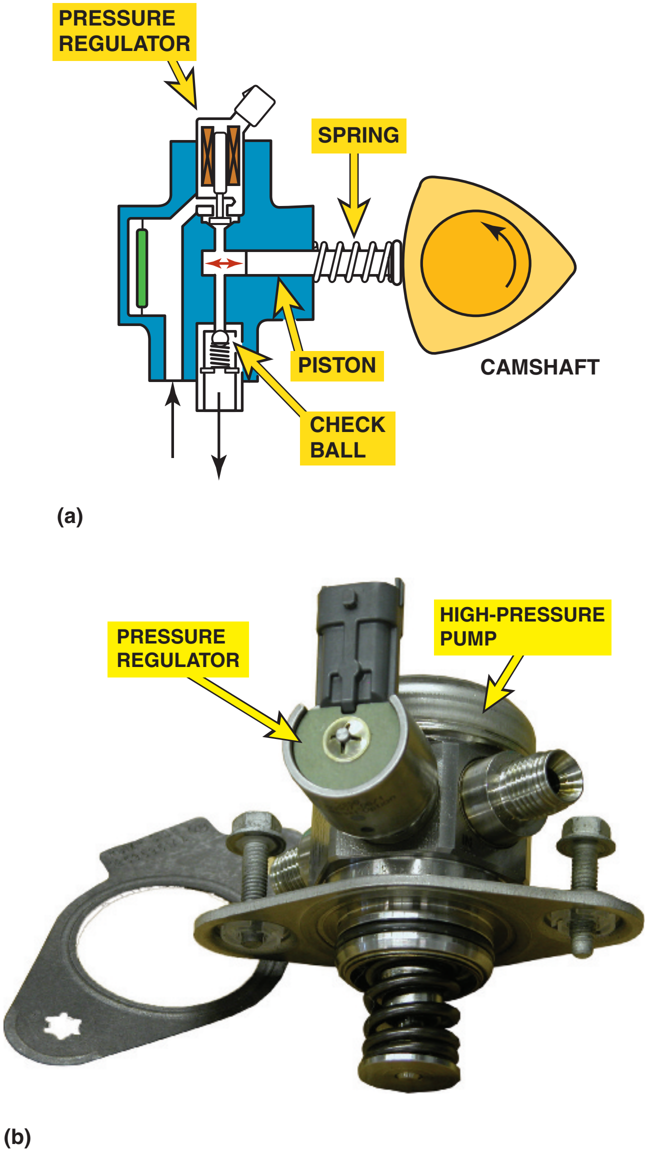

FIGURE 76–5 (a) A typical camshaft-driven high-pressure pump used to increase fuel pressure to 2,000 PSI or higher. (b) The high-pressure pump assembly removed from the engine. Many GDI engines use a roller where the high-pressure pump rides against the cam lobes to help reduce friction and wear.

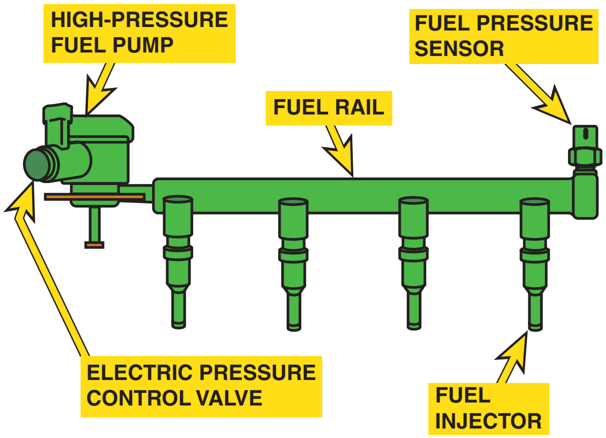

FIGURE 76–6 A GDI fuel rail and pump assembly with the electric pressure control valve.

PORT FUEL-INJECTION SYSTEM COMPARED WITH GDI SYSTEM

	PORT FUEL INJECTION	GASOLINE DIRECT INJECTION
Fuel pressure	35–60 PSI	Lift pump—50 to 60 PSI High-pressure pump—500 to 2,900 PSI
Injection pulse width at idle	1.5–3.5 ms	About 0.4 ms (400 µs)
Injector resistance	12–16 ohms	1–3 ohms
Injector voltage	6 V for low-resistance injectors, 12 V for most injectors	50–90 V
Number of injections per event	One	1–3
Engine compression ratio	8:1–11:1	11:1–13:1

CHART 76–1

A comparison chart showing the major differences between a port fuel-injection system and a GDI system.

for better fuel economy. The injection occurs during the intake stroke. This mode is used under steady, light-load conditions.

- **Stratified mode.** In this mode of operation, the injection occurs just before the spark occurs resulting in lean combustion, reducing fuel consumption.
- **Homogeneous stratified mode.** In this mode, there are two injections of fuel:
  - The first injection is during the intake stroke.
  - The second injection is during the compression stroke.

  As a result of these double injections, the rich air–fuel mixture around the spark plug is ignited first. Then, the rich mixture ignites the leaner mixture. The advantages of this mode include lower exhaust emissions than the stratified mode and less fuel consumption than the homogeneous lean mode.
- **Homogeneous knock protection mode.** The purpose of this mode is to reduce the possibility of spark knock from occurring under heavy loads at low engine speeds. There are two injections of fuel:
  - The first injection occurs on the intake stroke.
  - The second injection occurs during the compression stroke with the overall mixture being stoichiometric.

  As a result of this mode, the PCM does not need to retard ignition timing as much to operate knock-free.
- **Stratified catalyst heating mode.** In this mode, there are two injections:
  - The first injection is on the compression stroke just before combustion.

- The second injection is after combustion occurs to heat the exhaust. This mode is used to quickly warm the catalytic converter and to burn the sulfur from the NO_x catalyst.

PISTON TOP DESIGNS

GDI systems use a variety of shapes of piston and injector locations, depending on make and model of engine. Three of the most locations, used designs include the following:

- **Spray-guided combustion.** In this design, the injector is placed in the center of the combustion chamber and injects fuel into the dished-out portion of the piston. The shape of the piston helps guide and direct the mist of fuel in the combustion chamber. ● **SEE FIGURE 76–7**.
- **Swirl combustion.** This design uses the shape of the piston and the position of the injector at the side of the combustion chamber to create turbulence and swirl of the air–fuel mixture. ● **SEE FIGURE 76–8**.

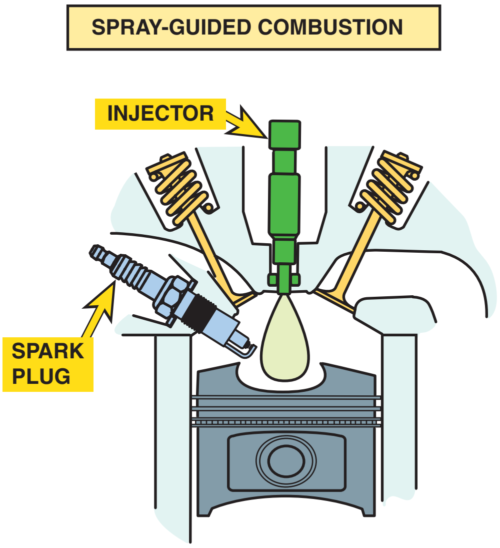

FIGURE 76–7 In this design, the fuel injector is at the top of the cylinder and sprays fuel into the cavity of the piston.

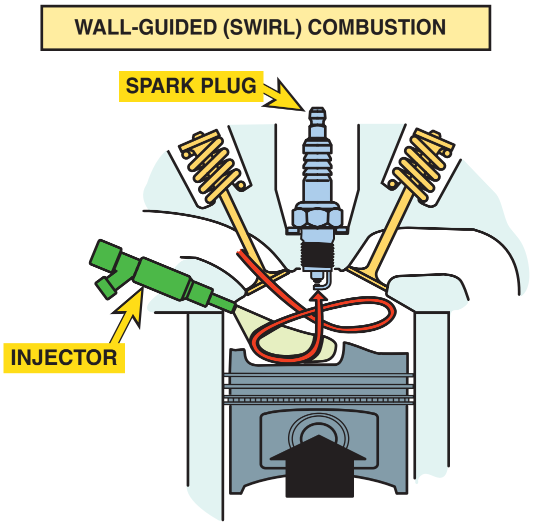

FIGURE 76–8 The side injector combines with the shape of the piston to create a swirl as the piston moves up on the compression stroke.

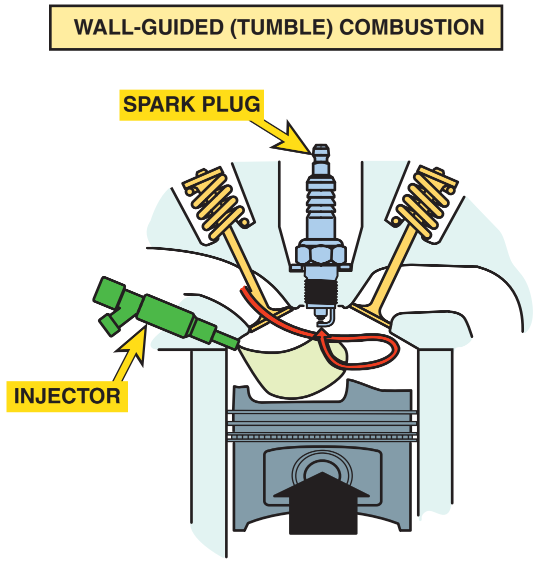

FIGURE 76–9 The piston creates a tumbling force as it moves upward.

- **Tumble combustion.** Depending on when the fuel is injected into the combustion chamber helps determine how the air–fuel mixture is moved or tumbled. ● **SEE FIGURE 76–9**.

PORT- AND DIRECT-INJECTION SYSTEMS

OVERVIEW Many vehicles use gasoline direct injection and in some engines they also use a conventional port fuel injection system. The system combines direct-injection injectors located in the combustion chamber with port fuel injectors in the intake manifold near the intake valve. The two injection systems work together to supply the fuel needed by the engine. ● **SEE FIGURE 76–10**. for how the two systems are used throughout the various stages of engine operation.

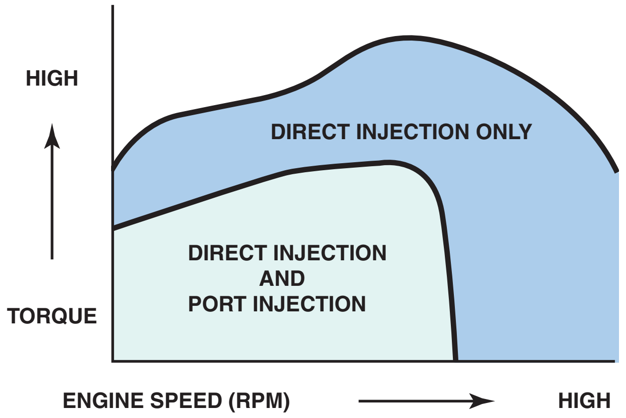

FIGURE 76–10 Notice that there are conditions when the port fuel injector, located in the intake manifold, and the gasoline direct injector, located in the cylinder, both operate to provide the proper air–fuel mixture.

COLD-START WARM-UP To help reduce exhaust emissions after a cold start, the fuel system uses a stratified charge mode. This results in a richer air–fuel mixture near the spark plug and allows for the spark to be retarded to increase the temperature of the exhaust. As a result of the increased exhaust temperature, the catalytic converter rapidly reaches operating temperature, which reduces exhaust emissions.

ENGINE START SYSTEM

An engine equipped with gasoline direct injection could use the system to start the engine. This is most useful during idle stop mode when the engine is stopped while the vehicle is at a traffic light to save fuel. The steps used in the Mazda start-stop system, called the *smart idle stop system (SISS)*, allow the engine to be started without a starter motor and include the following steps:

STEP 1 The engine is stopped. The normal stopping position of an engine when it stops is 70 degrees before top dead center, plus or minus 20 degrees. This is because the engine stops with one cylinder on the compression stroke and the PCM can determine the cylinder position, using the crankshaft and camshaft position sensors.

STEP 2 When a command is made to start the engine by the PCM, fuel is injected into the cylinder that is on the compression stroke and ignited by the spark plug.

STEP 3 The piston on the compression stroke is forced downward forcing the crankshaft to rotate counterclockwise or in the opposite direction to normal operation.

STEP 4 The rotation of the crankshaft forces the companion cylinder toward the top of the cylinder.

STEP 5 Fuel is injected and the spark plug is fired, forcing the piston down, causing the crankshaft to rotate in the normal (clockwise) direction. Normal combustion events continue allowing the engine to keep running.

GDI ISSUES

NOISE ISSUES GDI systems operate at high pressure and the injectors can often be heard with the engine running and the hood open. This noise can be a customer concern because the clicking sound is similar to noisy valves. If a noise issue is the customer concern, check the following:

- Check a similar vehicle to determine if the sound is louder or more noticeable than normal.
- Check that nothing under the hood is touching the fuel rail. If another line or hose is in contact with the fuel rail, the sound of the injectors clicking can be transmitted throughout the engine, making the sound more noticeable.
- Check for any technical service bulletins (TSBs) that may include new clips or sound insulators to help reduce the noise.

CARBON ISSUES Carbon is often an issue in engines equipped with GDI systems. Carbon can affect engine operation by accumulating in two places:

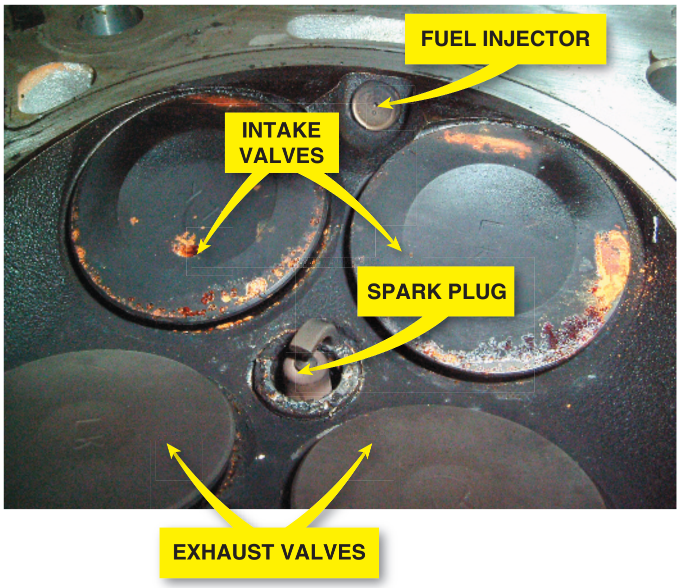

FIGURE 76–11 There may become a driveability issue because the GDI injector is exposed to combustion carbon and fuel residue.

- **On the injector itself.** Because the injector tip is in the combustion chamber, fuel residue can accumulate on the injector, reducing its ability to provide the proper spray pattern and amount of fuel. Some injector designs are more likely to be affected by carbon than others. For example, if the injector uses small holes, these tend to become clogged more than an injector that uses a single slit opening where the fuel being sprayed out tends to blast away any carbon. ● **SEE FIGURE 76–11**.
- **The backside of the intake valve.** This is a common place for fuel residue and carbon to accumulate on engines equipped with gasoline direct injection. The accumulation of carbon on the intake valve can become so severe that the engine will start and idle, but lack power to accelerate the vehicle. The carbon deposits restrict the airflow into the cylinder enough to decrease engine power.

NOTE: Engines that use both port fuel and GDI injectors do not show intake valve deposits. It is thought that the fuel being sprayed onto the intake valve from the port fuel injector helps keep the intake valve clean.

CARBON PREVENTION Most experts recommend the use of Techron®, a fuel system dispersant, to help keep carbon from accumulating. The use of a dispersant every six months or every 6,000 miles has proven to help prevent injector and intake valve deposits.

If the lack of power is discovered and there are no stored diagnostic trouble codes, a conventional carbon cleaning procedure will likely restore power if the intake valves are coated.

SERVICING PRECAUTIONS Because of the high pressures involved, it is important to adhere to safety precautions when working on GDI system which include the following:

- Don't reuse high-pressure lines. The ball-ends deform when tightened and will not seal if reused. ● **SEE FIGURE 76–12**.

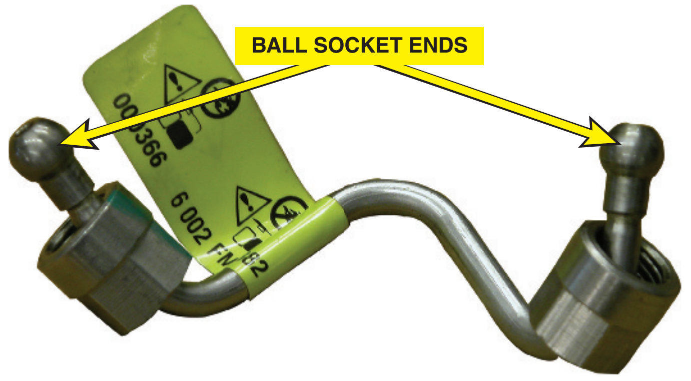

FIGURE 76–12 The high-pressure lines use a ball and socket connection. The ball end deforms when the line is tightened and must be replaced with a new part whenever it is removed.

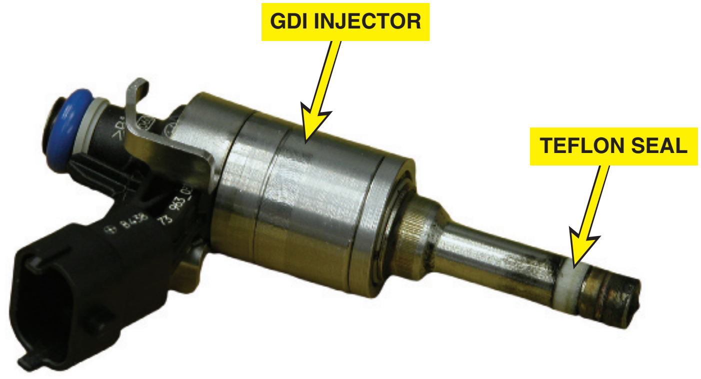

FIGURE 76–13 Whenever a GDI fuel injector is removed, a new Teflon seal must be installed to ensure a leak-free connection in the combustion chamber.

- Always use a torque wrench when tightening fuel line fittings.
- Do not loosen any fuel fittings with the engine cranking or running.
- Always replace the Teflon seal whenever replacing or reinstalling an GDI injector. ● **SEE FIGURE 76–13**.

Always check service information for the exact procedures to follow when working on a GDI system.

REVIEW QUESTIONS

1. What are two advantages of gasoline direct injection compared with port fuel injection?
2. What are two disadvantages of gasoline direct injection compared with port fuel injection?
3. How is the fuel delivery system different from a port fuel-injection system?
4. What are the basic modes of operation of a GDI system?
5. What should be replaced anytime it is removed from the high-pressure GDI fuel system?

CHAPTER QUIZ

1. Where is the fuel injected in an engine equipped with gasoline direct injection?
   - **a.** Into the intake manifold near the intake valve
   - **b.** Directly into the combustion chamber
   - **c.** Above the intake port
   - **d.** In the exhaust port
2. The fuel pump inside the fuel tank on a vehicle equipped with gasoline direct injection produces about what fuel pressure?
   - **a.** 5 to 10 PSI
   - **b.** 10 to 20 PSI
   - **c.** 20 to 40 PSI
   - **d.** 50 to 60 PSI
3. The high-pressure fuel pumps used in GDI systems are powered by _________.
   - **a.** electricity (DC motor)
   - **b.** electricity (AC motor)
   - **c.** the camshaft
   - **d.** the crankshaft
4. The high-pressure fuel pump pressure is regulated by using _________.
   - **a.** an electric pressure-control valve
   - **b.** a vacuum-biased regulator
   - **c.** a mechanical regulator at the inlet to the fuel rail
   - **d.** a non-vacuum biased regulator
5. A GDI equipped engine can _________.
   - **a.** be used to start the engine
   - **b.** be used without an ignition system
   - **c.** meet emissions standards without a catalytic converter
   - **d.** All of the above
6. The fuel injectors used on a GDI system are pulsed on using what voltage?
   - **a.** 12 to 14 volt
   - **b.** 50 to 90 volt
   - **c.** 100 to 110 volt
   - **d.** 200 to 220 volt
7. Which mode of operation results in a richer air–fuel mixture near the spark plug?
   - **a.** Stoichiometric
   - **b.** Homogeneous
   - **c.** Stratified
   - **d.** Knock protection
8. Some engines that use a GDI system have carbon issues _________.
   - **a.** on the intake valves
   - **b.** on the exhaust valves
   - **c.** on the fuel injectors
   - **d.** Both a and c
9. Why should any high-pressure line removed be replaced with a new part on a GDI system?
   - **a.** The ball-ends deform when tightened and will not seal if reused
   - **b.** The high-pressure lines are part of the high-pressure pump and must be replaced as an assembly
   - **c.** The torque needed to remove the lines causes the lines to be damaged
   - **d.** All of the above
10. A GDI-equipped engine may have specially shaped _________.
    - **a.** head bolts
    - **b.** pistons
    - **c.** valve guides
    - **d.** engine mounts

Chapter

77

ELECTRONIC THROTTLE CONTROL SYSTEM

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe electronic throttle control systems.
- Explain how an electronic throttle control system works.
- Describe the APP sensor.
- Describe the throttle body assembly.
- Describe TP sensors.
- Describe how to diagnose faults in an electronic throttle control system.
- Explain how to service an electronic throttle system.

KEY TERMS:

Accelerator pedal position (APP) sensor 909 • Coast-down stall 915 • Default position 911 • Drive-by-wire 909 • Electronic throttle control (ETC) 909 • Fail safe position 911 • Neutral position 911 • Servomotor 911 • Throttle position (TP) sensor 909

ELECTRONIC THROTTLE CONTROL (ETC) SYSTEM

ADVANTAGES OF ETC The absence of any mechanical linkage between the throttle pedal and the throttle body requires the use of an electric actuator motor. The electronic throttle system has the following advantages over the conventional cable:

- Eliminates the mechanical throttle cable, thereby reducing the number of moving parts.
- Eliminates the need for cruise control actuators and controllers.
- Helps reduce engine power for traction control (TC) and electronic stability control (ESC) systems.
- Used to delay rapid applications of torque to the transmission/transaxle to help improve driveability and to smooth shifts.
- Helps reduce pumping losses by causing the electronic throttle to open at highway speeds with greater fuel economy. The ETC opens the throttle to maintain engine and vehicle speed as the powertrain control module (PCM) leans the air–fuel ratio, retards ignition timing, and introduces additional exhaust gas recirculation (EGR) to reducing pumping losses.
- Used to provide smooth engine operation, especially during rapid acceleration.
- Eliminates the need for an idle air control valve.

The electronic throttle can be called **drive-by-wire**, but most vehicle manufacturers use the term **electronic throttle control (ETC)** to describe the system that opens the throttle valve electrically.

PARTS INVOLVED The typical ETC system includes the following components:

1. **Accelerator pedal position (APP) sensor,** also called *accelerator pedal sensor (APS)*
2. The electronic throttle actuator (servomotor), which is part of the electronic throttle body
3. A **throttle position (TP) sensor**
4. An electronic control unit, which is usually the PCM

● **SEE FIGURE 77–1**.

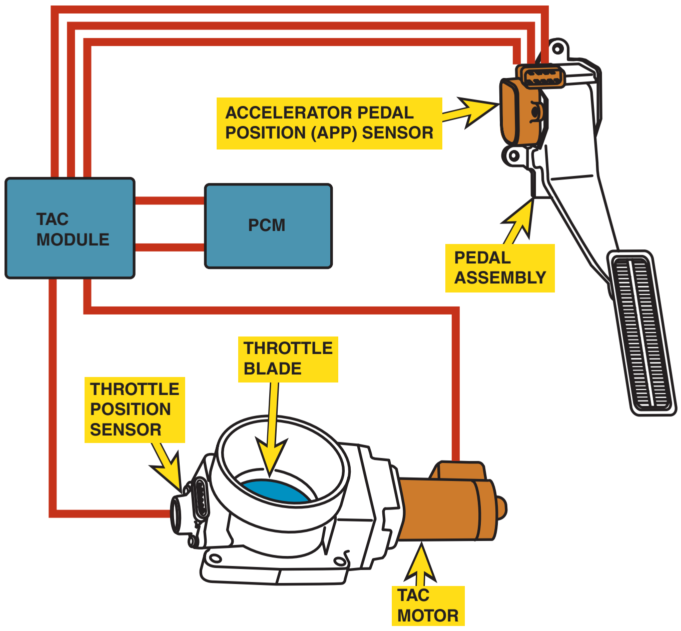

FIGURE 77–1 The throttle pedal is connected to the APP sensor. The electronic throttle body includes a throttle position sensor to provide throttle angle feedback to the vehicle computer. Some systems use a throttle actuator control (TAC) module to operate the throttle blade (plate).

NORMAL OPERATION OF THE ETC SYSTEM

Driving a vehicle equipped with an ETC system is about the same as driving a vehicle with a conventional mechanical throttle cable and throttle valve. However, the driver may notice some differences, which are to be considered normal. These normal conditions include the following:

- The engine may not increase above idle speed when depressing the accelerator pedal when the gear selector is in PARK.
- If the engine speed does increase when the accelerator is depressed with the transmission in PARK or NEUTRAL, the engine speed will likely be limited to less than 2,000 RPM.
- While accelerating rapidly, there is often a slight delay before the engine responds. ● **SEE FIGURE 77–2**.
- While at cruise speed, the accelerator pedal may or may not cause the engine speed to increase if the accelerator pedal is moved slightly.

APP SENSOR

CABLE-OPERATED SYSTEM Honda Accords until the 2008 model year used a cable attached to the accelerator pedal to operate the APP sensor located under the hood. A similar arrangement was used in Dodge RAM trucks in 2003. In both of these applications, the throttle cable was simply moving the APP sensor and not moving the throttle plate. The throttle plate is controlled by the PCM and moved by the ETC motor.

TWO SENSORS The APP sensor uses two and sometimes three separate sensors, which act together to give accurate accelerator pedal position information to the controller, but also are used to check that the sensor is working properly. The APP sensor uses two different signals. Both signals increase, but at different rates. The controller compares the signals with a look-up table to determine the pedal position. Using two or three signals improves redundancy should one sensor fail, and allows the PCM to quickly detect a malfunction. When three sensors are used, the third signal can either decrease or increase with pedal position, but its voltage range will still be different from the other two. ● **SEE FIGURE 77–3**.

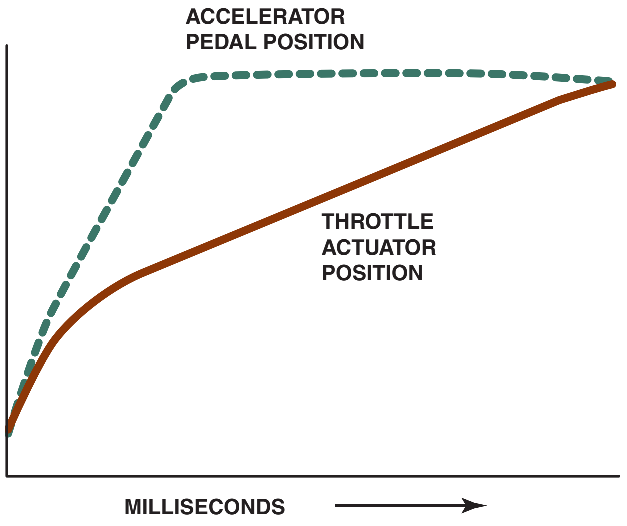

FIGURE 77–2 The opening of the throttle plate can be delayed as long as 30 milliseconds (0.030 sec) to allow time for the amount of fuel needed to catch up to the opening of the throttle plate.

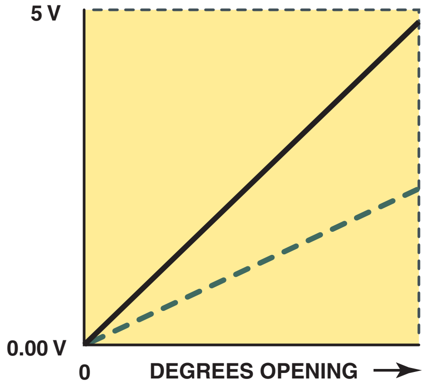

FIGURE 77–3 A typical APP sensor, showing two different output voltage signals that are used by the PCM to determine accelerator pedal position. Two (or three in some applications) are used as a double check because this is a safety-related sensor.

THROTTLE BODY ASSEMBLY

PARTS INCLUDED The throttle body assembly contains the following components:

- Throttle plate
- Electric actuator DC motor
- Dual TP sensors

- Gears used to multiply the torque of the DC motor
- Springs used to hold the throttle plate in the default location

THROTTLE PLATE AND SPRING The throttle plate is held slightly open by a concentric clock spring. The spring applies a force that will close the throttle plate if power is lost to the actuator motor. The spring is also used to open the throttle plate slightly from the fully closed position.

ELECTRONIC THROTTLE BODY MOTOR The actuator is a DC electric motor and is often called a **servomotor**. The throttle plate is held in a **default position** by a spring inside the throttle body assembly. This partially open position, also called the **neutral position** or the **fail safe position**, is about 16% to 20% open. This default position varies, depending on the vehicle and usually results in an engine speed of 1,200 to 1,500 RPM.

- The throttle plate is driven closed to achieve speeds lower than the default position, such as idle speed.
- The throttle plate is driven open to achieve speeds higher than the default position, such as during acceleration. ● **SEE FIGURE 77–4**.

FREQUENTLY ASKED QUESTION

What Is the "Spring Test"?

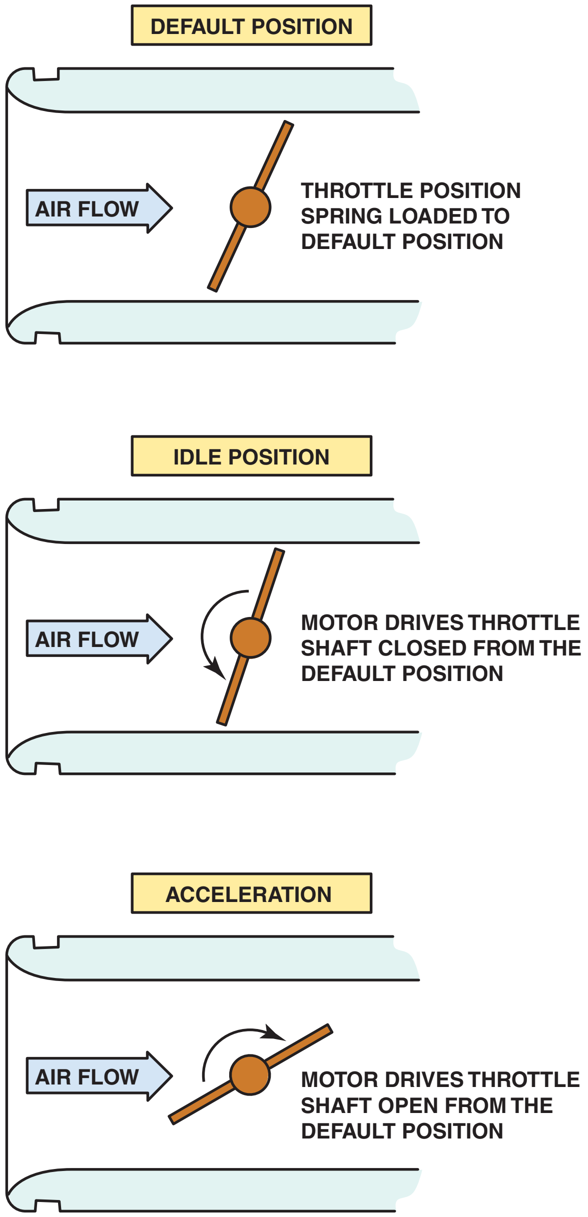
The spring test is a self-test performed by the PCM whenever the engine is started. The PCM operates the throttle to check if it can react to the command and return to the default (home) position. This self-test is used by the PCM to determine that the spring and motor are working correctly and may be noticed by some vehicle owners by the following factors:

- A slight delay in the operation of the starter motor. It is when the ignition is turned to the on position that the PCM performs the test. While it takes just a short time to perform the test, it can be sensed by the driver that there could be a fault in the ignition switch or starter motor circuits.
- A slight "clicking" sound may also be heard coming from under the hood when the ignition is turned on. This is normal and is related to the self-test on the throttle as it opens and closes.

FREQUENTLY ASKED QUESTION

Why Not Use a Stepper Motor for ETC?

A stepper motor is a type of motor that has multiple windings and is pulsed by a computer to rotate a certain number of degrees when pulsed. The disadvantage is that a stepper motor is too slow to react compared with a conventional DC electric motor and is the reason a stepper motor is not used in ETC systems.



DEFAULT POSITION
AIR FLOW
THROTTLE POSITION SPRING LOADED TO DEFAULT POSITION
IDLE POSITION
AIR FLOW
MOTOR DRIVES THROTTLE SHAFT CLOSED FROM THE DEFAULT POSITION
ACCELERATION
AIR FLOW
MOTOR DRIVES THROTTLE SHAFT OPEN FROM THE DEFAULT POSITION

FIGURE 77–4 The default position for the throttle plate is in slightly open position. The servomotor then is used to close it for idle and open it during acceleration.

The throttle plate motor is driven by a bidirectional pulse-width modulated (PWM) signal from the PCM or ETC module using an H-bridge circuit. ● **SEE FIGURE 77–5**.

The H-bridge circuit is controlled by the PMC by the following:

- Reversing the polarity of power and ground brushes to the DC motor
- Pulse-width modulating the current through the motor

The PCM monitors the position of the throttle from the two TP sensors. The PCM then commands the throttle plate to the desired position. ● **SEE FIGURE 77–6**.

THROTTLE POSITION (TP) SENSOR

PURPOSE AND FUNCTION Two throttle position sensors are used in the throttle body assembly to provide throttle position signals to the PCM. Two sensors are used as a fail-safe measure

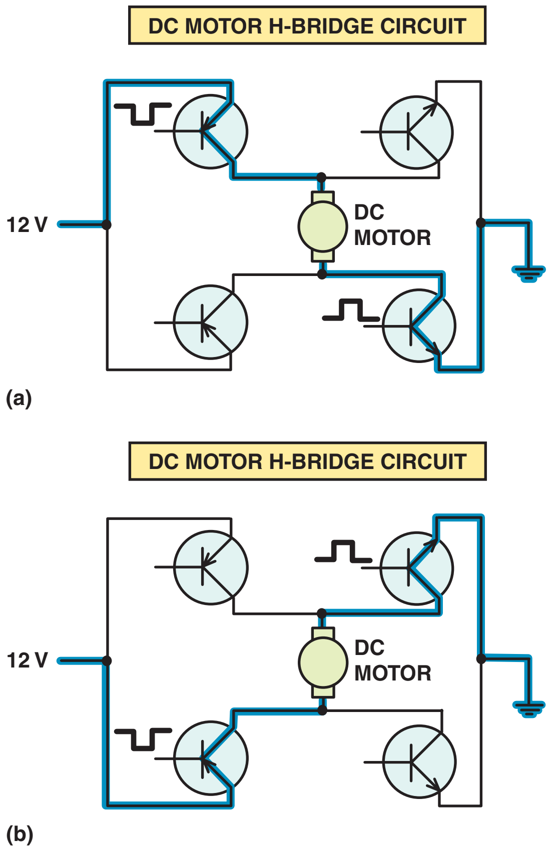


FIGURE 77–5 (a) An H-bridge circuit is used to control the direction of the DC electric motor of the ETC unit. (b) To reverse the direction of operation, the polarity of the current through the motor is reversed.

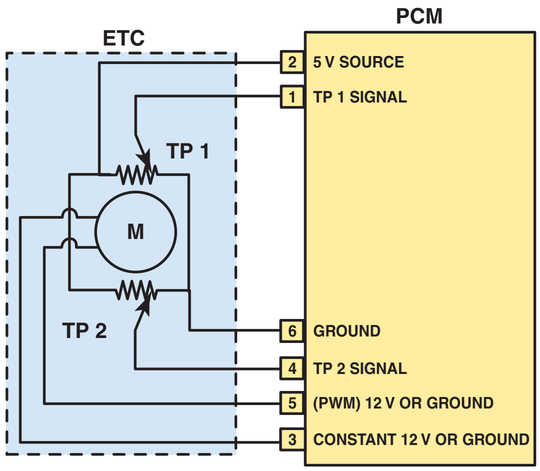

FIGURE 77–6 Schematic of a typical ETC system. Note that terminal #5 is always PWM and that terminal #3 is always constant, but both power and ground are switched to change the direction of the motor.

and for diagnosis. There are two types of TP sensors used in ETC systems: potentiometers and Hall-effect.

THREE-WIRE POTENTIOMETER SENSORS These sensors use a 5-volt reference from the PCM and produce an analog (variable) voltage signal that is proportional to the throttle plate position. The two sensors produce opposite signals as the throttle plate opens:

- One sensor starts at low voltage (about 0.5 volt) and increases as the throttle plate is opened.

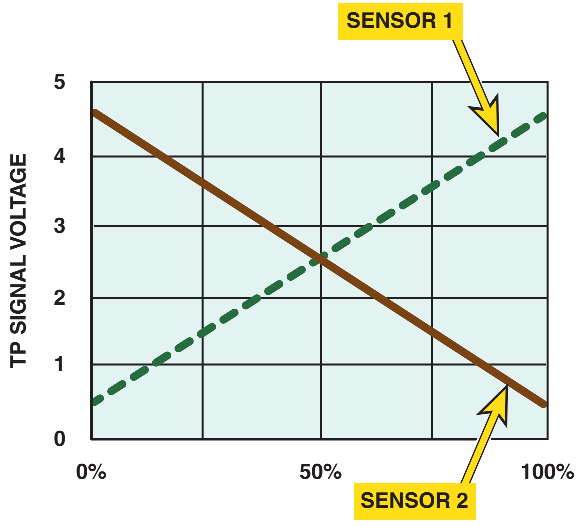

FIGURE 77–7 The two TP sensors used on the throttle body of an electronic throttle body assembly produce opposite voltage signals as the throttle is opened. The total voltage of both combined at any throttle plate position is 5 volts.

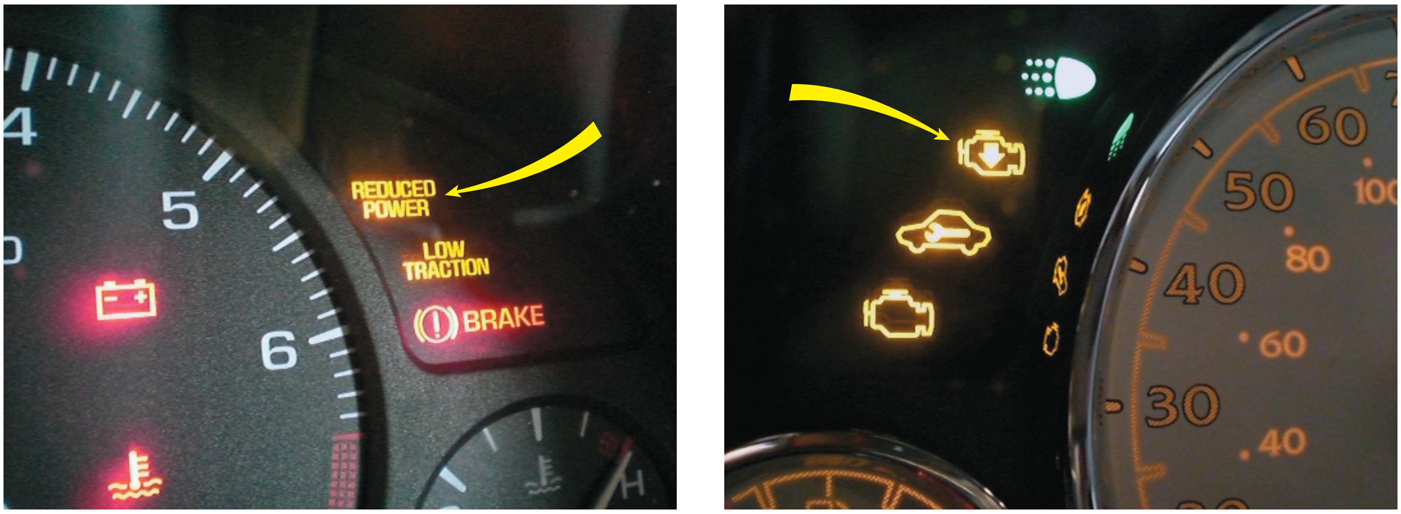
- The second sensor starts at a higher voltage (about 4.5 volt) and produces a lower voltage as the throttle plate is opened. ● **SEE FIGURE 77–7**.

HALL-EFFECT TP SENSORS Some vehicle manufacturers, such as Honda use a noncontact Hall-effect TP sensor. Because there is no physical contact, this type of sensor is less likely to fail due to wear.

DIAGNOSIS OF ETC SYSTEMS

FAULT MODE ETC systems can have faults like any other automatic system. Due to the redundant sensors in APP sensors and throttle position sensor, many faults result in a "limp home" situation instead of a total failure. The limp home mode is also called the "fail-safe mode" and indicates the following actions performed by the PCM:

- Engine speed is limited to the default speed (about 1,200 to 1,600 RPM).
- There is slow or no response when the accelerator pedal is depressed.
- The cruise control system is disabled.
- A diagnostic trouble code (DTC) is set.
- An ETC warning lamp on the dash will light. The warning lamp may be labeled differently, depending on the vehicle manufacturer. For example,
  - **General Motors vehicle**—Reduced power lamp (● **SEE FIGURE 77–8)**
  - **Ford**—Wrench symbol (amber or green) (● **SEE FIGURE 77–9)**
  - **Chrysler**—Red lightning bolt symbol (● **SEE FIGURE 77–10)**
- The engine will run and can be driven slowly. This limp-in mode operation allows the vehicle to be driven off of the road and to a safe location.



(a) (b)

FIGURE 77–8 (a) A "reduced power" warning light indicates a fault with the ETC system on some General Motors vehicles. (b) A symbol showing an engine with an arrow pointing down is used on some General Motors vehicles to indicate a fault with the ETC system.

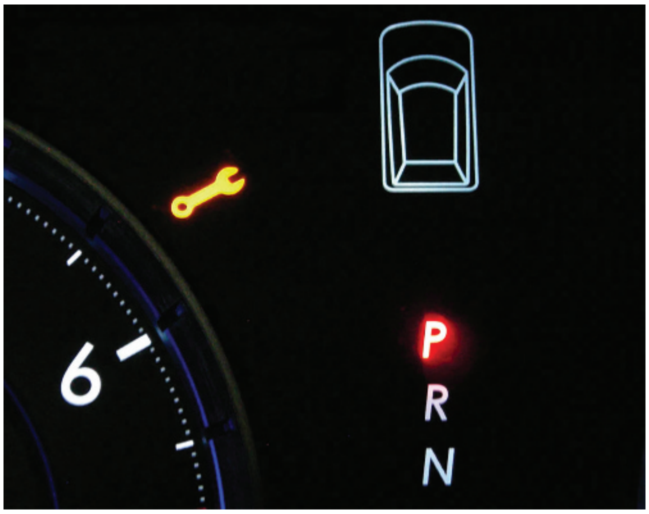


FIGURE 77–9 A wrench symbol warning lamp on a Ford vehicle. The symbol can also be green.

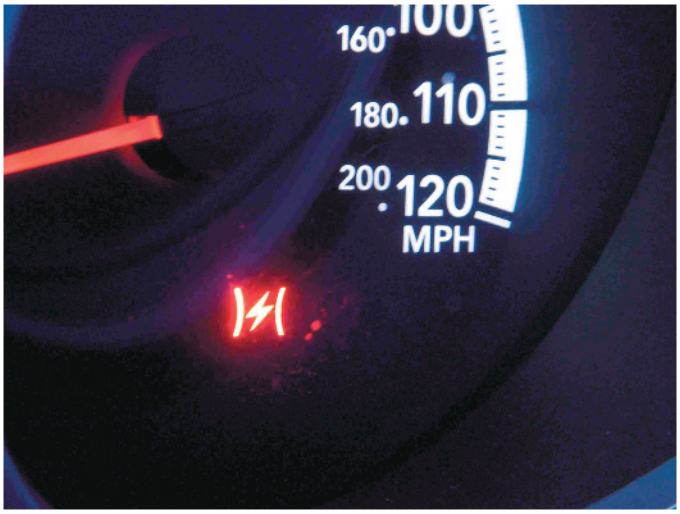

FIGURE 77–10 A symbol used on a Chrysler vehicle indicating a fault with the ETC.

FREQUENTLY ASKED QUESTION

How Do You Calibrate a New APP Sensor?

Whenever an APP sensor is replaced, it should be calibrated before it will work correctly. Always check service information for the exact procedure to follow after APP sensor replacement. Here is a typical example of the procedure:

STEP 1 Make sure the accelerator pedal is fully released.

STEP 2 Turn the ignition switch on (engine off) and wait at least 2 seconds.

STEP 3 Turn the ignition switch off and wait at least 10 seconds.

STEP 4 Turn the ignition switch on (engine on) and wait at least 2 seconds.

STEP 5 Turn the ignition switch off and wait at least 10 seconds.

The ETC may enter the limp-in mode if any of the following has occurred:

- Low battery voltage has been detected
- PCM failure
- One TP and the MAP sensors have failed
- Both TP sensors have failed
- The ETC actuator motor has failed
- The ETC throttle spring has failed

VACUUM LEAKS The ETC system is able to compensate for many vacuum leaks. A vacuum leak at the intake manifold, for example, will allow air into the engine that is not measured by the mass airflow sensor. The ETC system will simply move the throttle as needed to achieve the proper idle speed to compensate for the leak.

DIAGNOSTIC PROCEDURE If a fault occurs in the ETC system, check service information for the specified procedure to follow for the vehicle being checked. Most vehicle service information includes the following steps:

STEP 1 Verify the customer concern.

STEP 2 Use a factory scan tool or an aftermarket scan tool with original equipment capability and check for DTCs.

STEP 3 If there are stored ETCs, follow service information instructions for diagnosing the system.

STEP 4 If there are no stored ETCs, check scan tool data for possible fault areas in the system.

SCAN TOOL DATA Scan data related to the ETC system can be confusing. Typical data and the meaning include the following:

- **APP indicated angle.** The scan tool will display a percentage ranging from 0% to 100%. When the throttle is released, the indicated angle should be 0%. When the throttle is depressed to wide open, the reading should indicate 100%.

CASE STUDY

The High Idle Toyota

The owner of a Toyota Camry complained that the engine would idle at over 1,200 RPM compared with a normal 600 to 700 RPM. The vehicle would also not accelerate. Using a scan tool, a check for DTCs showed one code: P2101—"TAC motor circuit low."

Checking service information led to the inspection of the ETC throttle body assembly. With the ignition key out of the ignition and the inlet air duct off the throttle body, the technician used a screwdriver to see if the throttle plate worked.

Normal operation—The throttle plate should move and then spring back quickly to the default position.

Abnormal operation—If the throttle plate stays where it is moved or does not return to the default position, there is a fault with the throttle body assembly. ● **SEE FIGURE 77–11**.

The technician replaced the throttle body assembly with an updated version and proper engine operation was restored. The technician disassembled the old throttle body and found it was corroded inside due to moisture entering the unit through the vent hose. ● **SEE FIGURE 77–12**.

Summary:

Complaint—Customer stated that the engine would idle at over 2,000 RPM.

Cause—A stored P2101 DTC was stored indicating a fault with the throttle body assembly.

Correction—The throttle body was replaced with an improved version that placed the vent tube in a different position to help avoid water getting into the assembly.

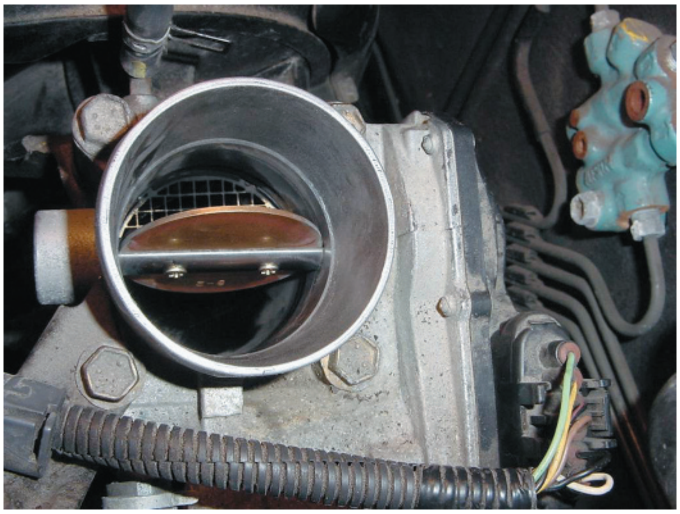

FIGURE 77–11 The throttle plate stayed where it was moved, which indicates that there is a problem with the electronic throttle body control assembly.

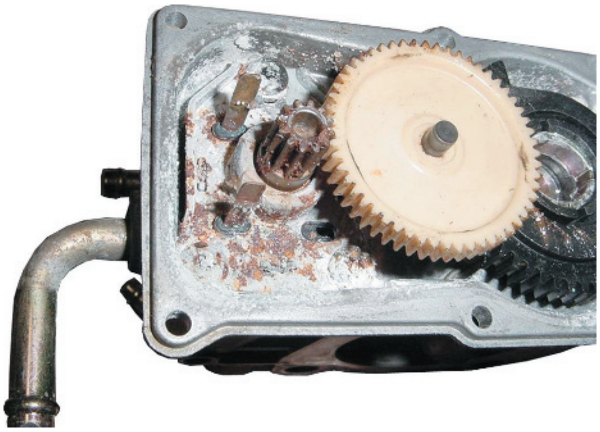

FIGURE 77–12 A corroded ETC assembly shown with the cover removed.

- **TP desired angle.** The scan tool will display a percentage ranging from 0% to 100%. This represents the desired throttle angle as commanded by the driver of the vehicle.
- **TP indicated angle.** The TP indicated angle is the angle of the measured throttle opening and it should agree with the TP desired angle.
- **TP sensors 1 and 2.** The scan tool will display "agree" or "disagree." If the PCM or TAC module receives a voltage signal from one of the TP sensors that is not in the proper relationship to the other TP sensor, the scan tool will display *disagree*.

ETC THROTTLE FOLLOWER TEST On some vehicles, such as many Chrysler vehicles, the operation of the ETC can be tested using a factory or factory-level scan tool. To perform this test, use the "throttle follower test" procedure as shown on the scan tool. An assistant is needed to check that the throttle plate is moving as the accelerator pedal is depressed. This test cannot be done normally because the PCM does not normally allow the throttle plate to be moved unless the engine is running.

SERVICING ELECTRONIC THROTTLE SYSTEMS

ETC-RELATED PERFORMANCE ISSUES The only service that an ETC system may require is a cleaning of the throttle body. Throttle body cleaning is a routine service procedure on port fuel-injected engines and is still needed when the throttle is being opened by an electric motor rather than a throttle cable tied to a mechanical accelerator pedal. The throttle body may need cleaning if one or more of the following symptoms are present:

- Lower than normal idle speed
- Rough idle
- Engine stalls when coming to a stop (called a **coast-down stall**)

If any of the above conditions exists, a throttle body cleaning will often correct these faults.

CAUTION: Some vehicle manufacturers add a nonstick coating to the throttle assembly and warn that cleaning could remove this protective coating. Always follow the vehicle manufacturer's recommended procedures.

THROTTLE BODY CLEANING PROCEDURE Before attempting to clean a throttle body on an engine equipped with an ETC system, be sure that the ignition key is out of the vehicle and the ready light is off if working on a Toyota/Lexus hybrid electric vehicle to avoid the possibility of personal injury.

To clean the throttle, perform the following steps:

STEP 1 With the ignition off and the key removed from the ignition, remove the air inlet hose from the throttle body.

STEP 2 Spray throttle body cleaner onto a shop cloth.

STEP 3 Open the throttle body and use the shop cloth to remove the varnish and carbon deposits from the throttle body housing and throttle plate.

CAUTION: Do not spray cleaner into the throttle body assembly. The liquid cleaner could flow into and damage the TP sensors.

WARNING

The electric motor that operates the throttle plate is strong enough to cut off a finger. ● **SEE FIGURE 77–13**.

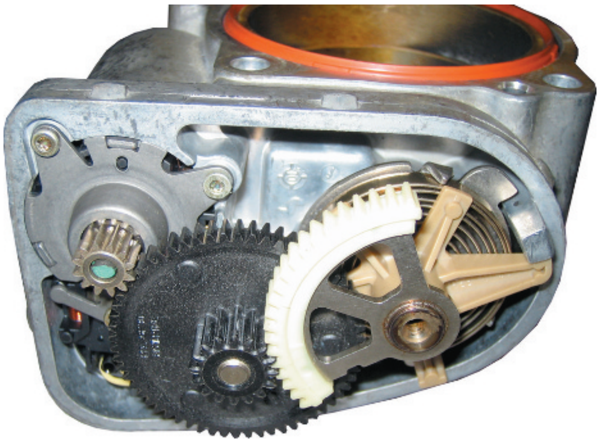

FIGURE 77–13 Notice the small motor gear on the left drives a larger plastic gear (black), which then drives the small gear in mesh with the section of a gear attached to the throttle plate. This results in a huge torque increase from the small motor and helps explain why it could be dangerous to insert a finger into the throttle body assembly.

STEP 4 Reinstall the inlet hose being sure that there are no air leaks between the hose and the throttle body assembly.

STEP 5 Start the engine and allow the PCM to learn the correct idle. If the idle is not correct, check service information for the specified procedures to follow to perform a throttle relearn.

THROTTLE BODY RELEARN PROCEDURE When installing a new throttle body or PCM or sometimes after cleaning the throttle body, the throttle position has to be learned by the PCM. After the following conditions have been met, a typical throttle body relearn procedure for a General Motors vehicle includes the following:

- Accelerator pedal released
- Battery voltage higher than 8 volts
- Vehicle speed must be zero
- Engine coolant temperature (ECT) higher than 40°F (5°C) and lower than 212°F (100°C)
- Intake air temperature (IAT) higher than 40°F (5°C)
- No throttle DTCs set

If all of the above conditions are met, perform the following steps:

STEP 1 Turn the ignition on (engine off) for 30 seconds.

STEP 2 Turn the ignition off and wait 30 seconds.

Start the engine and the idle learn procedure should cause the engine to idle at the correct speed.

REVIEW QUESTIONS

1. What parts can be deleted if an engine uses an ETC system instead of a conventional accelerator pedal and cable to operate the throttle valve?
2. How can the use of an ETC system improve fuel economy?
3. How is the operation of the throttle different on a system that uses an ETC system compared with a conventional mechanical system?
4. What component parts are included in an ETC system?
5. What is the default or limp-in position of the throttle plate?

CHAPTER QUIZ

1. The use of an ETC system allows the elimination of all *except* __________.
   - a. accelerator pedal
   - b. mechanical throttle cable (most systems)
   - c. cruise control actuator
   - d. idle air control
2. To what extent is the throttle plate spring loaded to hold the throttle slightly open?
   - a. 3% to 5%
   - b. 8% to 10%
   - c. 16% to 20%
   - d. 22% to 28%
3. What type of electric motor is the throttle plate actuator motor?
   - a. Stepper motor
   - b. DC motor
   - c. AC motor
   - d. Brushless motor
4. The actuator motor is controlled by the PCM through what type of circuit?
   - a. Series
   - b. Parallel
   - c. H-bridge
   - d. Series-parallel
5. When does the PCM perform a self-test of the ETC system?
   - a. During cruise speed when the throttle is steady
   - b. During deceleration
   - c. During acceleration
   - d. When the ignition switch is first rotated to the on position before the engine starts
6. What type is the throttle position sensor used in the throttle body assembly of an ETC system?
   - a. A single potentiometer
   - b. Two potentiometers that read in the opposite direction
   - c. A Hall-effect sensor
   - d. Either b or c
7. A green wrench symbol is displayed on the dash. What does this mean?
   - a. A fault in the ETC in a Ford vehicle has been detected
   - b. A fault in the ETC in a Honda vehicle has been detected
   - c. A fault in the ETC in a Chrysler vehicle has been detected
   - d. A fault in the ETC in a General Motors vehicle has been detected
8. A technician is checking the operation of the ETC system by depressing the accelerator pedal with the ignition in the on (run) position (engine off). What is the most likely result if the system is functioning correctly?
   - a. The throttle goes to wide open when the accelerator pedal is depressed all the way
   - b. No throttle movement
   - c. The throttle will open partially but not all of the way
   - d. The throttle will perform a self-test by closing and then opening to the default position
9. With the ignition off and the key out of the ignition, what should happen if a technician uses a screwdriver and pushes on the throttle plate in an attempt to open the valve?
   - a. Nothing. The throttle should be kept from moving by the motor, which is not energized with the key off.
   - b. The throttle should move and stay where it is moved and not go back unless moved back.
   - c. The throttle should move, and spring back to the home position when released.
   - d. The throttle should move closed, but not open further than the default position.
10. The throttle body may be cleaned (if recommended by the vehicle manufacturer) if what conditions are occurring?
    - a. Coast-down stall
    - b. Rough idle
    - c. Lower-than-normal idle speed
    - d. Any of the above

Chapter 78

FUEL-INJECTION SYSTEM DIAGNOSIS AND SERVICE

LEARNING OBJECTIVES:

After studying this chapter, the reader will be able to:

- Explain fuel-injection system diagnosis including scan tool diagnosis.
- Describe how to test for an injector pulse.
- Describe how to check fuel-injection resistance.
- Describe the pressure-drop balance test.
- Describe injection voltage-drop tests.
- Describe scope-testing fuel injectors.
- Describe how to service the fuel-injection system.

KEY TERMS:

Noid light 918 • Peak-and-hold injector 921 • Saturation 921

FUEL-INJECTION SYSTEM DIAGNOSIS

VISUAL INSPECTION All fuel-injection systems require the proper amount of clean fuel delivered to the system at the proper pressure and the correct amount of filtered air. The following items should be carefully inspected before proceeding to more detailed tests:

- Check the air filter and replace as needed.
- Check the air induction system for obstructions.
- Check the conditions of all vacuum hoses. Replace any hose that is split, soft (mushy), or brittle.

DIAGNOSTIC STEPS To determine if a port fuel-injection system—including the fuel pump, injectors, and fuel-pressure regulator—is operating correctly, take the following steps:

1. Attach a fuel-pressure gauge to the Schrader valve on the fuel rail. ● **SEE FIGURE 78–1**.
2. Turn the ignition key on or start the engine to build up the fuel-pump pressure (to about 35 to 45 PSI).

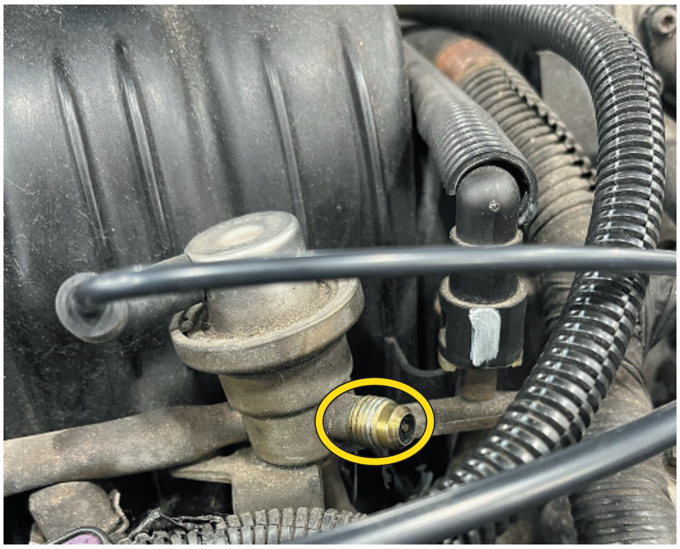

FIGURE 78–1 A fuel pressure gauge can be connected to many older fuel injection systems at the threaded port on the fuel rail.

3. Wait 20 minutes and observe the fuel pressure retained in the fuel rail and note the PSI reading. The fuel pressure should not drop more than 20 PSI (140 kPa) in 20 minutes. If the drop is less than 20 PSI in 20 minutes, everything is

okay; if the drop is *greater,* there is a possible problem with the following:

- The check valve in the fuel pump
- Injectors, lines, or fittings
- A fuel-pressure regulator

To determine which unit is defective, perform the following:

- Reenergize the electric fuel pump.
- Clamp the fuel *supply* line, and wait 10 minutes (see CAUTION). If the pressure drop does not occur, replace the fuel pump. If the pressure drop still occurs, continue with the next step.
- Repeat the pressure buildup of the electric pump and clamp the fuel return line. If the pressure drop time is now okay, replace the fuel-pressure regulator.
- If the pressure drop still occurs, one or more of the injectors is leaking. Remove the injectors with the fuel rail and hold over paper. Replace those injectors that drip one or more drops after 10 minutes with pressurized fuel.

CAUTION: Do not clamp plastic fuel lines. Connect shutoff valves to the fuel system to shut off supply and return lines. ● **SEE FIGURE 78–2**.

FUEL-SYSTEM SCAN TOOL DIAGNOSTICS Diagnosing a faulty fuel system can be a difficult task. However, it can be made easier by utilizing the information available via the serial data stream. By observing the long-term fuel trim and the short-term fuel trim, a determination can be made on how the fuel system is performing. Short-term fuel trim and long-term fuel trim can help zero in on specific areas of trouble. Readings should be taken at idle and at 3,000 RPM. **SEE CHART 78–1**.

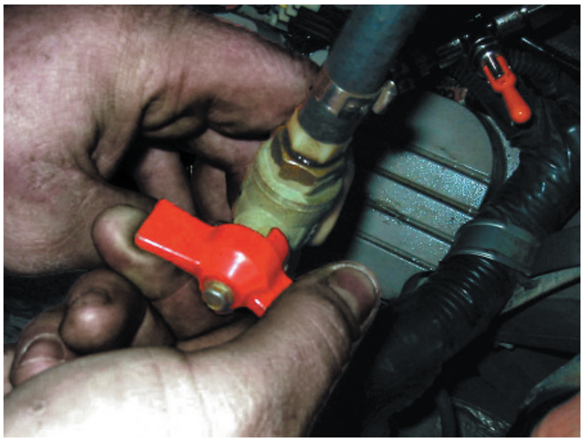

FIGURE 78–2 Shutoff valves must be used on vehicles equipped with plastic fuel lines to isolate the cause of a pressure drop in the fuel system.

Condition	Long-Term Fuel Trim at Idle	Long-Term Fuel Trim at 3000 RPM
System normal	0% ± 10%	0% ± 10%
Vacuum leak	HIGH	OK
Fuel flow problem	OK	HIGH
Low fuel pressure	HIGH	HIGH
High fuel pressure	*OK or LOW	*OK or LOW

*High fuel pressure will affect trim at idle, at 3000 RPM, or both.

CHART 78–1

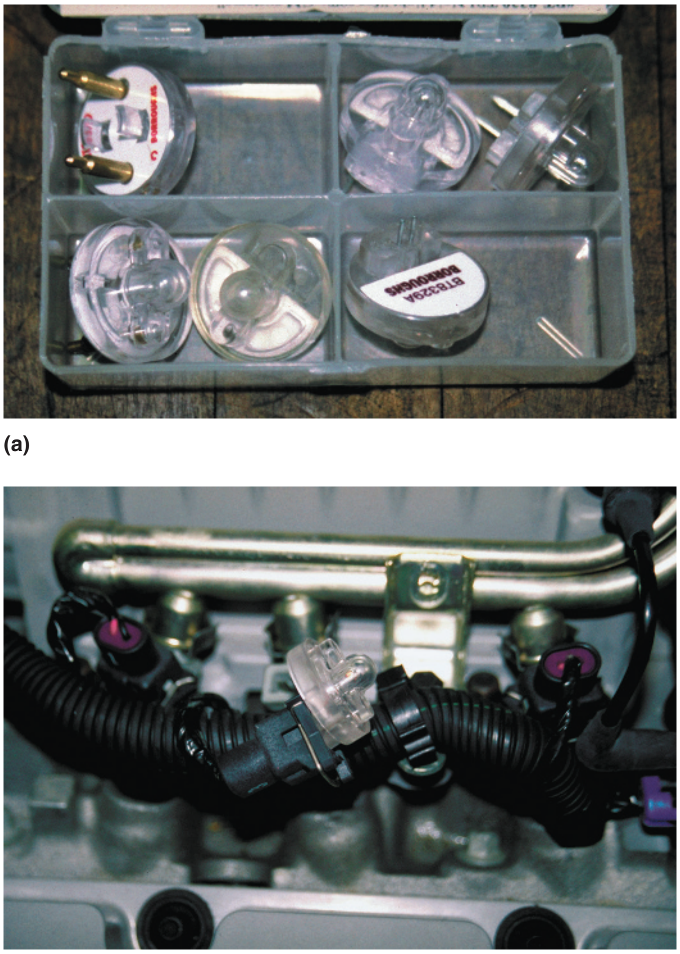
Fuel trim levels and possible causes if not within 10%.

TESTING FOR AN INJECTOR PULSE

One of the first checks that should be performed when diagnosing a no-start condition is whether the fuel injectors are being pulsed by the computer. Checking for proper pulsing of the injector is also important in diagnosing a weak or dead cylinder.

A **noid light** is designed to electrically replace the injector in the circuit and to flash if the injector circuit is working correctly. ● **SEE FIGURE 78–3**. To use a noid light, disconnect the electrical connector at the fuel injector and plug the noid light into the injector harness connections. Crank or start the engine. The noid light should flash regularly.

NOTE: The term *noid* is simply an abbreviation of the word *solenoid*. Injectors use a movable iron core and are therefore solenoids. Therefore, a noid light is a replacement for the solenoid (injector).



(a)

(b)

FIGURE 78–3 (a) Noid lights are usually purchased as an assortment so that one is available for any type or size of injector wiring connector. (b) The connector is unplugged from the injector and a noid light is plugged into the injector connector. The noid light should flash when the engine is being cranked if the power circuit and the pulsing to ground by the computer are functioning okay.

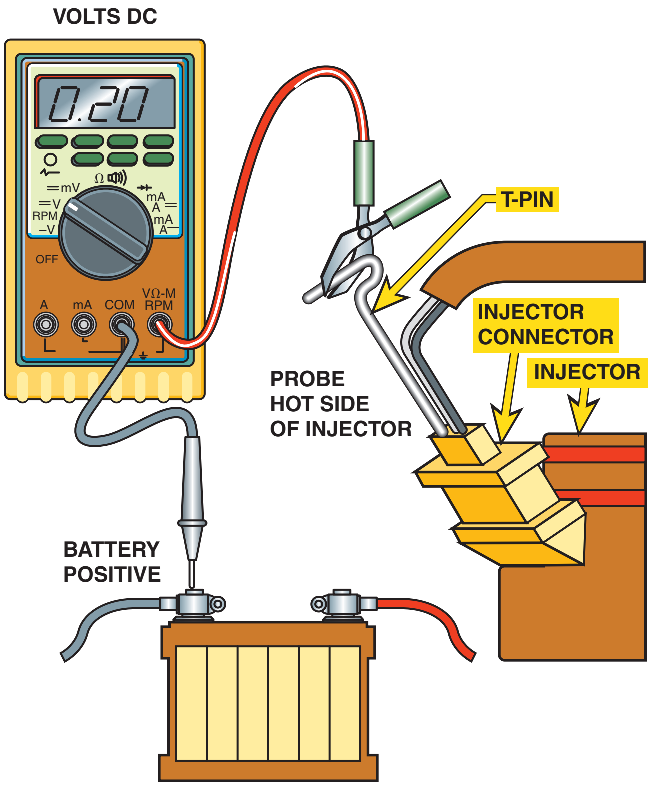


FIGURE 78–4 Use a DMM set to read DC volts to check the voltage drop of the positive circuit to the fuel injector. A reading of 0.5 volt or less is generally considered to be acceptable.

Possible noid light problems and causes include the following:

1. **The light is off and does not flash.** The problem is an open in either the power side or ground side (or both) of the injector circuit.
2. **The noid light flashes dimly.** A dim noid light indicates excessive resistance or low voltage available to the injector. Both the power and ground side must be checked.
3. **The noid light is on and does not flash.** If the noid light is on, both a power and a ground are present. Because the light does not flash (blink) when the engine is being cranked or started, a short-to-ground fault exists either in the computer itself or in the wiring between the injector and the computer.

CAUTION: A noid lamp must be used with caution. The computer may show a good noid light operation and have low supply voltage. ● **SEE FIGURE 78–4.**

CHECKING FUEL-INJECTOR RESISTANCE

Each port fuel injector must deliver an equal amount of fuel or the engine will idle roughly or perform poorly.

The electrical balance test involves measuring the injector coil-winding resistance. For best engine operation, all injectors should have the same electrical resistance. To measure the resistance, carefully release the locking feature of the connector and remove the connector from the injector.

NOTE: Some engines require specific procedures to gain access to the injectors. Always follow the manufacturers' recommended procedures.

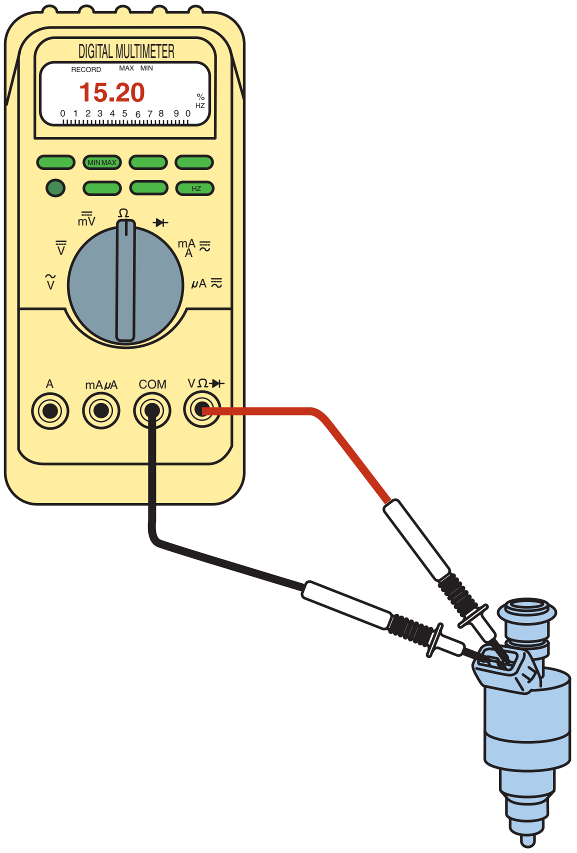

FIGURE 78–5 Connections and settings necessary to measure fuel-injector resistance.

With an ohmmeter, measure the resistance across the injector terminals. Be sure to lowest ohmmeter setting of the digital ohmmeter to read in tenths (0.1) of an ohm. ● **SEE FIGURES 78–5 AND 78–6.** Check service information for the resistance specification of the injectors. Measure the resistance of all of the injectors. Replace any injector that does not fall within the resistance range of the specification. The resistance of the injectors should be measured twice—once when the engine (and injectors) are cold and once after the engine has reached normal operating temperature. If any injector measures close to specification, make certain that the terminals of the injector are electrically sound, and perform other tests to confirm an injector problem before replacement.

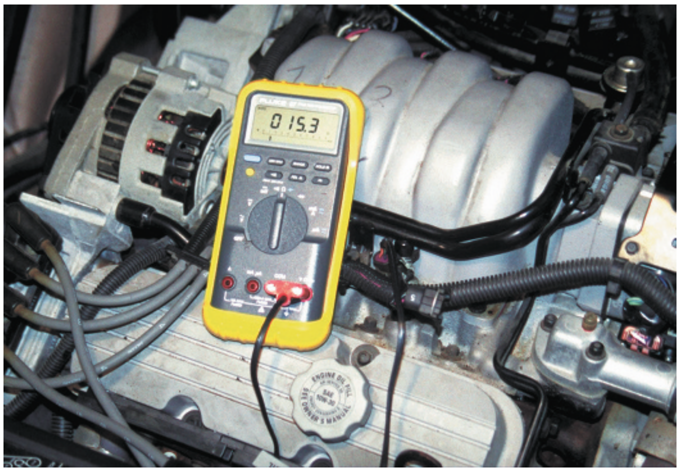

FIGURE 78–6 To measure fuel-injector resistance, a technician constructed a short wiring harness with a double banana plug that fits into the V and COM terminals of the meter and an injector connector at the other end. This setup makes checking resistance of fuel injectors quick and easy.

TYPICAL RESISTANCE VALUES There are two basic types of injectors, which have an effect on their resistance, including the following:

1. **Low-resistance injectors.** The features of a low-resistance injectors include the following:
    - Uses a "peak and hold" type firing where a high current, usually about 4 amperes, is used to open the injector, then it is held open by using a lower current, which is usually about 1 ampere.
    - All throttle body injection (TBI) injectors and some port fuel injectors are low-resistance injectors and are fired using a peak-and-hold circuit by the PCM.
    - The resistance value of a peak-and-hold-type injector is usually 1.5 to 4.0 ohms.
2. **Higher-resistance injectors.** The features of a higher-resistance injectors include the following:
    - Uses a constant low current, usually 1 ampere, to open the injector.
    - Is called a "saturated" type of injector because the current flows until the magnetic field is strong enough to open the injector.
    - Most port fuel injectors are of the saturated type.
    - The resistance value of a saturated injector is usually 12 to 16 ohms.

PRESSURE-DROP BALANCE TEST

The pressure balance test involves using an electrical timing device to pulse the fuel injectors on for a given amount of time, usually 500 milliseconds or 0.5 seconds, and observing the drop in pressure that accompanies the pulse. If the *fuel flow* through each injector is equal, the drop in pressure in the system will be equal. Most manufacturers recommend that the pressures be within about 1.5 PSI (10 kPa) of each other for satisfactory engine performance. This test method not only tests the electrical functioning of the injector (for definite time and current pulse), but also tests for mechanical defects that could affect fuel flow amounts.

The purpose of running this injector balance test is to determine which injector is restricted, inoperative, or delivering fuel differently than the other injectors. Replacing a complete set of injectors can be expensive. The basic tools needed are the following:

- Accurate pressure gauge with pressure relief
- Injector pulser with time control
- Necessary injector connection adapters
- Safe receptacle for catching and disposing of any fuel released

STEP 1 Attach the pressure gauge to the fuel delivery rail on the supply side. Make sure the connections are safe and leakproof.

STEP 2 Attach the injector pulser to the first injector to be tested.

STEP 3 Turn the ignition key to the on position to prime the fuel rail. Note the static fuel-pressure reading. ● **SEE FIGURE 78–8.**

STEP 4 Activate the pulser for the timed firing pulses.

STEP 5 Note and record the new static rail pressure after the injector has been pulsed.

STEP 6 Reenergize the fuel pump and repeat this procedure for all of the engine injectors.

STEP 7 Compare the two pressure readings and compute the pressure drop for each injector. Compare the pressure drops of the injectors to each other. Any variation in pressure drops will indicate an uneven fuel delivery rate between the injectors.

For example,

Injector	1	2	3	4	5	6
Initial pressure	40	40	40	40	40	40
Second pressure	30	30	35	30	20	30
Pressure drop	10	10	5	10	20	10
Possible problem	OK	OK	Restriction	OK	Leak	OK

TECH TIP

Equal Resistance Test

All fuel injectors should measure the specified resistance. However, the specification often indicates the temperature of the injectors be at room temperature and of course will vary according to the temperature. Rather than waiting for all of the injectors to achieve room temperature, measure the resistance and check that they are all within 0.4 ohm of each other. To determine the difference, record the resistance of each injector and subtract the lowest resistance reading from the highest resistance reading to get the difference. If more than 0.4 ohm, then further testing will be needed to verify defective injector(s). ● **SEE FIGURE 78–7.**

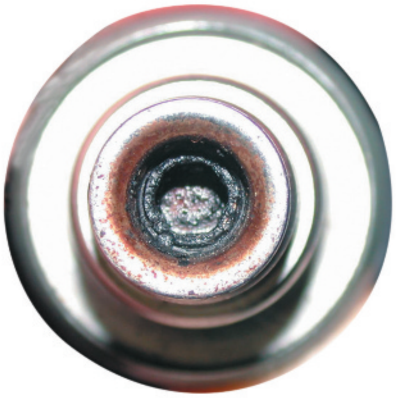

FIGURE 78–7 If an injector has the specified resistance, this does not mean that it is okay. This injector had the specified resistance, yet it did not deliver the correct amount of fuel because it was clogged.

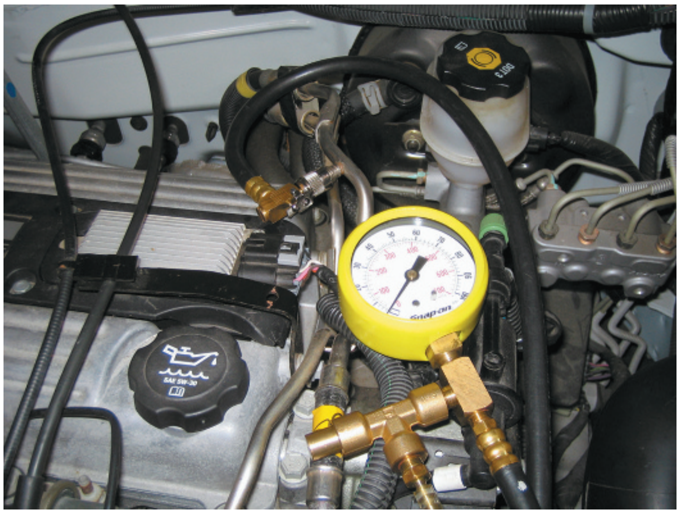

FIGURE 78–8 Connect a fuel-pressure gauge to the fuel rail at the Schrader valve.

INJECTOR VOLTAGE-DROP TESTS

Another test of injectors involves pulsing the injector and measuring the voltage drop across the windings as current is flowing. A typical voltage-drop tester is shown in ● **FIGURE 78–9**. The tester, which is recommended for use by General Motors Corporation, pulses the injector while a digital multimeter is connected to the unit, which will display the voltage drop as the current flows through the winding.

CAUTION: Do not test an injector using a pulse-type tester more than one time without starting the engine to help avoid a hydrostatic lock caused by the flow of fuel into the cylinder during the pulse test.

Record the highest voltage drop observed on the meter display during the test. Repeat the voltage-drop test for all of the injectors. The voltage drop across each injector should be within 0.1 volt of each other. If an injector has a higher-than-normal voltage drop, the injector windings have higher-than-normal resistance.

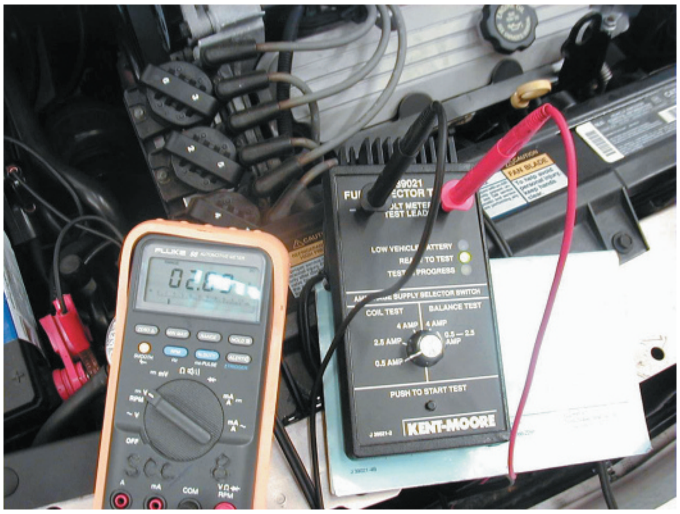

FIGURE 78–9 An injector tester being used to check the voltage drop through the injector while the tester is sending current through the injectors. This test is used to check the coil inside the injector. This same tester can be used to check for equal pressure drop of each injector by pulsing the injector on for 500 ms.

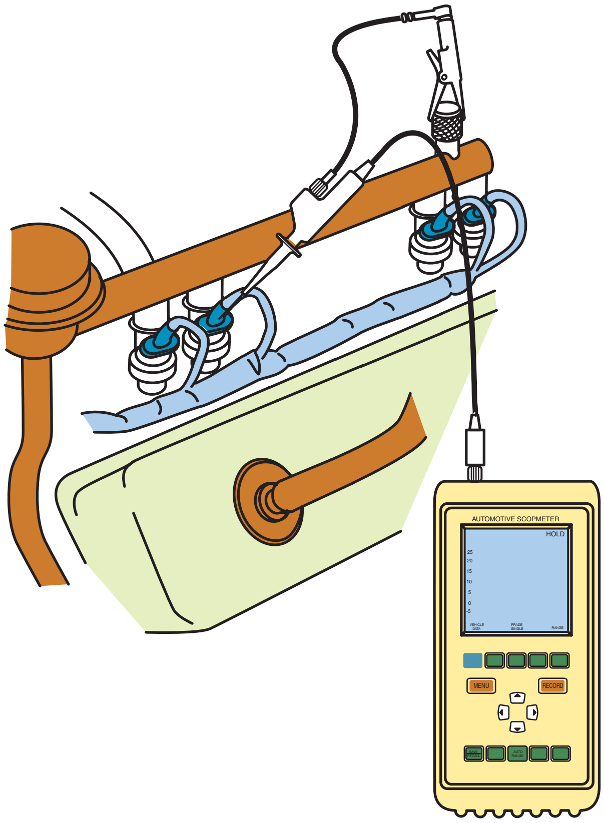

FIGURE 78–10 A DSO can be easily connected to an injector by carefully back-probing the electrical connector.

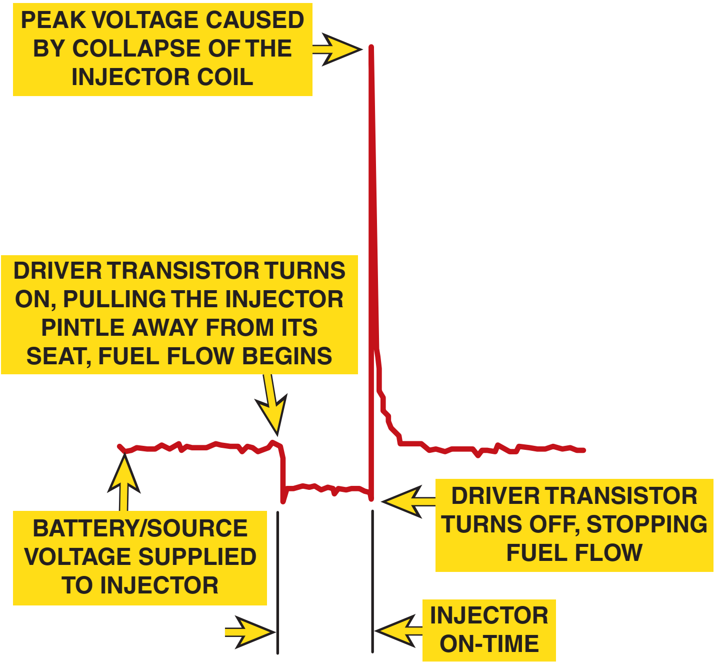
SCOPE-TESTING FUEL INJECTORS

A scope (analog or digital storage) can be connected into each injector circuit. There are three types of injector drive circuits and each type of circuit has its own characteristic pattern. ● **SEE FIGURE 78–10** for an example of how to connect a scope to read a fuel-injector waveform.

SATURATED SWITCH TYPE In a saturated switch-type injector-driven circuit, voltage (usually a full 12 volts) is applied to the injector. The ground for the injector is provided by the vehicle computer. When the ground connection is completed, current flows through the injector windings. Due to the resistance and inductive reactance of the coil itself, it requires a fraction of a second (about 3 milliseconds or 0.003 seconds) for the coil to reach **saturation** or maximum current flow. Most saturated switch-type fuel injectors have 12 to 16 ohms of resistance. This resistance, as well as the computer switching circuit, control and limit the current flow through the injector. A voltage spike occurs when the computer shuts off (opens the injector ground-side circuit) the injectors. ● **SEE FIGURE 78–11**.

PEAK-AND-HOLD TYPE A **peak-and-hold** type is typically used for TBI and some port low-resistance injectors. Full battery voltage is applied to the injector and the ground side is controlled through the computer. The computer provides a high initial current flow (about 4 amperes) to flow through the injector windings to open the injector core. Then the computer reduces the current to a lower level (about 1 ampere). The hold current is enough to keep the injector open, yet conserves energy and reduces the heat buildup that would occur if the full current flow



PEAK VOLTAGE CAUSED BY COLLAPSE OF THE INJECTOR COIL
DRIVER TRANSISTOR TURNS ON, PULLING THE INJECTOR PINTLE AWAY FROM ITS SEAT, FUEL FLOW BEGINS
BATTERY/SOURCE VOLTAGE SUPPLIED TO INJECTOR
DRIVER TRANSISTOR TURNS OFF, STOPPING FUEL FLOW
INJECTOR ON-TIME

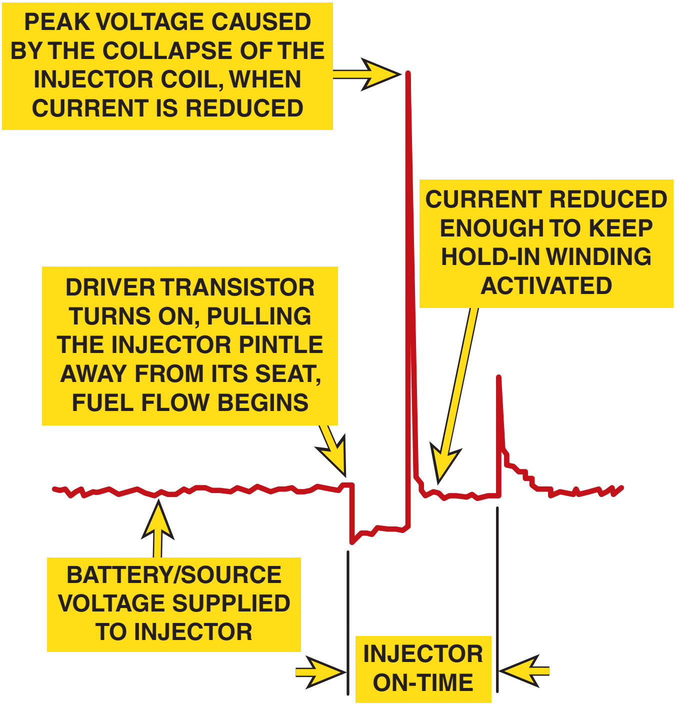
FIGURE 78–11 The injector on-time is called the pulse width.

remains on as long as the injector is commanded on. Typical peak-and-hold-type injector resistance ranges from 2 to 4 ohms.

The scope pattern of a typical peak-and-hold-type injector shows the initial closing of the ground circuit, then a voltage spike as the current flow is reduced. Another voltage spike occurs when the lower level current is turned off (opened) by the computer. ● **SEE FIGURE 78–12**.

PULSE-WIDTH MODULATED TYPE A pulse-width modulated type of injector drive circuit uses lower-resistance coil injectors. Battery voltage is available at the positive terminal of the injector and the computer provides a variable-duration connection to ground on the negative side of the injector. The computer can vary the time intervals that the injector is grounded for very precise fuel control.

Each time the injector circuit is turned off (ground circuit opened), a small voltage spike occurs. It is normal to see multiple voltage spikes on a scope connected to a pulse-width modulated type of fuel injector. ● **SEE FIGURE 78–13**.



PEAK VOLTAGE CAUSED BY THE COLLAPSE OF THE INJECTOR COIL, WHEN CURRENT IS REDUCED
CURRENT REDUCED ENOUGH TO KEEP HOLD-IN WINDING ACTIVATED
DRIVER TRANSISTOR TURNS ON, PULLING THE INJECTOR PINTLE AWAY FROM ITS SEAT, FUEL FLOW BEGINS
BATTERY/SOURCE VOLTAGE SUPPLIED TO INJECTOR
INJECTOR ON-TIME

FIGURE 78–12 A typical peak-and-hold fuel-injector wave form. Most fuel injectors that measure less than 6 ohms will usually display a similar waveform.

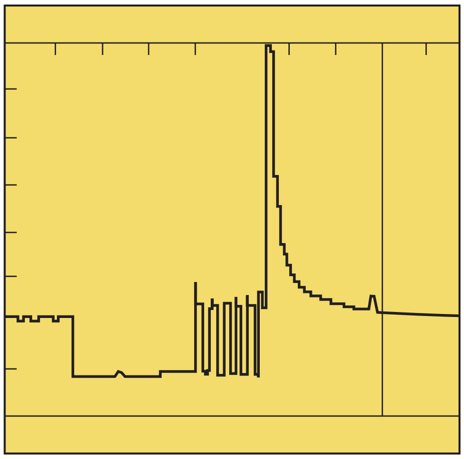


FIGURE 78–13 A waveform of a pulse-width modulated fuel injector. At the end, when the voltage is removed, there is an inductive spike created similar to the spike created but other types of injectors.

FUEL-INJECTION SERVICE

NEED FOR SERVICE All engines using fuel injection do require some type of fuel-system maintenance. Normal wear and tear with today's underhood temperatures and changes in gasoline quality contribute to the buildup of olefin wax, dirt, water, and many other additives. Unique to each engine is an air-control design that also may contribute different levels of carbon deposits, such as oil control.

FREQUENTLY ASKED QUESTION

If Three of Six Injectors Are Defective, Should I Also Replace the Other Three?

This is a good question. Many service technicians "recommend" that the three good injectors be replaced along with the other three that tested as being defective. The reasons given by these technicians include the following:

- All six injectors have been operating under the same fuel, engine, and weather conditions.
- The labor required to replace all six is just about the same as replacing only the three defective injectors.
- Replacing all six at the same time helps ensure that all of the injectors are flowing the same amount of fuel so that the engine is operating most efficiently.

With these ideas in mind, the customer should be informed and offered the choice. Complete sets of injectors, such as those in ● **FIGURE 78–14** can be purchased at a reasonable cost.

FIGURE 78–14 A set of six reconditioned injectors. The sixth injector is barely visible at the far right.

CASE STUDY

There Is No Substitute for a Thorough Visual Inspection

An intermittent "check engine" light and a random-misfire diagnostic trouble code (DTC) P0300 was being diagnosed. A scan tool did not provide any help because all systems seemed to be functioning normally. Finally, the technician removed the engine cover and discovered a mouse nest. ● **SEE FIGURE 78–15**.

Summary:

Complaint—Customer stated that the "Check Engine" light was on.
Cause—A stored P0300 DTC was stored indicating a random misfire had been detected caused by an animal that had partially eaten some fuel-injector wires.
Correction—The mouse nest was removed and the wiring was repaired.

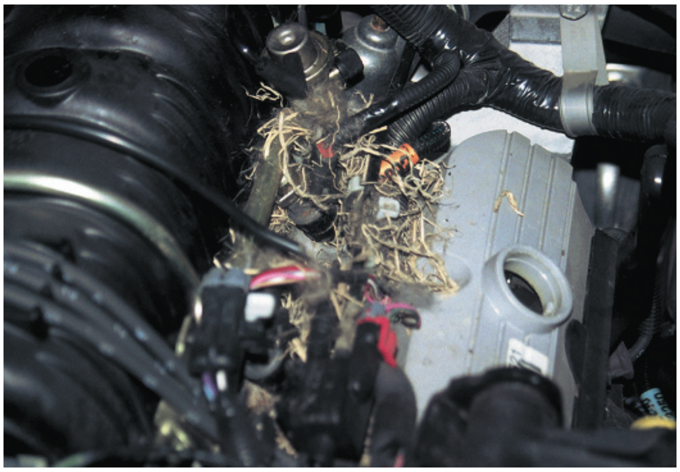

FIGURE 78–15 When the cover is removed from the top of the engine, a mouse or some other animal nest is visible. The animal had already eaten through a couple of injector wires. At least the cause of the intermittent misfire was discovered.

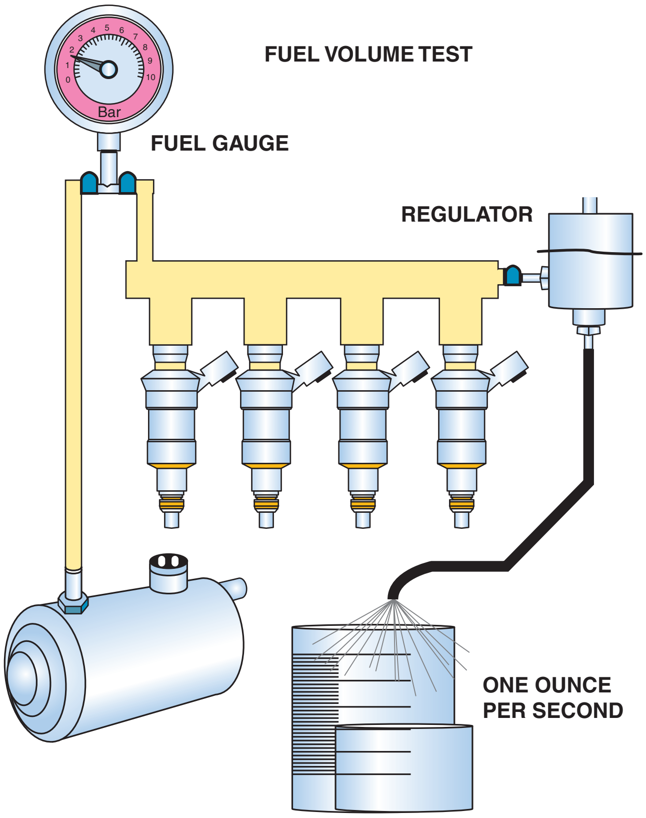

FIGURE 78–16 Checking fuel-pump volume using a hose from the outlet of the fuel-pressure regulator into a calibrated container.

FUEL-INJECTION SERVICE Fuel-injection system service should include the following operations:

1. **Check fuel-pump operating pressure and volume.** The missing link here is volume. Most working technicians assume that if the pressure is correct, the volume is also okay. Hook up a fuel-pressure tester to the fuel rail inlet to quickly test the fuel pressure with the engine running. At the same time, test the volume of the pump by sending fuel into the holding tank. (One ounce per second is the usual specification.) ● **SEE FIGURE 78–16**. A two-line system tester is the recommended procedure to use and is attached to the fuel inlet and the return on the fuel rail. The vehicle onboard system is looped and returns fuel to the tank.
2. **Test the fuel-pressure regulator for operation and leakage.** At this time, the fuel-pressure regulator would be tested for operational pressure and proper regulation, including leakage. (This works well as the operator has total control of rail pressure with a unit control valve.) Below are some points to consider:
   - Good pressure does not mean proper volume. For example, a clogged filter may test okay on pressure, but the restriction may not allow proper volume under load. ● **SEE FIGURE 78–17**.
   - It is a good idea to use the vehicle's own gasoline to service the system versus a can of shop gasoline that has been sitting around for some time.
   - Pressure regulators do fail and a lot more do not properly shut off fuel, causing higher-than-normal pump wear and shorter service life.

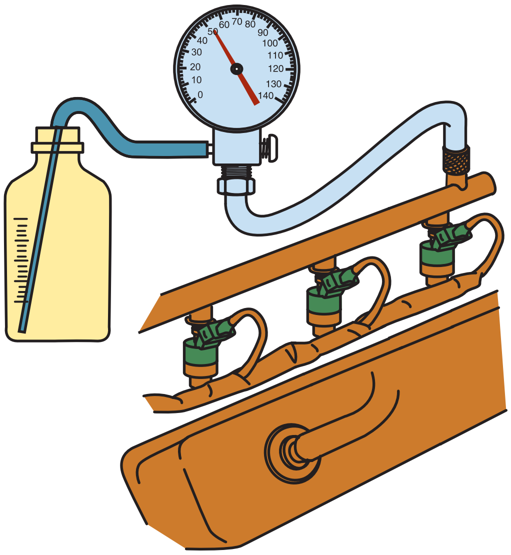

FIGURE 78–17 Testing fuel-pump volume using a fuel-pressure gauge with a bleed hose inserted into a suitable container. The engine is running during this test.

3. **Flush the entire fuel rail and upper fuel-injector screens including the fuel-pressure regulator.** Raise the input pressure to a point above regulator setting to allow a constant flow of fuel through the inlet pressure side of the system, through the fuel rail, and out the open fuel-pressure regulator. In most cases the applied pressure is 75 to 90 PSI (517 to 620 kPa), but will be maintained by the presence of a regulator. At this point, cleaning chemical is added to the fuel at a 5:1 mixture and allowed to flow through the system for 15 to 30 minutes. ● **SEE FIGURE 78–18**. Results are best on a hot engine with the fuel supply looped and the engine not running.
4. **Decarbon the engine assembly.** On most vehicles, the injector spray will help the decarboning process. On others, you may need to enhance the operation with external addition of a mixture through the PCV hose, throttle plates, or idle air controls.
5. **Clean the throttle plate and idle air control passages.** Doing this service alone on most late-model engines will show a manifold vacuum increase of up to 2 inches Hg. ● **SEE FIGURE 78–19**. This works well as air is drawn into IAC passages on a running engine and will clean the passages without IAC removal.
6. **Relearn the onboard computer.** Some vehicles may have been running in such a poor state of operation that the onboard computer may need to be relearned. Consult service information for the suggested relearn procedures for each particular vehicle.

All of the previously listed steps may be performed using a two-line fuel-injector service unit such as Carbon Clean, Auto Care, Injector Test, DeCarbon, or Motor-Vac.

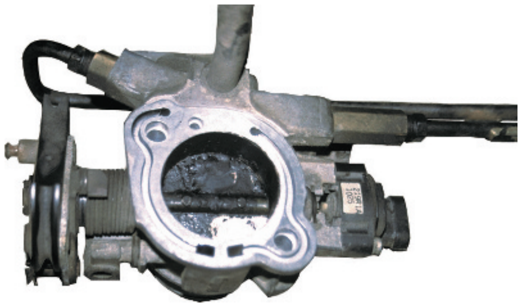

FIGURE 78–19 To thoroughly clean a throttle body, it is sometimes best to remove it from the vehicle. The throttle plate may need to be cleaned if the engine tends to stall, hesitate or has a rough idle.

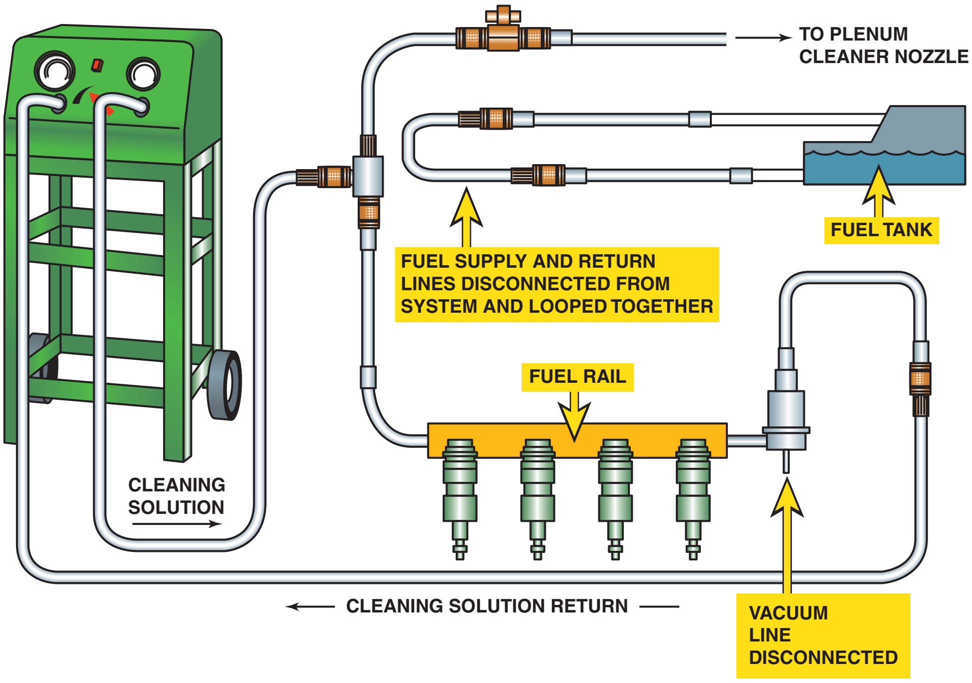

FIGURE 78–18 A typical two-line cleaning machine hookup, showing an extension hose that can be used to squirt a cleaning solution into the throttle body while the engine is running on the cleaning solution and gasoline mixture.

FUEL-INJECTION SYMPTOM CHART

Symptom	Possible Causes
Hard cold starts	• Low fuel pressure • Leaking fuel injectors • Contaminated fuel • Low-volatility fuel • Dirty throttle plate
Garage stalls	• Low fuel pressure • Insufficient fuel volume • Restricted fuel injector • Contaminated fuel • Low-volatility fuel
Poor cold performance	• Low fuel pressure • Insufficient fuel volume • Contaminated fuel • Low-volatility fuel
Tip-in hesitation (hesitation just as the accelerator pedal is depressed)	• Low fuel pressure • Insufficient fuel volume • Intake valve deposits • Contaminated fuel • Low-volatility fuel

TECH TIP

Check the Injectors at the "Bends and the Ends"

Injectors that are most likely to become restricted due to clogging of the filter basket screen are the injectors at the ends of the rail, especially on returnless systems where dirt can accumulate. Also the injectors that are located at the bends of the fuel rail are also subject to possible clogging due to the dirt being deposited where the fuel makes a turn in the rail.

TECH TIP

Use an Injector Tester

The best way to check injectors is to remove them all from the engine and test them using an injector tester. A typical injector tester uses a special nonflammable test fluid that has the same viscosity as gasoline. The tester pulses the injectors, and the amount of fuel delivered, as well as the spray pattern can be seen. Many testers are capable of varying the frequency of the pulse, as well as the duration that helps find intermittent injector faults. ● **SEE FIGURE 78–20**.

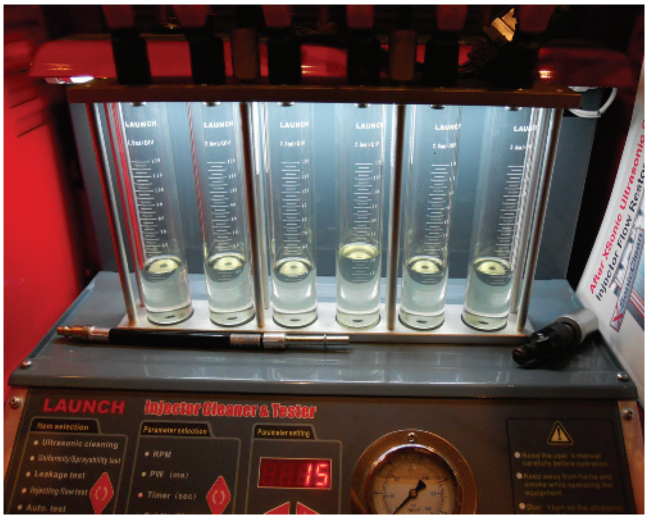

FIGURE 78–20 The amount each injector is able to flow is displayed in glass cylinders are each injector for a quick visual check.

WARNING

Before opening any part of the high-pressure section of a gasoline direct injection (GDI) system, the pressure must be bled off. The high pressures of this fuel system can cause injury or death. If any of the high-pressure lines are removed, even temporarily, they MUST be replaced because the ends use a ball-fitting that deforms to create the high-pressure seal. Once this seal has been opened, a new ball end must be used to insure a proper seal. ● **SEE FIGURE 78–21**.

Always check service information for the exact procedures to follow for the vehicle being serviced.

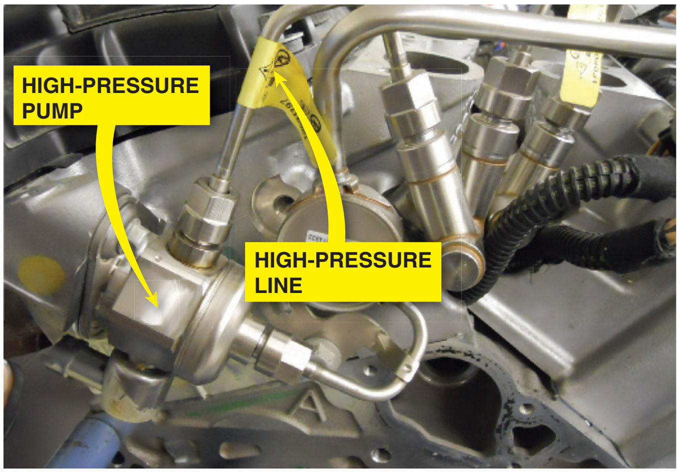

FIGURE 78–21 The line that has the yellow tag is a high-pressure line and this line must be replaced with a new part if removed even for a few minutes to gain access to another part.

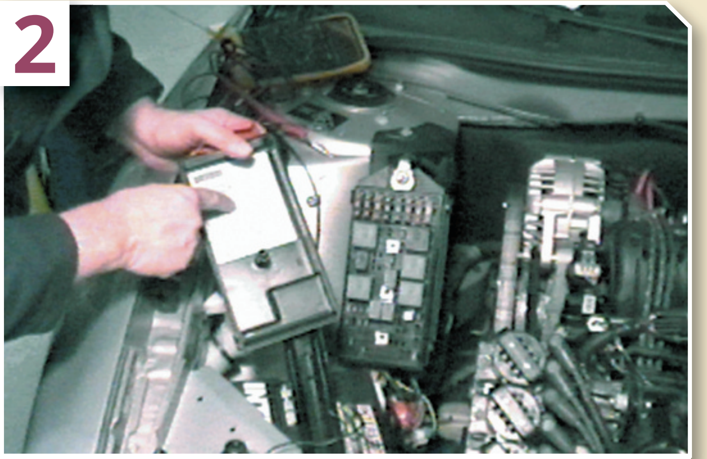
FUEL-PUMP RELAY CIRCUIT DIAGNOSIS

1

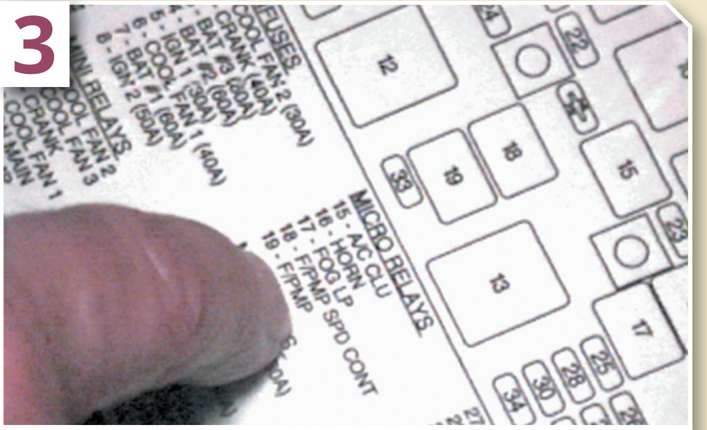
The tools needed to diagnose a circuit containing a relay include a digital multimeter (DMM), a fused jumper wire, and an assortment of wiring terminals.

2



Start the diagnosis by locating the relay center. It is under the hood on this General Motors vehicle, so access is easy. Not all vehicles are this easy.

3



FUSES

19 - F/PMP

The chart under the cover for the relay center indicates the location of the relay that controls the electric fuel pump.

4

Locate the fuel-pump relay and remove it by using a puller if necessary. Try to avoid rocking or twisting the relay to prevent causing damage to the relay terminals or the relay itself.

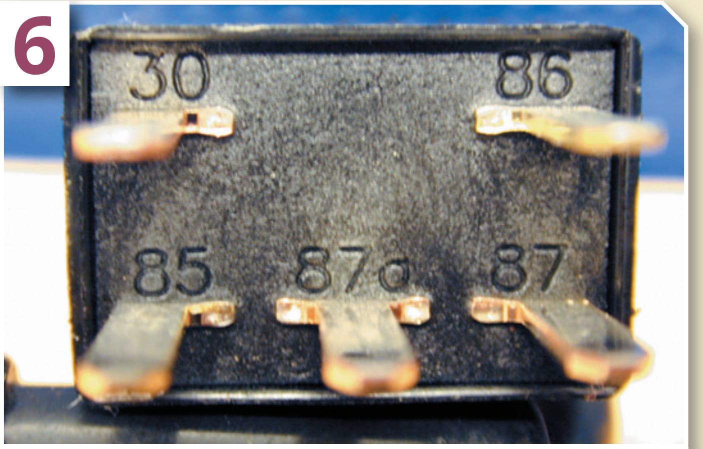
Terminals 85 and 86 represent the coil inside the relay. Terminal 30 is the power terminal, 87a is the normally closed contact, and 87 is the normally open contact.

6

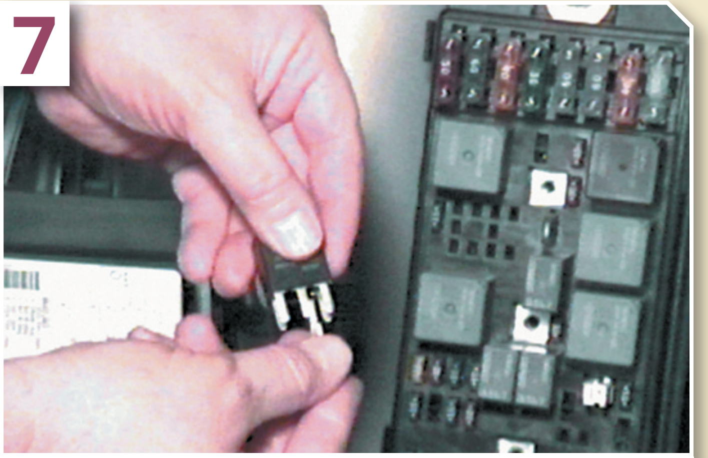


30
86
85
87a
87

The terminals are also labeled on most relays.

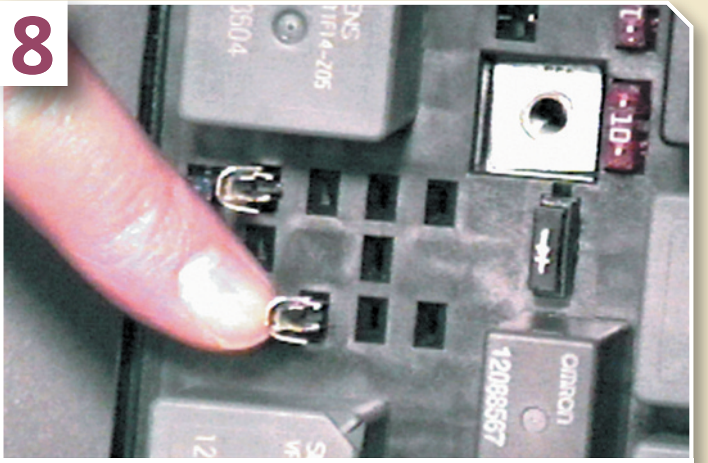
STEP BY STEP

7



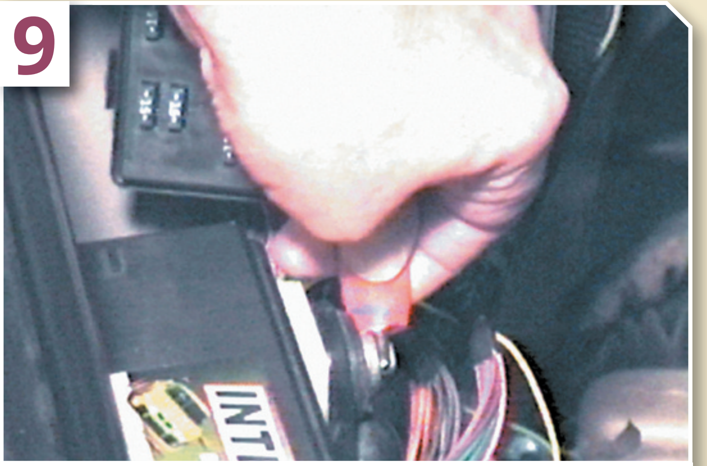
To help make good electrical contact with the terminals without doing any harm, select the proper-size terminal from the terminal assortment.

8



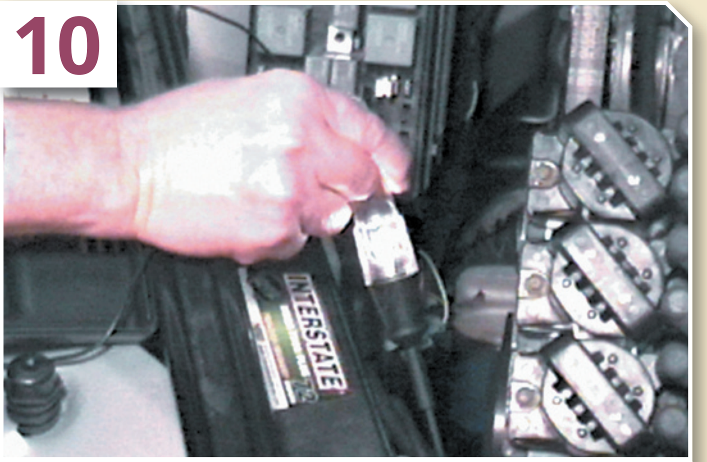
Insert the terminals into the relay socket in 30 and 87.

9



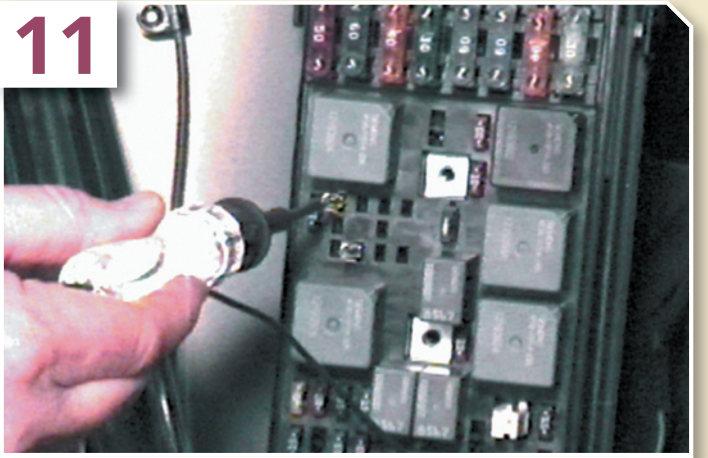
To check for voltage at terminal 30, use a test light or a voltmeter. Start by connecting the alligator clip of the test light to the positive (1) terminal of the battery.

10



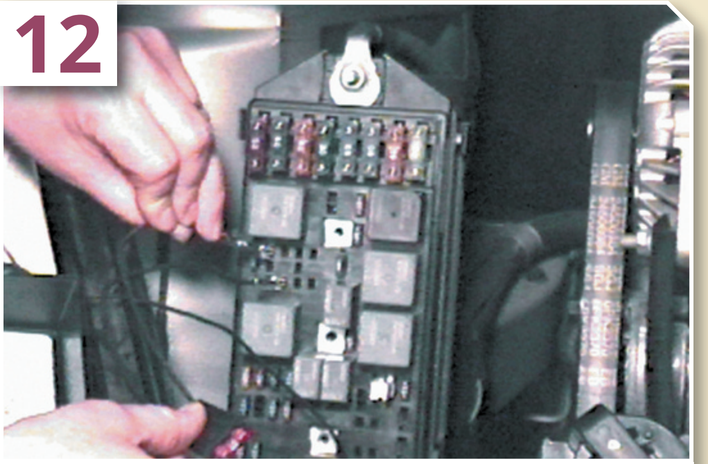
Touch the test light to the negative (–) terminal of the battery or a good engine ground to check the test light.

11



Use the test light to check for voltage at terminal 30 of the relay. The ignition may have to be in the on (run) position.

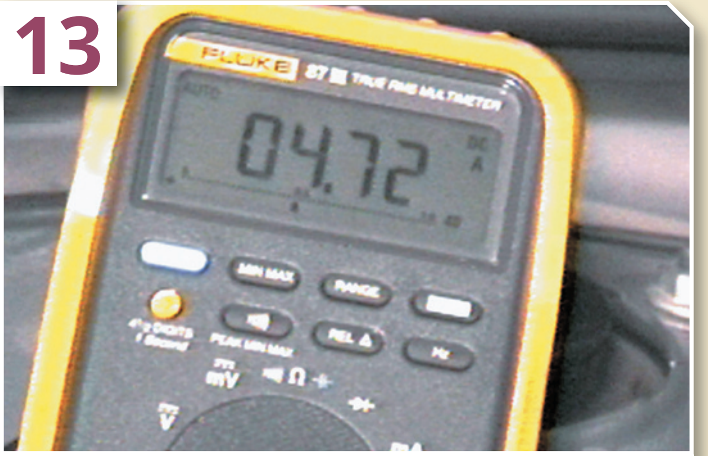
12



To check to see if the electric fuel pump can be operated from the relay contacts, use a fused jumper wire and touch the relay contacts that correspond to terminals 30 and 87 of the relay.

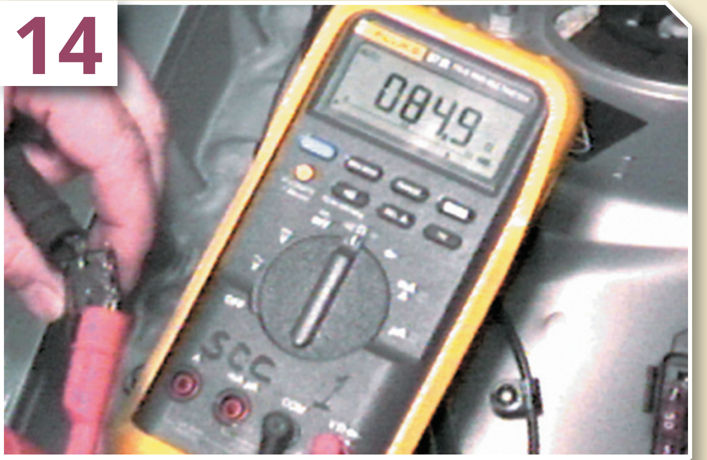
FUEL-PUMP RELAY CIRCUIT DIAGNOSIS

13



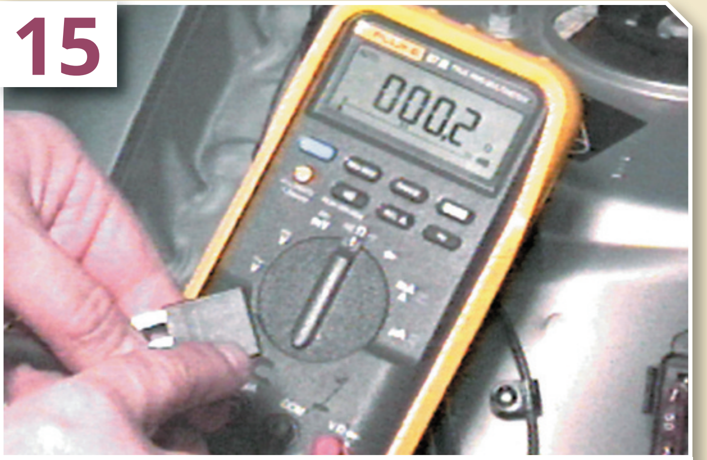
Connect the leads of the meter to contacts 30 and 87 of the relay socket. The reading of 4.7 amperes is okay because the specification is 4 to 8 amperes.

14



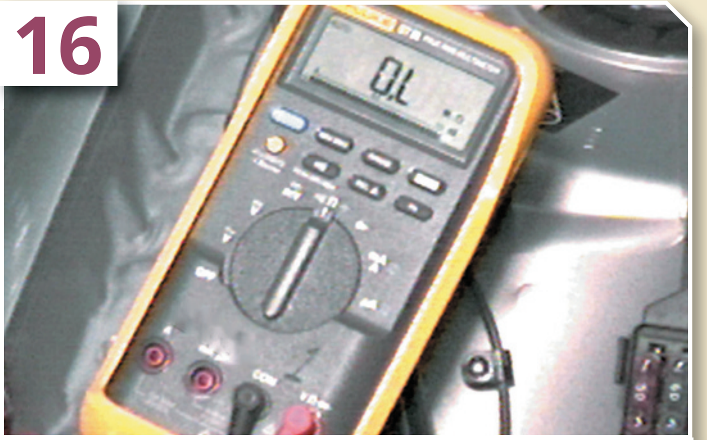
Set the meter to read ohms (Ω) and measure the resistance of the relay coil. The usual reading for most relays is between 60 and 100 ohms.

15



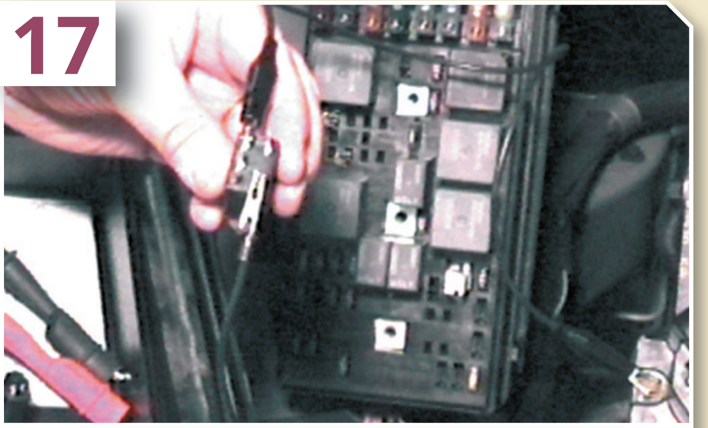
Measure between terminal 30 and 87a. Terminal 87a is the normally closed contact, and there should be little, if any, resistance between these two terminals, as shown.

16



To test the normally open contacts, connect one meter lead to terminal 30 and the other lead to terminal 87. The ohmmeter should show an open circuit by displaying OL.

17



Connect a fused jumper wire to supply 12 volts to terminal 86 and a ground to terminal 85 of the relay. If the relay clicks, then the relay coil is able to move the armature (movable arm) of the relay.

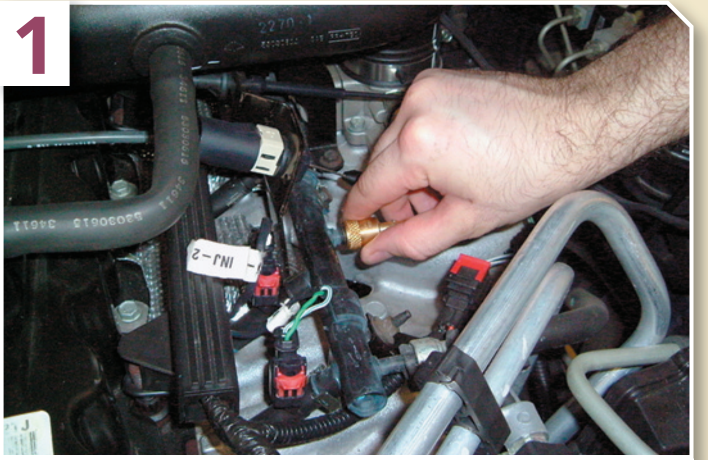
18

After testing, be sure to reinstall the relay and the relay cover.

FUEL INJECTOR CLEANING

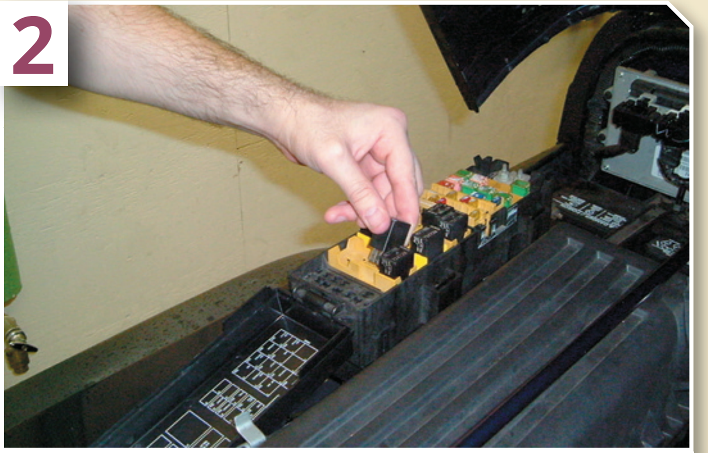
STEP BY STEP

1



Start the fuel injector cleaning process by bringing the vehicle's engine up to operating temperature. Shut off the engine, remove the cap from the fuel rail test port, and install the appropriate adapter.

2



The vehicle's fuel pump is disabled by removing its relay or fuse. In some cases, it may be necessary to disconnect the fuel pump at the tank if the relay or fuse powers more than just the pump.

3

UAS
Automotive

Turn the outlet valve of the canister to the OFF or CLOSED position.

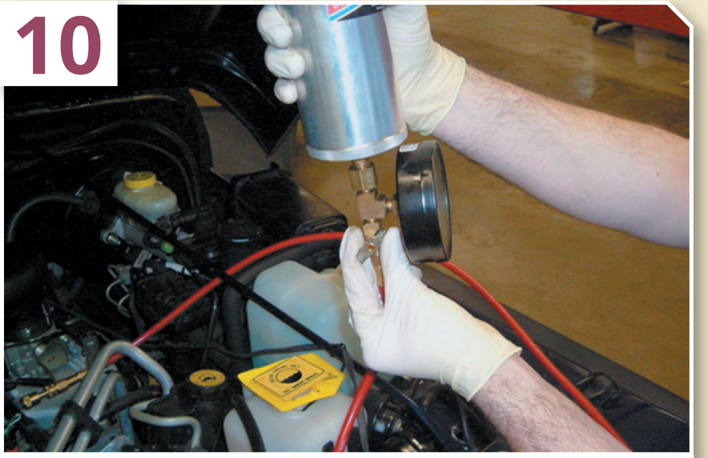
Canister pressure should be adjusted to 5 PSI below system fuel pressure. An alternative for return-type systems is to block the fuel return line to the tank.

10

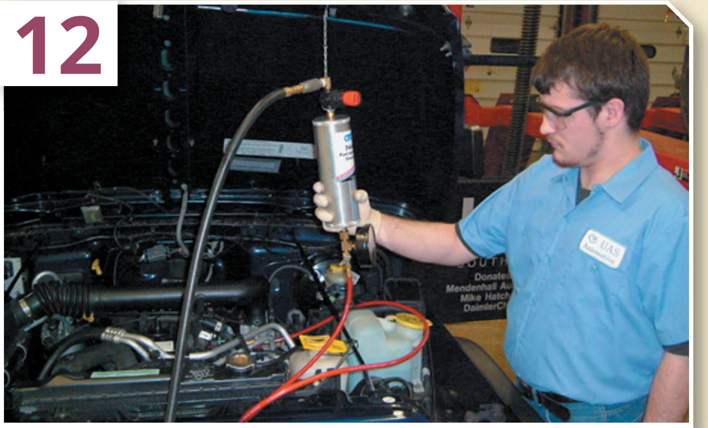


Open the outlet valve on the canister.

11

Start the vehicle's engine and let run at 1000–1500 RPM. The engine is now running on fuel injector cleaning fluid provided by the canister.

12



Continue the process until the canister is empty and the engine stalls. Remove the cleaning equipment, enable the vehicle's fuel pump, and run the engine to check for leaks.

REVIEW QUESTIONS

1. In what ways can fuel injectors be tested?
2. What are the characteristics of a saturated switch-type fuel injector?
3. What is the purpose of the injector pressure-drop balance test?
4. Why would fuel injectors at the bends and ends of the fuel rail tend to become clogged?
5. What does an injector voltage drop test indicate?

CHAPTER QUIZ

1. Most port fuel-injected engines operate on how much fuel pressure?
   - **a.** 3 to 5 PSI (21 to 35 kPa)
   - **b.** 9 to 13 PSI (62 to 90 kPa)
   - **c.** 35 to 45 PSI (240 to 310 kPa)
   - **d.** 55 to 65 PSI (380 to 450 kPa)
2. Fuel injectors can be tested using ______________.
   - **a.** an ohmmeter
   - **b.** an injector pulser
   - **c.** a scope
   - **d.** Any of the above
3. Which injector test is used to find a clogged injector?
   - **a.** Voltage drop test
   - **b.** Scope test
   - **c.** Pressure drop test
   - **d.** None of these
4. Port fuel-injection systems generally use what type of injector driver?
   - **a.** Peak and hold
   - **b.** Saturated switch
   - **c.** Pulse-width modulated
   - **d.** Pulsed
5. Fuel-injector resistance is being discussed. Technician A says that some injectors have a normal resistance of 1.5 to 4 ohms. Technician B says that some injectors have a normal resistance of 12 to 16 ohms. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
6. The fuel pressure drops rapidly when the engine is turned off. Technician A says that one or more injectors could be leaking. Technician B says that a defective check valve in the fuel pump could be the cause. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
7. In a typical port fuel-injection system, which injectors are most subject to becoming restricted?
   - **a.** Any of them equally
   - **b.** The injectors at the end of the rail on a returnless system
   - **c.** The injectors at the bends in the rail
   - **d.** Either b or c
8. What component pulses the fuel injector on most vehicles?
   - **a.** Electronic control unit (computer)
   - **b.** Ignition module
   - **c.** Crankshaft sensor
   - **d.** Both b and c
9. Fuel-injection service is being discussed. Technician A says that the throttle plate(s) should be cleaned. Technician B says that the fuel rail should be cleaned. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
10. If the throttle plate needs to be cleaned, what symptoms will be present regarding the operation of the engine?
    - **a.** Stalls
    - **b.** Rough idle
    - **c.** Hesitation on acceleration
    - **d.** Any of the above

Chapter

VEHICLE EMISSIONS STANDARDS AND TESTING

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss normal engine combustion.
- Discuss exhaust analysis and combustion efficiency.
- Discuss the catalytic converter.
- Explain diagnosis using exhaust analysis.
- Explain engine fault possibilities.
- Discuss US and European emission standards.
- Explain vehicle emission testing.

KEY TERMS:

Carbon dioxide (CO_2) 932 • Carbon monoxide (CO) 932 • Federal Test Procedure (FTP) 939 • Hydrocarbons (HC) 932 • Lean indicator 935 • Nitrogen (N_2) 932 • Oxygen (O_2) 932 • Oxides of Nitrogen (NO_x) 932 • Ozone 936 • Rich indicator 935 • Smog 936 • Stoichiometric ratio 932 • Water (H_2O) 932

NORMAL ENGINE COMBUSTION

AIR AND GASOLINE Engines consume about 15 times more air by weight than gasoline; this ratio of air to fuel is called the **stoichiometric ratio**. This ratio, which is 14.7:1 for gasoline, is the ratio where all of the fuel is consumed in the combustion process and uses all of the available oxygen.

- Entering the engine combustion chamber is fuel (HC) plus air (**nitrogen (N_2)** is 78% and **oxygen (O_2)** is 21% of the air). ● **SEE FIGURE 79–1**.
- During combustion, the HC combines with the air to form **water (H_2O)**, carbon dioxide (CO_2) plus nitrogen (N_2) and some other non-desirable gases.
- Engines consume about 15 times more air by with than gasoline (14.7:1 at stoichiometric ratio). Some of the other gases include the following:
    - Unburned **hydrocarbons (HC)**—If perfect combustion occurs inside the engine, there should not be any leftover unburned fuel. If there is HC gas exiting the tailpipe, it indicates that all of the fuel has not been burned. ● **SEE FIGURE 79–2**.

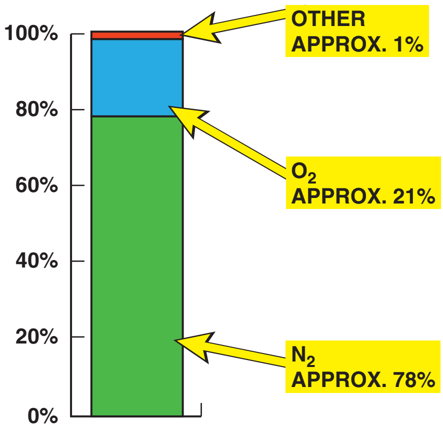

FIGURE 79–1 The air entering the engine consists of mostly nitrogen (78%) with about 21% oxygen and about 1% other gases.

- **Carbon monoxide (CO)**—During combustion, all of the carbon in the fuel should be converted to **carbon dioxide (CO_2)**, if there is enough oxygen available. If there is not enough oxygen available in the combustion chamber, incomplete combustion occurs, creating CO instead of. ● **SEE FIGURE 79–3**.
- **Oxides of Nitrogen (NO_x)**—Nitrogen is 78% of the air, so having some leftover is normal; however, if the

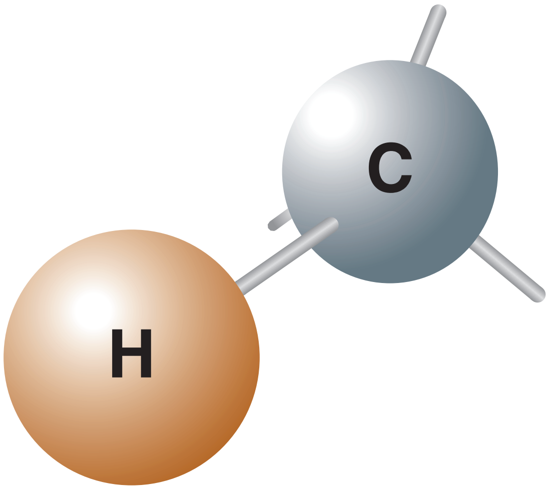

FIGURE 79–2 Hydrocarbons can include many combinations of hydrogen and carbon.

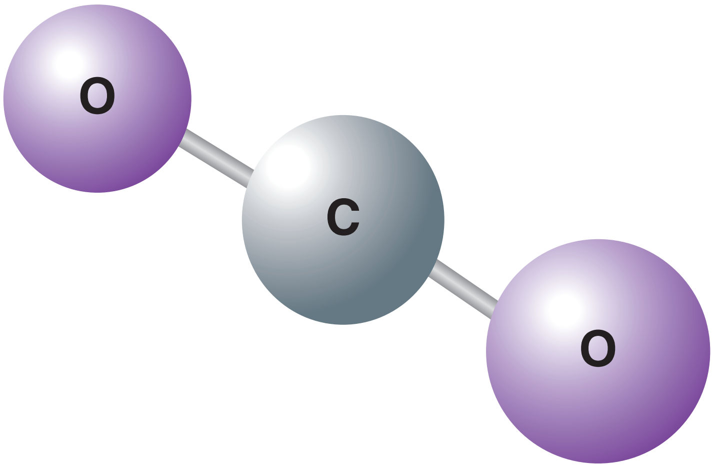

FIGURE 79–3 Carbon dioxide has two oxygen atoms attached to the one carbon atom and is a stable molecule.

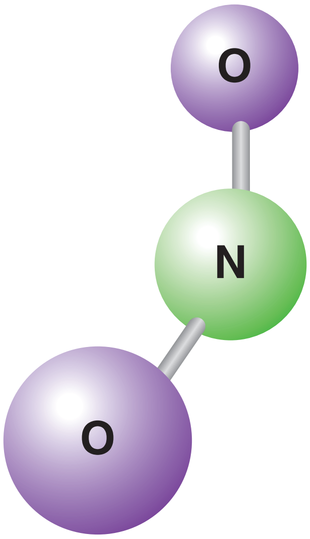

FIGURE 79–4 NO and NO_2 shown together are referred to as NO_x.

combustion temperatures and pressures are high enough, some of the nitrogen (N_2) combines with the oxygen to form NO and NO_2, which are harmful exhaust gases and referred to as oxides of nitrogen (NO_x), where the "x" represents the a number. ● **SEE FIGURE 79–4.**

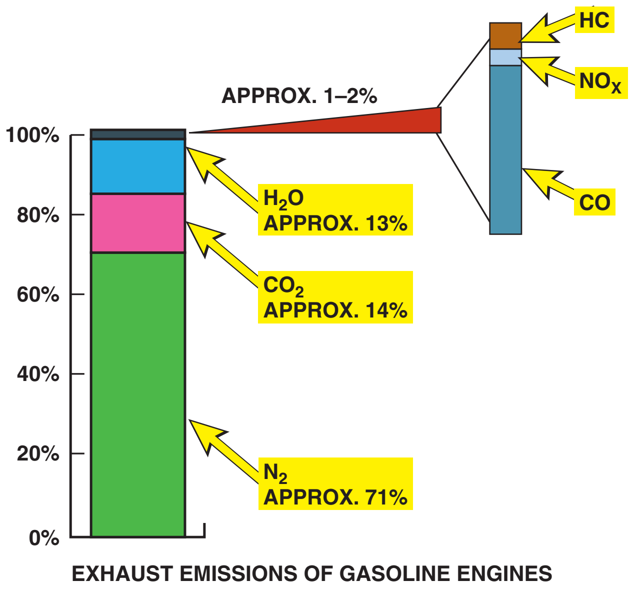

FIGURE 79–5 A chart showing that about 13% of the exhaust emissions is water (H_2O) in the form of steam.

FREQUENTLY ASKED QUESTION

Why Is Steam Seen from the Tailpipe When Cold Outside, But Not Always?

Steam is water vapor and is invisible. However, when an engine is cold, the water vapor created by combustion partially condenses into small droplets of water that are visible as "steam" from the tailpipe of vehicle when the engine is cold. After the exhaust system has been heated, the water vapor no longer condenses in the exhaust system, so it is not visible after the engine is warm. ● **SEE FIGURE 79–5.**

EXHAUST ANALYSIS AND COMBUSTION EFFICIENCY

HYDROCARBONS Hydrocarbons are unburned gasoline and are measured in parts per million (ppm). A correctly operating engine should burn (oxidize) almost all the gasoline; therefore, very little unburned gasoline should be present in the exhaust. Acceptable levels of HC are 50 ppm or less. High levels of HC could be due to excessive oil consumption caused by weak piston rings or worn valve guides. The most common cause of excessive HC emissions is a fault in the ignition system. Items that should be checked include the following:

- Spark plugs
- Secondary ignition fault such as coils, spark plug boots, or wiring

CARBON MONOXIDE **Carbon monoxide (CO)** is unstable and will easily combine with any oxygen to form stable CO_2. The fact that CO combines with oxygen is the reason that CO is a poisonous gas (in the lungs, it combines with oxygen to form CO_2 and deprives the brain of oxygen). CO levels of a properly operating engine should be less than 0.5%. High levels of CO can be caused by clogged or restricted crankcase ventilation devices, such as the pressure control valve (PCV) valve, hose(s), and tubes. Other items that might cause excessive CO include the following:

- Incorrect idle speed
- Too-high fuel-pump pressure
- Any other items that can cause a rich condition

CARBON DIOXIDE Carbon dioxide is the result of oxygen in the engine combining with the carbon of the gasoline. An acceptable level of CO_2 is between 12% and 15%. A high reading indicates an efficiently operating engine. If the CO_2 level is low, the mixture may be either too rich or too lean.

OXYGEN There is about 21% oxygen in the atmosphere, and most of this oxygen should be "used up" during the combustion process to oxidize all the hydrogen and carbon (hydrocarbons) in the gasoline. Levels of O_2 should be very low (about 0.5%). High levels of O_2, especially at idle, could be due to an exhaust system leak.

NOTE: Adding 10% alcohol to gasoline provides additional oxygen to the fuel and will result in lower levels of CO and higher levels of O_2 in the exhaust.

OXIDES OF NITROGEN (NO_X) An **oxide of nitrogen (NO)** is a colorless, tasteless, and odorless gas when it leaves the engine, but as soon as it reaches the atmosphere and mixes with more oxygen, nitrogen oxides (NO_2) are formed. NO_2 is reddish-brown and has an acid and pungent smell. NO and NO_2 are grouped together and referred to as NO_X, where *x* represents any number of oxygen atoms. NO_X, the symbol used to represent all oxides of nitrogen, is the fifth gas commonly tested using a five-gas analyzer. The exhaust gas recirculation (EGR) system is the major controlling device limiting the formation of NO_X. ● **SEE FIGURE 79–6**.

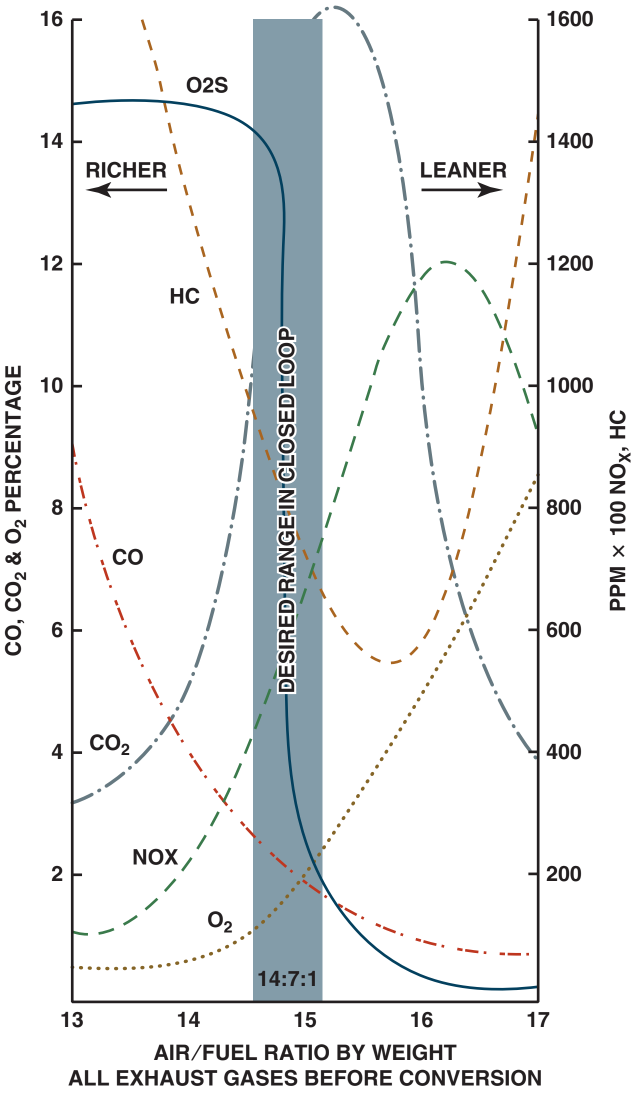

FIGURE 79–6 Exhaust emissions are very complex. When the air–fuel mixture becomes richer, some exhaust emissions are reduced, while others increase.

CATALYTIC CONVERTER

EFFECT ON EXHAUST GASES The catalytic converter is used to help reduce exhaust emissions by helping the oxygen in the exhaust to oxidize the HC and CO in the exhaust stream to form harmless water (H_2O) and CO_2. It also helps separate the nitrogen from the oxygen in NO_X to produce just nitrogen (N_2) and oxygen (O_2). ● **SEE FIGURE 79–7** and **CHART 79–1**.

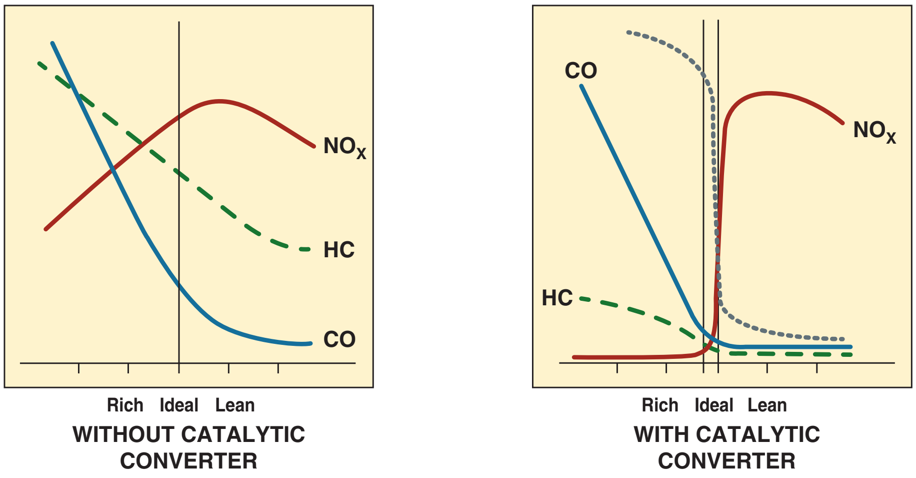

FIGURE 79–7 The image on the left shows exhaust gases exiting an engine without a catalytic converter with rich exhaust being toward the left of the vertical line and lean exhaust to the right of the line. The image on the right shows the exhaust after it has been treated by the catalytic converter.

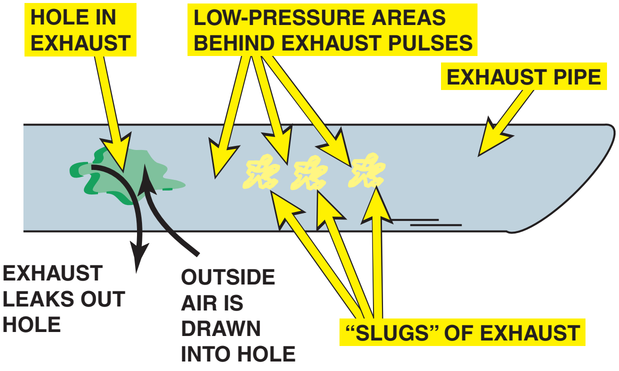
EXHAUST GAS	TYPICAL SPECIFICATIONS
Unburned hydrocarbons (HC)	30–50 ppm or less
Carbon Monoxide (CO)	0.3%–0.5% or less
Oxygen (O_2)	0%–2%
Carbon Dioxide (CO_2)	12%–15% or higher
Oxides of Nitrogen (NO_x)	Less than 100 ppm at idle and less than 1,000 ppm at wide-open throttle (WOT)

CHART 79–1

Typical specifications for gases for a vehicle equipped with a catalytic converter.



HOLE IN EXHAUST
LOW-PRESSURE AREAS BEHIND EXHAUST PULSES
EXHAUST PIPE
EXHAUST LEAKS OUT HOLE
OUTSIDE AIR IS DRAWN INTO HOLE
“SLUGS” OF EXHAUST

FIGURE 79–8 A hole in the exhaust system can cause outside air (containing oxygen) to be drawn into the exhaust system. This extra oxygen can be confusing to a service technician because the extra O_2 in the exhaust stream could be misinterpreted as a too-lean air–fuel mixture.

EXHAUST ANALYSIS AS A DIAGNOSTIC TOOL

RICH OR LEAN EXHAUST If the exhaust is rich, CO emissions will be higher than normal. If the exhaust is lean, O_2 emissions will be higher than normal.

- If CO is high, the exhaust is rich. This is why CO is called the “**rich indicator**.”
- If O_2 is high, the exhaust is lean. This is why O_2 is called the “**lean indicator**.”

Therefore, if the CO reading is the same as the O_2 reading, the engine is operating correctly. For example, if both CO and O_2 are 0.5% and the engine develops a vacuum leak, the O_2 will rise. If a fuel-pressure regulator were to malfunction, the resulting richer air–fuel mixture would increase CO emissions. Therefore, if both the rich indicator (CO) and the lean indicator (O_2) are equal, the engine is operating correctly.

If the exhaust is rich (too much fuel or not enough air), then the following can be observed:

- Both CO and HC will be high
- O_2 will be low
- CO_2 will be low

If the exhaust is lean (not enough fuel or too much air), then it will result in the following:

- O_2 will be high
- CO_2 will be low

TECH TIP

How to Find a Leak in the Exhaust System

A hole in the exhaust system can dilute the exhaust gases with additional oxygen (O_2). ● **SEE FIGURE 79–8**.

This additional O_2 in the exhaust can lead the service technician to believe that the air–fuel mixture is too lean. To help identify an exhaust leak, perform an exhaust analysis at idle and at 2,500 RPM (fast idle) and compare with the following:

- If the O_2 is high at idle and at 2,500 RPM, the mixture is lean at both idle and at 2,500 RPM.
- If the O_2 is low at idle and high at 2,500 RPM, this usually means the vehicle is equipped with a working AIR pump.
- If the O_2 is high at idle, but okay at 2,500 RPM, a hole in the exhaust or a small vacuum leak that is “covered up” at higher speed is indicated.

ENGINE FAULT POSSIBILITIES

HC TOO HIGH High HC exhaust emissions are usually caused by an engine misfire. What burns the fuel in an engine? The ignition system produces a spark at the spark plug to ignite the proper fuel–air mixture inside the combustion chamber. If a spark plug does not ignite the mixture, the resulting unburned fuel is pushed out of the cylinder on the exhaust stroke by the piston through the exhaust valves and into the exhaust system. Therefore, if any of the following ignition components or adjustments are not correct, excessive HC emission is likely:

1. Defective or worn spark plugs
2. Defective or loose spark plug boots or other faults in the primary or secondary ignition system

A lean air–fuel mixture can also cause a misfire. This condition is referred to as a *lean misfire*. A lean air–fuel mixture can be caused by low fuel pump pressure, a clogged fuel filter, or a restricted fuel injector.

CO TOO HIGH Excessive CO is an indication of too rich an air–fuel mixture. CO is the rich indicator. The higher the CO reading, the richer the air–fuel mixture. High concentrations of CO indicate that not enough oxygen was available for the amount of fuel. Common causes of high CO include the following:

- Too-high fuel pressure
- Clogged air intake or PCV valve
- Defective injectors

CASE STUDY

O2S Shows Rich, But Pulse Width Is Low

A service technician was attempting to solve a driveability problem. The powertrain control module (PCM) did not indicate any diagnostic trouble codes (DTCs). A check of the oxygen sensor voltage indicated a higher-than-normal reading almost all the time. The pulse width to the port injectors was lower than normal. The lower-than-normal pulse width indicates that the PCM is attempting to reduce fuel flow into the engine by decreasing the amount of on-time for all the injectors. What could cause a rich mixture if the injectors were being commanded to deliver a lean mixture?

Finally, the technician shut off the engine and took a careful look at the entire fuel-injection system. When the vacuum hose was removed from the fuel-pressure regulator, fuel was found dripping from the vacuum hose. The problem was a defective fuel-pressure regulator that allowed an uncontrolled amount of fuel to be drawn by the intake manifold vacuum into the cylinders. While the PCM tried to reduce fuel by reducing the pulse width signal to the injectors, the extra fuel being drawn directly from the fuel rail caused the engine to operate with too rich an air–fuel mixture.

Summary:

Complaint—Customer stated that the engine did not perform correctly.
Cause—No stored diagnostic trouble codes (DTCs) were found but the oxygen sensor reading was higher than normal indicating that the exhaust air–fuel mixture was too rich.
Correction—The fuel pressure regulator was found to be leaking causing fuel to be drawn into the intake causing the richer-then-normal air–fuel mixture. Replacing the fuel pressure regulator solved the driveability complaint.

TECH TIP

Your Nose Knows

Using the nose, a technician can often identify a major problem without having to connect the vehicle to an exhaust analyzer. For example,

- The strong smell of exhaust is due to excessive unburned hydrocarbon (HC) emissions. Look for an ignition system fault that could prevent the proper burning of the fuel.
- If your eyes start to burn or water, suspect excessive oxides of nitrogen (NO_x) emissions. The NO_X combine with the moisture in the eyes to form a mild solution of nitric acid. The acid formation causes the eyes to burn and water. Excessive NO_x exhaust emissions can be caused by a lack of proper amount of exhaust gas recirculation (EGR) or a variable valve timing issue. (This is usually noticed above idle on most vehicles.)
- Dizzy feeling or headache. This is commonly caused by excessive carbon monoxide (CO) exhaust emissions. Get into fresh air as soon as possible. A probable cause of high levels of CO is an excessively rich air–fuel mixture.

O_2 AND CO_2 RELATIONSHIP Two gas exhaust analyzers (HC and CO) work well, but both HC and CO are consumed (converted) inside the catalytic converter. The amount of leftover oxygen coming out of the tailpipe is an indication of leanness. The higher the O_2 level, the leaner the exhaust. Oxygen therefore is the lean indicator. Acceptable levels of O_2 are 0% to 2%.

NOTE: A hole in the exhaust system can draw outside air (oxygen) into the exhaust system. Therefore, to be assured of an accurate reading, carefully check the exhaust system for leaks. Using a smoke machine is an easy method to locate leaks in the exhaust system.

Carbon dioxide is a measure of efficiency. The higher the level of CO_2 in the exhaust stream, the more efficiently the engine is operating. Levels of 12% to 17% are considered to be acceptable. Because CO_2 levels peak at an air–fuel mixture of 14.7:1, a lower level of CO_2 indicates either a too-rich or a too-lean condition. The CO_2 measurement by itself does not indicate which condition is present. For example, if the CO_2 is 8%, it means the combustion efficiency is low and the air–fuel mixture is not correct. Look at O_2 and CO levels; a high O_2 indicates lean and a high CO indicates rich.

SMOG AND NO_x Oxides of nitrogen are formed by high temperature—over 2,500°F (1,370°C)—and/or pressures inside the combustion chamber. Oxides of nitrogen contribute to the formation of photochemical smog when sunlight reacts chemically with NO_x and unburned hydrocarbons. "**Smog**" is a term derived by combining the words *smoke* and *fog*. Ground-level ozone is a constituent of smog. **Ozone** is an enriched oxygen molecule with three atoms of oxygen (O_3) instead of the normal two atoms of oxygen (O_2). Ozone in the upper atmosphere is beneficial because it blocks out harmful ultraviolet rays that contribute to skin cancer. However, at ground level, this ozone (smog) is an irritant to the respiratory system. Because the formation of NO_x occurs mostly under load, the most efficient method to test for NO_x is to use a portable exhaust analyzer that can be carried in the vehicle while the vehicle is being driven under a variety of conditions.

A maximum reading of 1,000 ppm of NO_x under loaded driving conditions will generally mean that the vehicle will pass an enhanced I/M roller test. A reading of over 100 ppm at idle should be considered excessive.

ABNORMAL GAS READINGS The exhaust gases each have their own cause for being higher than normal or lower than normal and they are interconnected. ● **SEE CHART 79–2**.

EMISSION STANDARDS

TIER 1 AND TIER 2 Federal emissions standards are set by the Clean Air Act Amendments (CAAA) of 1990 and these standards are grouped by tier. All vehicles sold in the United States must meet Tier 1 standards that went into effect in 1994 and are

CARBON MONOXIDE (CO)	CARBON DIOXIDE (CO_2)	HYDROCARBONS (HC)	OXYGEN (O_2)	POSSIBLE ISSUES
Low	High	Low	Low	Normal readings. No issues
High	Low	High	High	Rich exhaust and misfire
Low	Low	High	High	Lean exhaust and misfire
High	High	High	High	Catalytic converter not working as designed plus possible other air–fuel ratio issues
High	Low	High	High	Rich exhaust
High	Low	High	Low	Possible defective thermostat

CHART 79–2

Possible issues based on the relative readings of the four exhaust gases.

CASE STUDY

The Case of the Retarded Exhaust Camshaft

A Toyota equipped with a double overhead camshaft (DOHC) six-cylinder engine failed the state-mandated enhanced exhaust emissions test for NO_x. The engine ran perfectly without spark knocking (ping), which is usually a major reason for excessive NO_x emissions. The technician checked the following:

- The cylinders, which were decarbonized using top engine cleaner
- The EGR valve, which was inspected and the EGR passages cleaned

After all the items were completed, the vehicle was returned to the inspection station where the Vehicle again failed for excessive NO_x emissions (better, but still over the maximum allowable limit). After additional hours of troubleshooting, the technician decided to go back to basics and start over again. A check of the vehicle history with the owner indicated that the only previous work performed on the engine was a replacement timing belt over a year before. The technician discovered that the exhaust cam timing was retarded by two teeth, resulting in late closing of the exhaust valve. The proper exhaust valve timing resulted in a slight amount of exhaust gas being retained in the cylinder. This extra exhaust was helped reduce NO_x emissions.

After repositioning the timing belt, the vehicle passed the emissions test well within the limits.

Summary:

Complaint—Customer stated that the vehicle failed an emission test due to excessive NO_x exhaust emissions.
Cause—The exhaust cam was discovered to be retarded by two teeth as a result of the timing belt being incorrectly installed during a previous repair.
Correction—The timing belt was properly aligned and the vehicle passed the emission test.

the least stringent. Additional Tier 2 standards which had been optional since 2001 were fully adopted by 2009. The current Tier 1 standards are different between automobiles and light trucks (SUVs, pickup trucks, and minivans), but Tier 2 standards are the same for both types.

There are several emission ratings that can be given to vehicles, and a certain percentage of a manufacturer's vehicles must meet different levels of ratings in order for the company to sell its products in affected regions. Beyond Tier 1, and in order of stringency, are the following levels:

- **TLEV** (Transitional Low-Emission Vehicle). More stringent for HC than Tier 1.
- **LEV** (also known as LEV I) (Low-Emission Vehicle). An intermediate California standard about twice as stringent as Tier 1 for HC and NO_x.
- **ULEV** (also known as ULEV I) (Ultra-Low-Emission Vehicle). A stronger California standard emphasizing very low HC emission.
- **ULEV II** (Ultra-Low-Emission Vehicle). A cleaner-than-average vehicle certified under the Phase II LEV standard.

Hydrocarbon and carbon monoxide emissions levels are nearly 50% lower than those of a LEV II-certified vehicle.

- **SULEV** (Super-Ultra-Low-Emission Vehicle). A California standard even tighter than ULEV, including much lower HC and NO_x emissions; roughly equivalent to Tier 2 Bin 2 vehicles.
- **ZEV** (Zero-Emission Vehicle). A California standard prohibiting any tailpipe emissions. The ZEV category is largely restricted to electric vehicles and hydrogen-fueled vehicles.

In these cases, any emissions that are created are produced at another site, such as a power plant or hydrogen reforming center, unless such sites run on renewable energy.

NOTE: A battery-powered electric vehicle charged from the power grid will still be up to 10 times cleaner than even the cleanest gasoline vehicles over their respective lifetimes.

- **PZEV** (Partial Zero-Emission Vehicle). Compliant with the SULEV standard and has near-zero evaporative emissions and a 15-year/150,000-mile warranty on its emission control equipment. Tier 2 standards are even more stringent. Tier 2 variations are appended with "II," such as LEV II or SULEV II.
- **ILEV** (Inherently Low-Emission Vehicle). Used by some states that allow certain vehicles to use the HOV lanes regardless of the number of people in the vehicle. Check state and local laws and regulations for the list of vehicles included.
- **AT-PZEV** (Advanced Technology Partial Zero-Emission Vehicle). If a vehicle meets the PZEV standards and is using

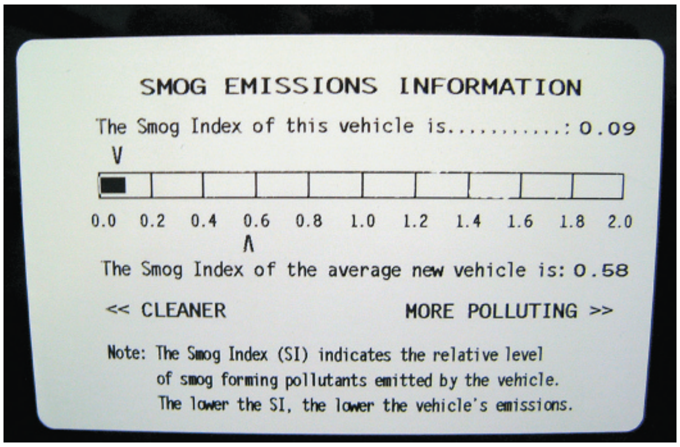
FIGURE 79–9 This vehicle emission control information (VECI) decal indicates this vehicle meets both national EPA Tier3. Bin 125 (T3B125) and California ULEV125 PC (passenger car) standard.

high-technology features, such as an electric motor or high-pressure gaseous fuel tanks for compressed natural gas, it qualifies as an AT-PZEV. Hybrid electric vehicles such as the Toyota Prius can qualify, as can internal combustion engine vehicles that run on natural gas (CNG), such as the Honda Civic GX. These vehicles are classified as "partial" ZEV because they receive partial credit for the number of ZEV vehicles that automakers would otherwise be required to sell in California.

- **NLEV** (National Low-Emission Vehicle). All vehicles nationwide must meet this standard, which started in 2001.

FEDERAL EPA BIN NUMBER The higher the tier number, the newer the regulation; the lower the bin number, the cleaner the vehicle. The Toyota Prius is a very clean Bin 2, while dirtier vehicles are given a higher bin number. ● **SEE FIGURE 79–9**.

SMOG EMISSION INFORMATION New vehicles are equipped with a sticker that shows the relative level of smog-causing emissions created by the vehicle compared to others on the market. Smog-causing emissions include unburned HC and NO_x. ● **SEE FIGURE 79–10**.



SMOG EMISSIONS INFORMATION

The Smog Index of this vehicle is...........: 0.09

0.0 0.2 0.4 0.6 0.8 1.0 1.2 1.4 1.6 1.8 2.0

The Smog Index of the average new vehicle is: 0.58

<< CLEANER MORE POLLUTING >>

Note: The Smog Index (SI) indicates the relative level of smog forming pollutants emitted by the vehicle. The lower the SI, the lower the vehicle's emissions.

FIGURE 79–10 This label on a Toyota Camry hybrid shows the relative smog-producing emissions, but this does not include CO_2, which may increase global warming.

CALIFORNIA STANDARDS The pre-2004 CARB standards as a whole were known as LEV I. Within that, there were four possible ratings: Tier 1, TLEV, LEV, and ULEV. The newest CARB-rating system (since January 1, 2004) is known as LEV II. Within that rating system there are three primary ratings: LEV, ULEV, and SULEV. States other than California are given the option to use the federal EPA standards, or they can adopt California's standards.

LEV III The latest emissions standards include maintaining the reduced emissions for 150,000 miles has several emission categories, depending on the level of emissions. The standards are more stringent than Tier 2 standards and include a number of other important changes:

- The required emission durability has been increased to 150,000 miles, up from 120,000 miles.
- Gasoline vehicles are tested—for exhaust and evaporative emissions—using gasoline containing 10% of ethanol (E10).
- Standards are for 2015–2025 vehicles sold in the United States. ● **SEE CHART 79–3**.

EUROPEAN STANDARDS Exhaust emissions of nitrogen oxides (NO_x), total hydrocarbon (THC), non-methane hydrocarbons (NMHC), carbon monoxide (CO), and particulate matter (PM) are regulated for most vehicle types, including cars, trucks in the European Union (EU). The EU also sets limits for CO_2 emission in units of grams per kilometer with the latest standard being 95 grams per km after 2020. Carbon dioxide is created by the combustion of fuel inside an internal combustion engine. Reducing the CO_2 emissions requires the less fuel be consumed which is one way the EU is mandating fuel economy standards. The ratings include the following:

- **Euro 1** (1993)
- **Euro 2** (1996)
- **Euro 3** (2000)
- **Euro 4** (2005)
- **Euro 5** (2009)
- **Euro 6** (2014)
- **Euro 7** (2025)

EMISSION CATEGORY	$NMOG + NO_x$ GRAM PER MILE (G/MI)	CO GRAM PER MILE (G/MI)	PARTICULATE MATTER (PM) GRAM PER MILE (G/MI)
LEV 160	0.160	4.2	0.01
ULEV 125	0.125	2.1	0.01
ULEV 70	0.070	1.7	0.01
ULEV 50	0.050	1.7	0.01
SULEV 30	0.030	1.0	0.01
SULEV 20	0.020	1.0	0.01

CHART 79–3

Non-methane organic gases (NMOG) and oxides of nitrogen are combined under one limit meaning that the hydrocarbons and the NO_x have to be both controlled to meet these standards. Particulate matter (PM) has in the past been associated with diesel engine emissions, but are now being tested on gasoline powered vehicles.

VEHICLE EMISSION TESTING

OBD-II TESTING In 1999, the EPA requested that states adopt OBD-II systems testing for 1996 and newer vehicles. The OBD-II system is designed to illuminate the malfunction indicator lamp (MIL) light and store trouble codes any time a malfunction exists that would cause the vehicle emissions to exceed 1 1/2 times the **Federal Test Procedure (FTP)** limits. If the OBD-II system is working correctly, the system should be able to detect a vehicle failure that would cause emissions to increase to an unacceptable level. The EPA has determined that the OBD-II system should detect emission failures of a vehicle even before that vehicle would fail an emissions test of the type that most states are employing.

The EPA has determined that, as the population of OBD-II-equipped vehicles increases and the population of older non-OBD-II-equipped vehicles decreases, tailpipe testing will no longer be necessary.

NOTE: If a state or local emission testing program still uses exhaust emission testing for older vehicles, check the information about the program and test procedures before having the vehicle tested.

The OBD-II testing program consists of a computer that can scan the vehicle OBD-II system using the DLC connector. The technician first performs a visual check of the vehicle MIL light to determine if it is working correctly. Next, the computer is connected to the vehicle's DLC connector. The computer will scan the vehicle OBD-II system and determine if there are any codes stored that are commanding the MIL light on. In addition, it will scan the status of the readiness monitors and determine if they have all run and passed. If the readiness monitors have all run and passed, it indicates that the OBD-II system has tested all the components of the emission control system. An OBD-II vehicle would fail this OBD-II test if the following conditions are present:

- The MIL light does not come on with the key on, engine off
- The MIL is commanded on
- A number (varies by state) of the readiness monitors has not been run. If none of these conditions are present, the vehicle will pass the emissions test.

REMOTE SENSING The EPA requires that, in high-enhanced areas, states perform on-the-road testing of vehicle emissions. The state must sample 0.5% of the vehicle population base in high-enhanced areas. This may be accomplished by using a remote sensing device. This type of sensing may be done through equipment that projects an infrared light through the exhaust stream of a passing vehicle. The reflected beam can then be analyzed to determine the pollutant-emission levels of the vehicle. If a vehicle fails this type of test, vehicle owners will receive notification in the mail that they must take the vehicle to a test facility to have the emissions tested.

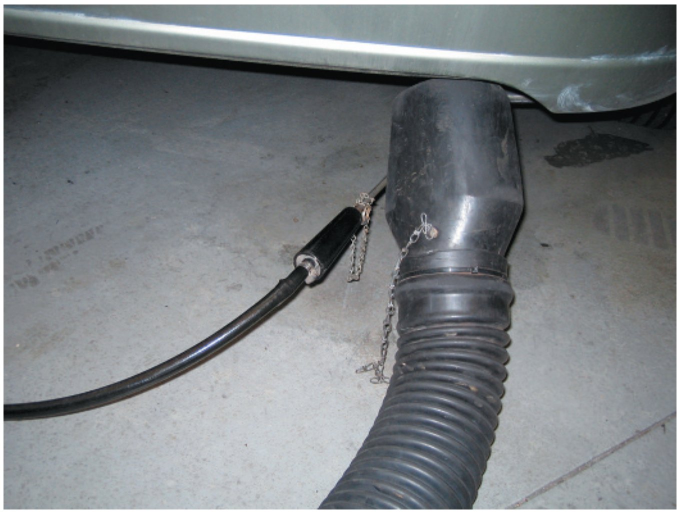


FIGURE 79–11 A partial stream sampling exhaust probe being used to measure exhaust gases in parts per million (ppm) or percent (%).

RANDOM ROADSIDE TESTING Some states may implement random roadside testing that would usually involve visual checks of the emission control devices to detect tampering. Obviously, this method is not very popular as it can lead to traffic tie-ups and delays on the part of commuters. Exhaust analysis is an excellent tool to use for the diagnosis of engine performance concerns. In areas of the country that require exhaust testing to be able to get license plates, exhaust analysis must be able to carry out the following:

- Establish a baseline for failure diagnosis and service.
- Identify areas of engine performance that are and are not functioning correctly.
- Determine that the service and repair of the vehicle have been accomplished and are complete.

● **SEE FIGURE 79–11**.

REVIEW QUESTIONS

1. What are the five exhaust gases and their maximum allowable readings for a fuel-injected vehicle equipped with a catalytic converter?
2. How is water formed during the combustion process?
3. What is the stoichiometric ratio and what does it mean?
4. How are oxides of nitrogen (NO_X) formed?
5. What is the most common cause of excessive hydrocarbon (HC) emissions?

CHAPTER QUIZ

1. Technician A says that high HC emission levels are often caused by a fault in the ignition system. Technician B says that high CO_2 emissions are usually caused by a richer-than-normal air–fuel mixture. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. HC and CO are high and CO_2 and O_2 are low. This could be caused by a ___________.
   a. rich mixture
   b. lean mixture
   c. defective ignition component
   d. clogged EGR passage

3. Which gas is generally considered to be the rich indicator? (The higher the level of this gas, the richer the air–fuel mixture.)
   a. HC
   b. CO
   c. CO_2
   d. O_2
4. The catalytic converter is used to help reduce exhaust emissions by helping the oxygen in the exhaust to oxidize the HC and CO in the exhaust stream to form ___________.
   a. oxides of nitrogen
   b. carbon dioxide
   c. carbon monoxide
   d. water and carbon dioxide
5. Which of these levels would apply to an electric vehicle?
   a. ULEV
   b. ZEV
   c. LEV
   d. TLEV
6. All of the gases are measured in percentages except ___________.
   a. HC
   b. CO
   c. CO_2
   d. O_2
7. After the following exhaust emissions were measured, how was the engine operating?
   HC 5,766 ppm, CO_2 8.2%, CO 4.6%, O_2 0.1%
   a. Too rich
   b. Too lean
   c. Operating at stoichiometric ratio
   d. Engine operating (coolant) temperature too high
8. Technician A says that NO_X formation is limited by the EGR system. Technician B says that NO_X is converted to N_2 and O_2 in the catalytic converter. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
9. A clogged EGR passage could cause excessive ___________ exhaust emissions.
   a. HC
   b. CO
   c. NO_X
   d. CO_2
10. A vehicle could fail a state emission inspection due to which of these?
    a. MIL is on
    b. MIL does not come on with key on, engine off
    c. Readiness monitors not run
    d. Any of these

Chapter 80

EVAPORATIVE EMISSIONS CONTROL AND EGR SYSTEMS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain the operation of an evaporative emission control (EVAP) system.
- Discuss enhanced evaporative control systems.
- Discuss leak detection pump systems.
- Discuss onboard refueling vapor recovery.
- Explain how to diagnose the EVAP system.
- Discuss the functions of an evaporative system monitor.
- Discuss the purpose and function of exhaust gas recirculation (EGR) systems.
- Explain the strategies to monitor on-board diagnostics generation II (OBD-II) exhaust gas recirculation (EGR) systems.
- Explain how to diagnose a defective EGR system.

KEY TERMS:

Adsorption 942 • Delta pressure feedback EGR (DPFE) sensor 951 • Detonation 950 • Digital EGR valve 950 • EGR valve position (EVP) sensor 950 • Evaporative control (EVAP) system 941 • Exhaust gas recirculation (EGR) 948 • Fuel tank pressure (FTP) 947 • Inert 949 • Leak detection pump (LDP) 944 • Linear EGR valve 950 • Nitrogen oxides (NO_X) 948 • Onboard refueling vapor recovery (ORVR) 945 • Pressure feedback EGR (PFE) sensor 950 • Purge valve 943 • Vent valve 943 • Volatile organic compounds (VOCs) 941

EVAPORATIVE EMISSION CONTROL SYSTEM

PURPOSE AND FUNCTION The purpose of the evaporative emission control system is to trap and hold gasoline vapors, also called **volatile organic compounds (VOCs)**. The **evaporative control (EVAP) system** includes the charcoal canister, hoses, and valves. These vapors are routed into a charcoal canister, then into the intake airflow, where they are burned in the engine, instead of being released into the atmosphere.

COMMON COMPONENTS The fuel tank filler caps used on vehicles with modern EVAP systems are a special design. Most EVAP fuel tank filler caps have a built-in pressure-vacuum relief valve. When pressure or vacuum exceeds a calibrated value, the valve opens. Once the pressure or vacuum has been relieved, the valve closes. If a sealed cap is used on an EVAP system that requires a pressure-vacuum relief design, a vacuum may develop in the fuel system, or the fuel tank may be damaged by fuel expansion or contraction. ● **SEE FIGURE 80–1**.

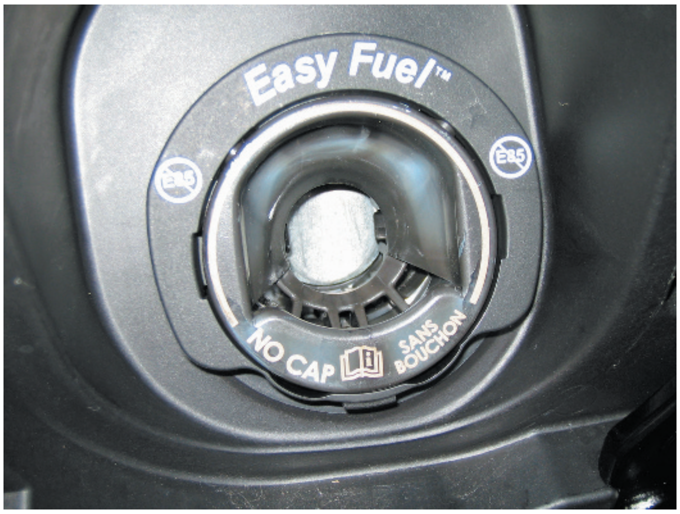

FIGURE 80–1 A capless system from a Ford does not use a replaceable cap; instead, it is spring-loaded closed.

FREQUENTLY ASKED QUESTION

When Filling My Fuel Tank, Why Should I Stop When the Pump Clicks Off?

Every fuel tank has an upper volume chamber that allows for expansion of the fuel when hot. The volume of the chamber is between 10% and 20% of the volume of the tank. For example, if a fuel tank has a capacity of 20 gallons, the expansion chamber volume is from 2 to 4 gallons. A hose is attached at the top of the chamber and vented to the charcoal canister. If extra fuel is forced into this expansion volume, liquid gasoline can be drawn into the charcoal canister. This liquid fuel can saturate the canister and create an overly rich air–fuel mixture when the canister purge valve is opened during normal vehicle operation. This extra-rich air–fuel mixture can cause the vehicle to fail an exhaust emissions test, reduce fuel economy, and possibly damage the catalytic converter. To avoid problems, simply add fuel to the next dime's worth after the nozzle clicks off. This ensures that the tank is full, yet not overfilled.

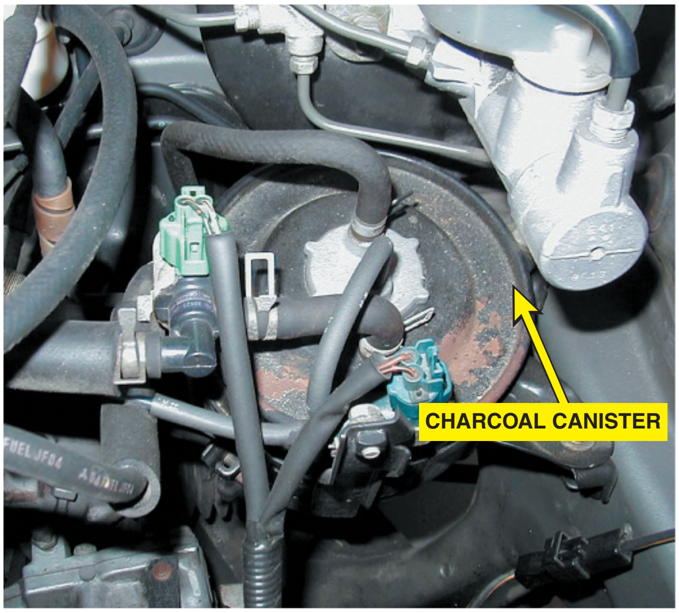

FIGURE 80–2 A charcoal canister can be located under the hood or underneath the vehicle.

EVAP SYSTEM OPERATION

The canister is located under the hood or underneath the vehicle and is filled with activated charcoal granules that can hold up to one-third of their own weight in fuel vapors. ● **SEE FIGURE 80–2**.

NOTE: Some vehicles with large or dual fuel tanks may have dual canisters.

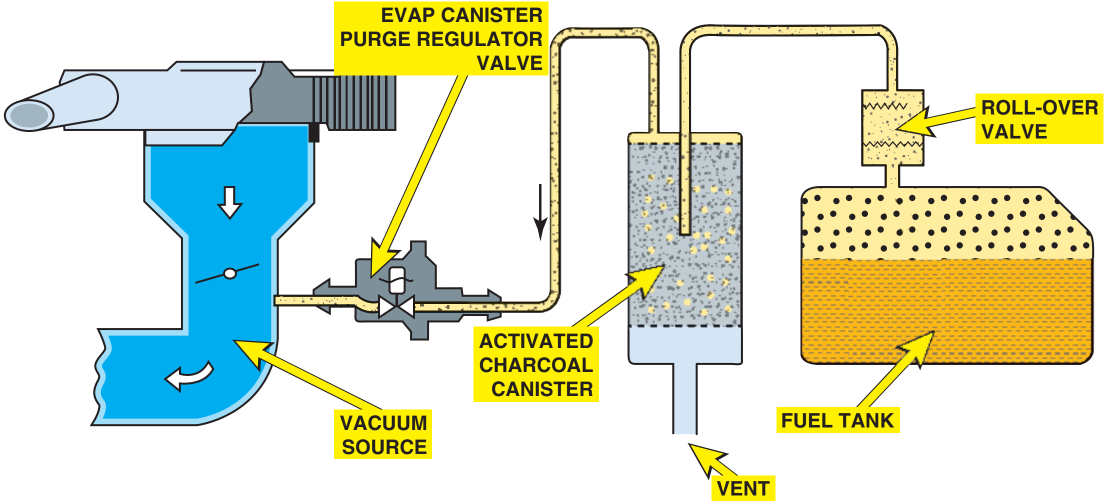
Activated charcoal is an effective vapor trap because of its great surface area. Each gram of activated charcoal has a surface area of 1,100 square meters, or more than 1/4 acre. Typical canisters hold either 300 or 625 grams of charcoal *with a surface area equivalent to 80 or 165 football fields.* By a process called **adsorption**, the fuel vapor molecules adhere to the carbon surface. This attaching force is not strong, so the system purges the vapor molecules quite simply by sending a fresh airflow through the charcoal:

- **Vapor purging.** During engine operation, stored vapors are drawn from the canister into the engine through a hose connected to the throttle body or the air cleaner. This "purging" process mixes unburned gasoline (hydrocarbons, abbreviated HCs) vapors from the canister with the existing air–fuel charge. ● **SEE FIGURES 80–3 AND 80–4**.
- **Computer-controlled purge.** The PCM controls when the canister purges on most engines. This is done by an electric vacuum solenoid and one or more purge valves. Under normal conditions, most engine control systems permit purging only during closed-loop operation at cruising speeds. During other engine operation conditions, such as open-loop mode, idle, deceleration, or wide-open throttle, the PCM prevents canister purging.

EVAPORATIVE PRESSURES

Pressures can build inside the fuel system and are usually measured in units of inches of water, abbreviated "in. H_2O" (28 inches H_2O equals 1 pound per square inch, or 1 PSI). Pressure buildup can be caused by the following:

- Fuel evaporation rates (volatility)
- Gas tank size (fuel surface area and volume)
- Fuel level (liquid versus vapor)



EVAP CANISTER PURGE REGULATOR VALVE
ROLL-OVER VALVE
ACTIVATED CHARCOAL CANISTER
VACUUM SOURCE
FUEL TANK
VENT

FIGURE 80–3 The EVAP system includes all of the lines, hoses, and valves, plus the charcoal canister.

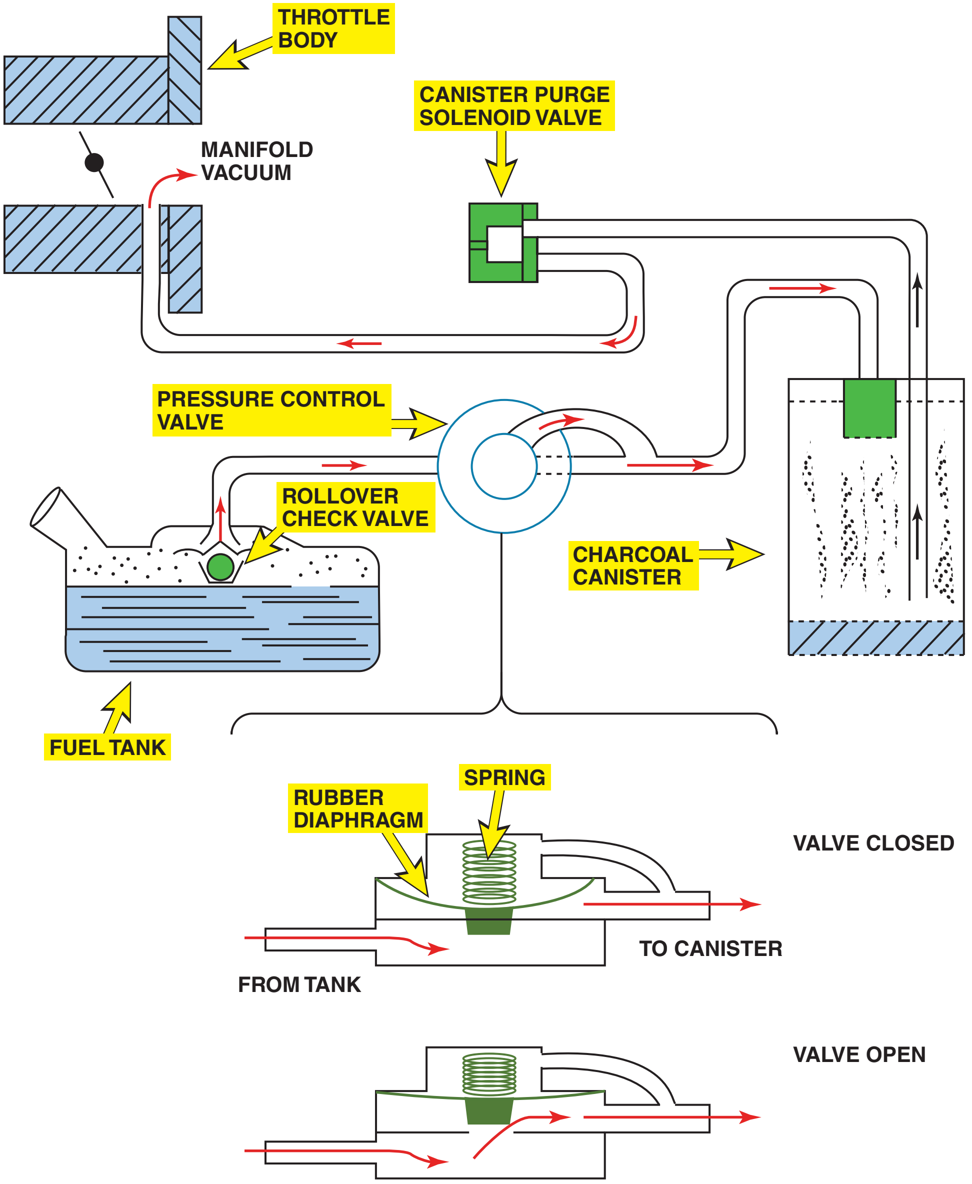


FIGURE 80–4 A typical EVAP system. Note that when the computer turns on the canister purge solenoid valve, manifold vacuum draws any stored vapors from the canister into the engine. Manifold vacuum also is applied to the pressure control valve. When this valve opens, fumes from the fuel tank are drawn into the charcoal canister and eventually into the engine. When the solenoid valve is turned off (or the engine stops and there is no manifold vacuum), the pressure control valve is spring-loaded shut to keep vapors inside the fuel tank from escaping to the atmosphere.

- Fuel slosh (driving conditions)
- Temperature (ambient, in-tank, close to the tank)
- Returned fuel from the rail

Some scan tools display other units of measure for the EVAP system that makes understanding the system difficult. ● **SEE CHART 80–1** for pressure conversions between pounds per square inch (PSI), inches of mercury (in. Hg), and inches of water (in. H_2O).

ENHANCED EVAPORATIVE CONTROL SYSTEM

BACKGROUND Beginning in 1996 with OBD-II vehicles, manufacturers are required to install systems that are able to detect both purge flow and evaporative system leakage:

- The systems on models produced between 1996 and 2000 must be able to detect a leak as small as 0.040 inches in diameter.
- Beginning in the model year 2000, the enhanced systems started a phase-in of 0.020-inch diameter leak detection.
- All vehicles built after 1995 have enhanced EVAP systems with the ability to detect purge flow and system leakage. If either of these two functions fails, the system is required to set a diagnostic trouble code (DTC) and turn on the malfunction indicator lamp (MIL) to warn the driver of the failure. ● **SEE FIGURE 80–5**.

VENT VALVE The canister **vent valve** is a *normally open* valve and is closed only when commanded by the PCM during testing of the system. The vent valve is closed only during testing by the PCM as part of the mandated OBD-II standards. The vent solenoid is located under the vehicle, in most cases, and is exposed to the environment, making this valve subject to rust and corrosion.

PURGE VALVE The canister **purge valve**, also called the *canister purge (CANP) solenoid,* is normally closed and is pulsed open by

PSI	INCHES HG	INCHES H_2O
14.7	29.93	407.19

CHART 80–1

Pressure conversions.

NOTE: 1 PSI = 28 in. H_2O
0.25 PSI = 7 in. H_2O

the PCM during purging. The purge valve is connected to intake manifold vacuum using a rubber hose to draw gasoline vapors from the charcoal canister into the engine when the purge valve is commanded open. Most purge valves are pulsed on and off to better control the amount of fumes being drawn into the intake manifold.

TECH TIP

Problems after Refueling? Check the Purge Valve

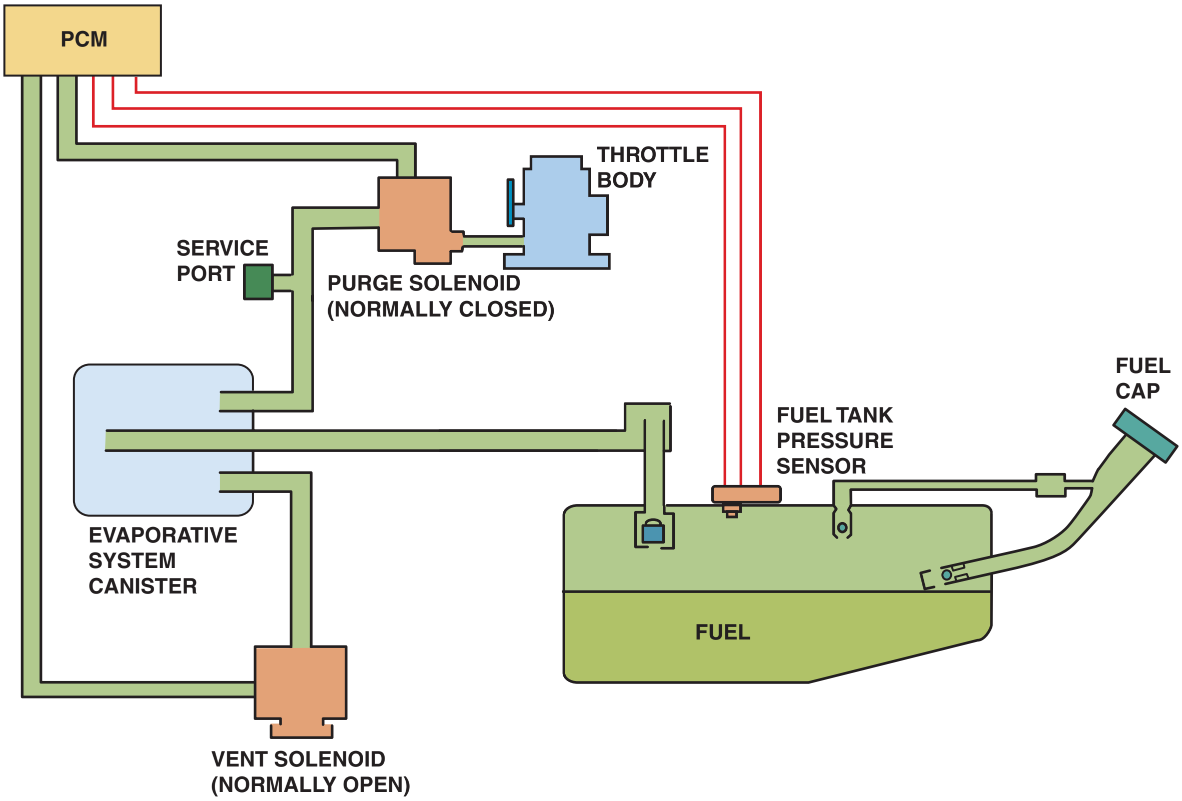
The purge valve is normally closed and open only when the PCM is commanding the system to purge. If the purge solenoid becomes stuck in the open position, gasoline fumes are allowed to flow directly from the gas tank to the intake manifold. When refueling, this results in a lot of fumes being forced into the intake manifold and, as a result, causes a hard-to-start condition after refueling. This also results in a rich exhaust, and likely black exhaust, when first starting the engine after refueling. While the purge solenoid is usually located under the hood of most vehicles and is less subject to rust and corrosion, as with the vent valve, it can still fail.

LEAK DETECTION PUMP SYSTEM

FUNCTION Many vehicles use a vacuum operated **leak detection pump (LDP)** as part of the evaporative control system diagnosis equipment. ● **SEE FIGURE 80–6.**

OPERATION The system works to test for leaks as follows:

- The purge solenoid is normally closed.
- The vent valve in the LDP is normally open. Filtered fresh air is drawn through the LDP to the canister.



PCM
THROTTLE BODY
SERVICE PORT
PURGE SOLENOID (NORMALLY CLOSED)
FUEL CAP
FUEL TANK PRESSURE SENSOR
EVAPORATIVE SYSTEM CANISTER
FUEL
VENT SOLENOID (NORMALLY OPEN)

FIGURE 80–5 An enhanced EVAP system is able to perform system and leak detection diagnosis.

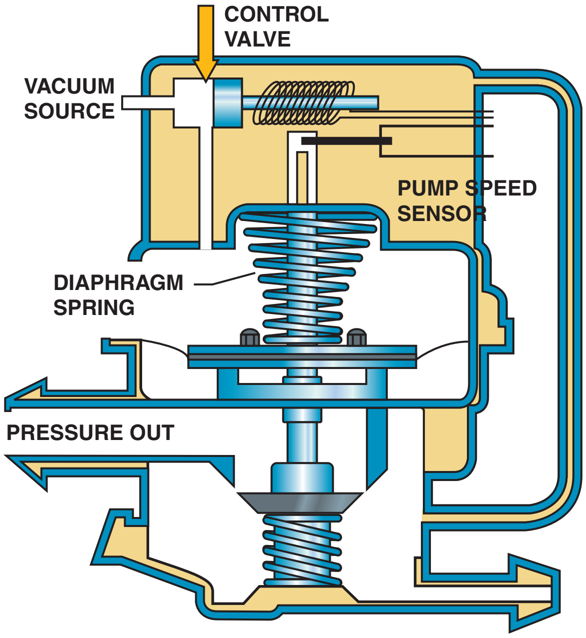


FIGURE 80–6 A leak detection pump (LDP) used on some Chrysler and other vehicles to pressurize (slightly) the fuel system to check for leaks.

- The LDP uses a spring attached to a diaphragm to apply pressure (7.5 in. H_2O) to the fuel tank.
- The PCM monitors the LDP switch that is triggered if the pressure drops in the fuel tank.
- The time between LDP solenoid off and LDP switch close is called the pump period. This time period is inversely proportional to the size of the leak. The shorter the pump period, the larger the leak. The longer the pump period, the smaller the leak.

EVAP large leak (greater than 0.080 inch): less than 0.9 second
EVAP medium leak (0.040 to 0.080 inch): 0.9 to 1.2 seconds
EVAP small leak (0.020 to 0.040 inch): 1.2 to 6 seconds

ONBOARD REFUELING VAPOR RECOVERY

PURPOSE The **onboard refueling vapor recovery (ORVR)** system was first introduced on some 1998 vehicles. Previously designed EVAP systems allowed fuel vapor to escape to the atmosphere during refueling.

OPERATION The primary feature of most ORVR systems is the restricted tank filler tube, which is about 1 inch (25 mm) in diameter. This reduced-size filler tube creates an aspiration effect, which tends to draw outside air into the filler tube. During refueling, the fuel tank is vented to the charcoal canister, which captures the gas fumes and, with air flowing into the filler tube, no vapors can escape to the atmosphere. ● **SEE FIGURE 80–7**.

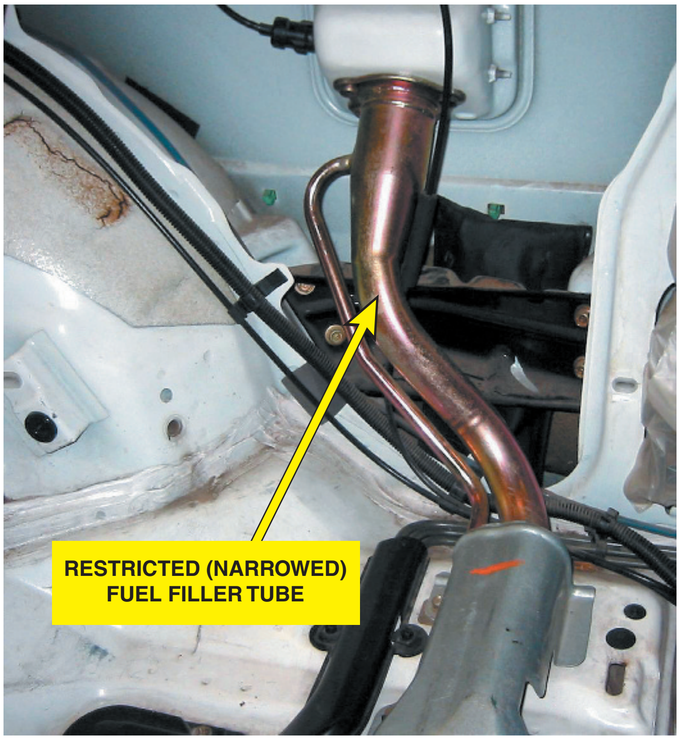

FIGURE 80–7 A restricted fuel fill pipe shown on vehicle with the interior removed.

DIAGNOSING THE EVAP SYSTEM

SYMPTOMS Before vehicle emissions testing began in many parts of the country, little service work was done on the evaporative emission system. Common engine performance problems that can be caused by a fault in this system include the following:

- **Poor fuel economy.** A leak in a vacuum-valve diaphragm can result in engine vacuum drawing in a constant flow of gasoline vapors from the fuel tank. This usually results in a drop in fuel economy of 2 to 4 miles per gallon (mpg). Use a hand-operated vacuum pump to check that the vacuum diaphragm can hold vacuum.
- **Poor performance.** A vacuum leak in the system can cause the engine to run rough. Age, heat, and time all contribute to the deterioration of rubber hoses.

STATE EVAP TESTS Enhanced exhaust emissions (I/M-240) testing tests the evaporative emission system. A leak in the system is tested by pressurizing the entire fuel system to a level below 1 PSI (about 14 in. H_2O). The system is typically pressurized with nitrogen, a nonflammable gas that makes up 78% of our atmosphere. The pressure in the system is then shut off and the pressure monitored. If the pressure drops below a set standard, then the vehicle fails the test. This test determines if there is a leak in the system.

HINT: To help pass the evaporative section of an enhanced emissions test, arrive at the test site with less than a half tank of fuel. This means that the rest of the volume of the fuel tank is filled with air. It takes longer for the pressure to drop from a small leak when the volume of the air is greater compared to when the tank is full and the volume of air remaining in the tank is small.

FIGURE 80–9 To test for a leak, this tester was set to the 0.020-inch hole and turned on. The ball rose in the scale on the left, and the red arrow was moved to that location. If, when testing the system for leaks, the ball rises higher than the arrow, then the leak is larger than 0.02 inch. If the ball does not rise to the level of the arrow, the leak is smaller than 0.020 inch.

LOCATING LEAKS IN THE SYSTEM Leaks in the evaporative emission control system cause the malfunction check gas cap indication lamp to light on some vehicles. ● **SEE FIGURE 80–8.**

A leak also causes a gas smell, which is most noticeable if the vehicle is parked in an enclosed garage. The first step is to determine if there is a leak in the system by setting the EVAP tester to rate the system for either a 0.040-inch or a 0.020-inch-hole-size leak. ● **SEE FIGURE 80–9.**

After it has been determined that a leak exists and it is larger than specified, one of two methods can be used to check for leaks in the evaporative system:

- **Smoke machine testing.** The most efficient method of leak detection is to introduce smoke under low pressure from a machine specifically designed for this purpose. ● **SEE FIGURE 80–10.**
- **Nitrogen gas pressurization.** This method uses nitrogen gas under a very low pressure (lower than 1 PSI) in the fuel system. The service technician then listens for the escaping air, using amplified headphones. ● **SEE FIGURE 80–11.**

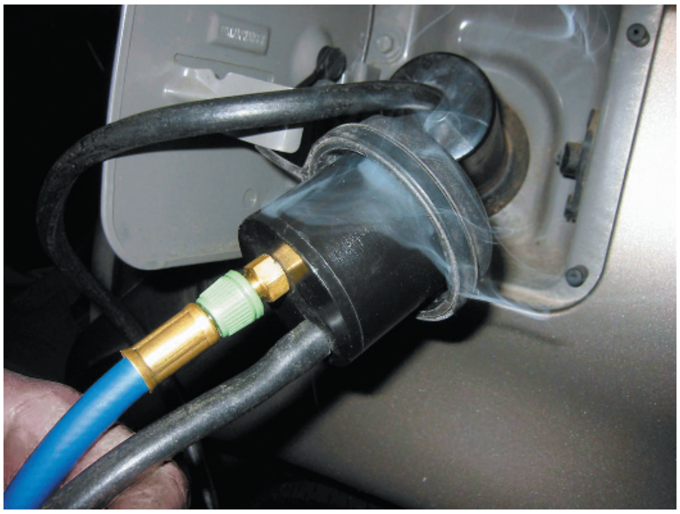

FIGURE 80–10 This unit is applying smoke to the fuel tank through an adapter, and the leak was easily found to be the gas cap seal.

EVAPORATIVE SYSTEM MONITOR

OBD-II REQUIREMENTS OBD-II computer programs not only detect faults, but also *periodically test various systems* and alert the driver before emissions-related components are harmed by system faults:

- Serious faults cause a blinking MIL or even an engine shutdown.
- Less serious faults may simply store a code, but not illuminate the MIL.

The OBD-II requirements did not affect fuel system design. However, one new component, a fuel evaporative canister purge line pressure sensor, was added for monitoring purge line pressure during tests. The OBD-II requirements state that vehicle fuel systems are to be routinely tested *while under way* by the PCM.

All OBD-II vehicles perform a canister purge system pressure test, as commanded by the PCM. While the vehicle is being driven, the vapor line between the canister and the purge valve is monitored for pressure changes:

- When the canister purge solenoid is open, the line should be under a vacuum since vapors must be drawn from the canister into the intake system. However, when the purge solenoid is closed, there should be no vacuum in the line. The pressure sensor detects if a vacuum is present, and the information is compared to the command given to the solenoid.
- If, during the canister purge cycle, no vacuum exists in the canister purge line, a code is set indicating a possible fault, which could be caused by an inoperative or clogged solenoid or a blocked or leaking canister purge fuel line. Likewise, if vacuum exists when no command for purge is given, a stuck solenoid is evident, and a code is set. The EVAP system monitor tests for purge volume and leaks.

A typical EVAP monitor first closes off the system to atmospheric pressure and opens the purge valve during cruise operation. A **fuel tank pressure (FTP)** sensor then monitors the rate with which vacuum increases in the system. The monitor uses this information to determine the purge volume flow rate. To test for leaks, the EVAP monitor closes the purge valve, creating a completely closed system. The fuel tank pressure sensor then monitors the leak-down rate. If the rate exceeds PCM-stored values, a leak greater than or equal to the OBD-II standard of 0.04 inch (1 mm) or 0.02 inch (0.5 mm) exists. After two consecutive failed trips testing either purge volume or the presence of a leak, the PCM lights the MIL and sets a DTC.

The fuel tank pressure sensor is similar to a MAP sensor, and instead of monitoring intake manifold absolute pressure, it is used to monitor fuel tank pressure. ● **SEE FIGURE 80–12**.

ENGINE-OFF NATURAL VACUUM System integrity (leakage) can also be checked after the engine is shut off. The premise is that a warm evaporative system cools down after the engine is shut off and the vehicle is stable. A slight vacuum is created in the gas tank during this cool-down period. If a specific level of vacuum is reached and maintained, the system is said to have integrity (no leakage). Actually, the vacuum is created after a period of time because the vapor pressure tends to increase after the engine is shut off and gradually decreases over time.

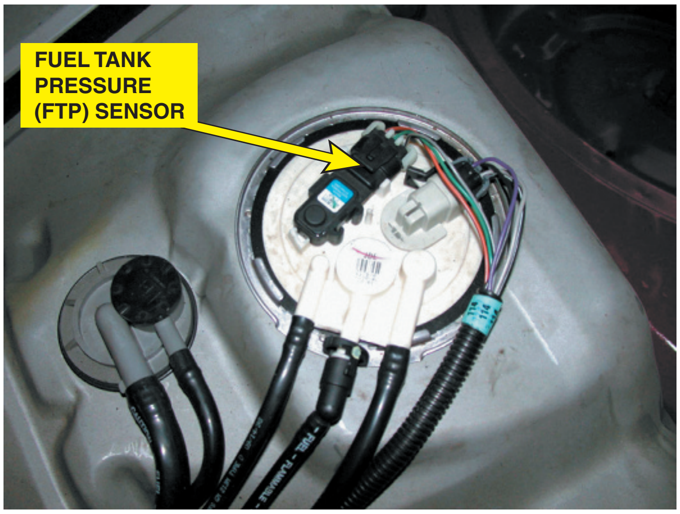

FIGURE 80–12 The fuel tank pressure sensor (black unit with three wires) looks like a MAP sensor and is usually located on top of the fuel pump module (white unit).

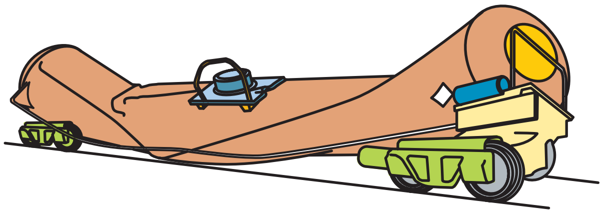

FIGURE 80–13 A tank car was cleaned using steam, and then both the bottom drain and the top vent were closed. The next day, the tank had collapsed because of the air pressure difference when the inside cooled. The higher outside air pressure caused the tank to collapse.

The PCM monitors the pressure rise and decrease over time and triggers a DTC if the pressure indicates a leak in the system. ● **SEE FIGURE 80–13**.

TYPICAL EVAP MONITOR The PCM runs the EVAP monitor when the following enable criteria are met:

- Barometric pressure (BARO) greater than 70 kPa (20.7 in. Hg or 10.2 PSI)
- Intake air temperature (IAT) between 39°F and 86°F (4°C to 30°C) at engine start-up
- Engine coolant temperature (ECT) between 39°F and 86°F (4°C to 30°C) at engine start-up
- ECT and IAT within 3°F of each other at engine start-up
- Fuel level within 15% to 85%
- Throttle position (TP) sensor between 9% and 35%

TECH TIP

Always Tighten the Cap Correctly

Many DTCs are set because the gas cap has not been properly installed. To be sure that a screw-type gas cap is properly sealed, tighten it until you hear three clicks. The clicking is a ratchet device, and the clicking does not harm the cap. Therefore, if a P0440 or similar DTC is set, check the cap. ● **SEE FIGURE 80–14**.

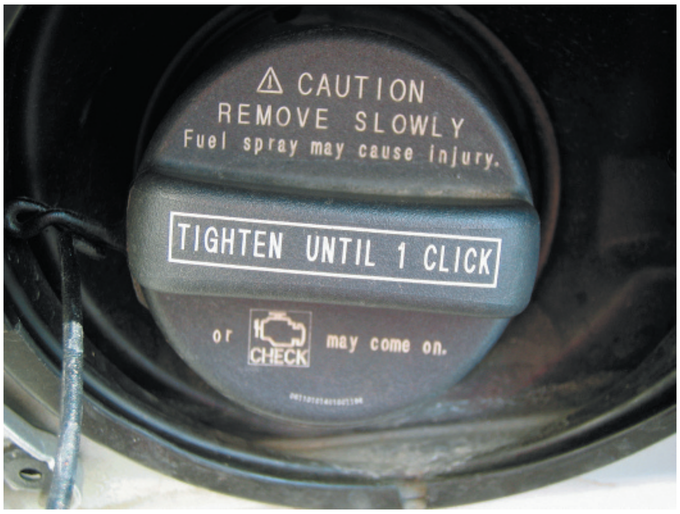

FIGURE 80–14 This Toyota cap warns that the check engine light comes on if not tightened until one click.

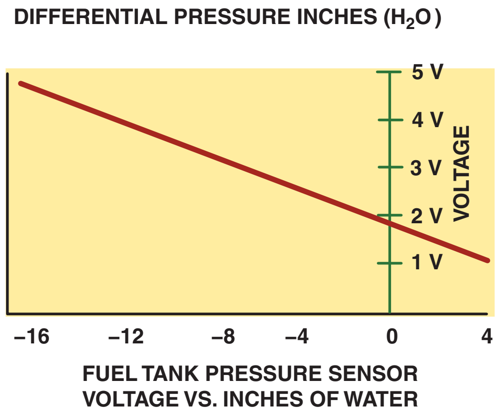

FIGURE 80–15 To easily check the fuel tank pressure sensor, remove the cap, and the sensor should read about 1.7 volts.

A typical EVAP monitor first closes off the system to atmospheric pressure and opens the purge valve during cruise operation. A FTP sensor then monitors the rate with which vacuum increases in the system. ● **SEE FIGURE 80–15.**

The monitor uses this information to determine the purge volume flow rate. To test for leaks, the EVAP monitor closes the purge valve, creating a completely closed system. The fuel tank pressure sensor then monitors the leak-down rate. If the rate exceeds PCM-stored values, a leak greater than or equal to the OBD-II standard of 0.04 inch (1 mm) or 0.02 inch (0.5 mm) exists.

RUNNING THE EVAP MONITOR Four tests are performed during a typical EVAP monitor. A DTC is assigned to each test:

1. **Weak vacuum test (P0440–large leak).** This test identifies gross leaks. During the monitor, the vent solenoid is closed, and the purge solenoid is duty cycled. The FTP should indicate a vacuum of approximately 6 to 10 inches H_2O.
2. **No flow during purging (P0441–no flow during purging).** This test uses the FTP sensor to determine that there was no change in fuel tank pressure during purging. This fault could be due to a defective purge valve or a gross leak caused by faults, such as a defective or missing gas cap.
3. **Small leak test (P0442–small leak).** After the large leak test passes, the PCM checks for a small leak by keeping the vent solenoid closed and closing the purge solenoid. The system is now sealed. The PCM measures the change in FTP voltage over time.
4. **Excess vacuum test (P0446).** This test checks for vent path restrictions. With the vent solenoid open and purge commanded, the PCM should not see excessive vacuum in the EVAP system. Typical EVAP system vacuum with the vent solenoid open is about 5 to 6 in. H_2O.

TECH TIP

Keep the Fuel Tank Properly Filled

Most evaporative system monitors do not run unless the fuel level is between 15% and 85%. In other words, if a driver always runs with close to an empty tank or always tries to keep the tank full, the EVAP monitor may not run. ● **SEE FIGURE 80–16.**

FIGURE 80–16 The fuel level must be above 15% and below 85% before the EVAP monitor runs on most vehicles.

EVAP SYSTEM-RELATED DIAGNOSTIC TROUBLE CODES

Diagnostic Trouble Code	Description	Possible Causes
P0440	Evaporative system fault	■ Loose gas cap ■ Defective EVAP vent ■ Cracked charcoal canister ■ EVAP vent or purge vapor line problems
P0442	Small leak detected	■ Loose gas cap ■ Defective EVAP vent or purge solenoid ■ EVAP vent or purge line problems
P0446	EVAP canister vent blocked	■ EVAP vent or purge solenoid electrical problems ■ Restricted EVAP canister vent line

EXHAUST GAS RECIRCULATION SYSTEMS

INTRODUCTION **Exhaust gas recirculation (EGR)** is an emission control system that lowers the amount of **nitrogen oxides (NO_x)** formed during combustion. In the presence of sunlight, NO_x reacts with hydrocarbons in the atmosphere to form ozone (O_3) or photochemical smog, an air pollutant.

NO_x FORMATION Nitrogen (N_2) and oxygen (O_2) molecules are separated into individual atoms of nitrogen and oxygen during the combustion process. These molecules then bond to form NO_x (NO, NO_2). When combustion flame front temperatures exceed 2,500°F (1,370°C), NO_x is formed inside the cylinder, which is then discharged into the atmosphere from the tailpipe. ● **SEE FIGURE 80–17.**

FIGURE 80–17 Nitrogen oxides (NO_x) create a red-brown haze that often hangs over major cities.

CONTROLLING NO_x To handle the NO_x generated above 2,500°F (1,370°C), the most efficient method to meet NO_x emissions without significantly affecting engine performance, fuel economy, and other exhaust emissions is to use exhaust gas recirculation (EGR). The EGR system routes small quantities, usually between 6% and 10%, of exhaust gas into the intake manifold.

Here, the exhaust gas mixes with and takes the place of some intake charge. This leaves less room for the intake charge to enter the combustion chamber. The recirculated exhaust gas is **inert** (chemically inactive) and does not enter into the combustion process. The result is a lower peak combustion temperature. When the combustion temperature is lowered, the production of oxides of nitrogen is reduced.

The EGR system has some means of interconnecting the exhaust and intake manifolds. ● **SEE FIGURE 80–18**.

The EGR valve controls the flow of exhaust gases through the interconnecting passages:

- On V-type engines, the intake manifold crossover is used as a source of exhaust gas for the EGR system. A cast passage connects the exhaust crossover to the EGR valve. The exhaust gas is sent from the EGR valve to openings in the manifold.
- On inline-type engines, an external tube is generally used to carry exhaust gas to the EGR valve. This tube is often designed to be long so that the exhaust gas is cooled before it enters the EGR valve.

EGR SYSTEM OPERATION Since small amounts of exhaust are all that is needed to lower peak combustion temperatures, the orifice through which the exhaust passes is small.

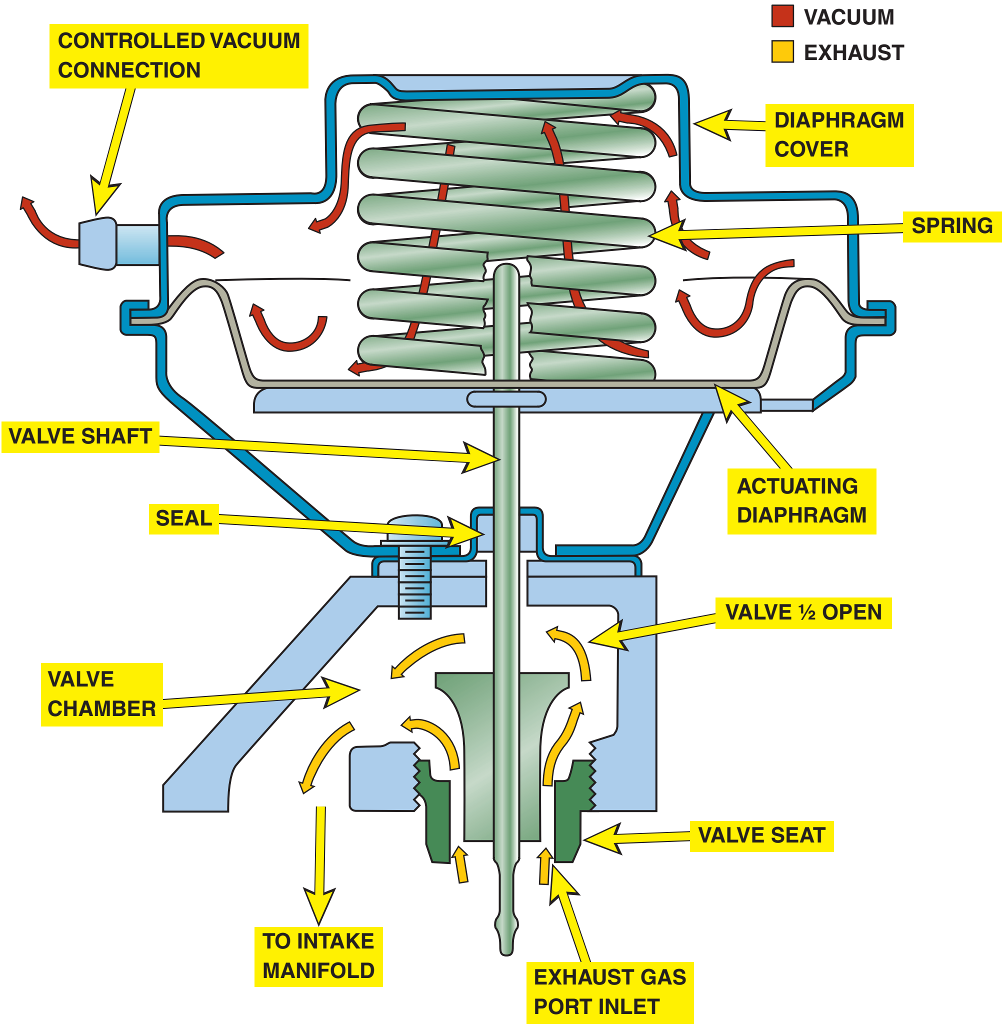

FIGURE 80–18 When the EGR valve opens, the exhaust gases flow through the valve and into passages in the intake manifold.

EGR is usually not required during the following conditions because the combustion temperatures are low:

- During idle speed
- When the engine is cold
- At wide-open throttle (WOT) (Not allowing EGR allows the engine to provide extra power when demanded. While the NO_x formation is high during these times, the overall effect of not using EGR during WOT conditions is minor.)

The level of NO_x emission changes according to engine speed, temperature, and load. Many systems use a cooler to reduce the temperature of the exhaust gases before they enter the intake manifold. The cooler the exhaust gases, the more effective they are at reducing the formation of NO_x.

EGR BENEFITS In addition to lowering NO_x levels, the EGR system also helps control detonation. **Detonation**, also called spark knock or ping, occurs when high pressure and heat cause the air–fuel mixture to ignite. This uncontrolled combustion can severely damage the engine.

Using the EGR system allows for greater ignition timing advance, and for the advance to occur sooner without detonation problems, which increases power and efficiency.

EGR VALVE POSITION SENSORS Most PCM vacuum-operated EGR systems use a sensor to indicate EGR operation. Onboard diagnostics generation II (OBD-II) EGR system monitors require an EGR sensor to verify that the valve opened. A linear potentiometer on the top of the EGR valve stem indicates valve position to the PCM. This is called an **EGR valve position (EVP) sensor**. Some later-model Ford EGR systems, however, use a feedback signal provided by an EGR exhaust back pressure sensor that converts the exhaust back pressure to a voltage signal. This sensor is called a **pressure feedback EGR (PFE) sensor**.

On some EGR systems, the top of the valve contains a vacuum regulator and EGR pintle-position sensor in one assembly sealed inside a nonremovable plastic cover. The pintle-position sensor provides a voltage output to the PCM, which increases as the duty cycle increases, allowing the PCM to monitor valve operation. ● **SEE FIGURE 80–19**.

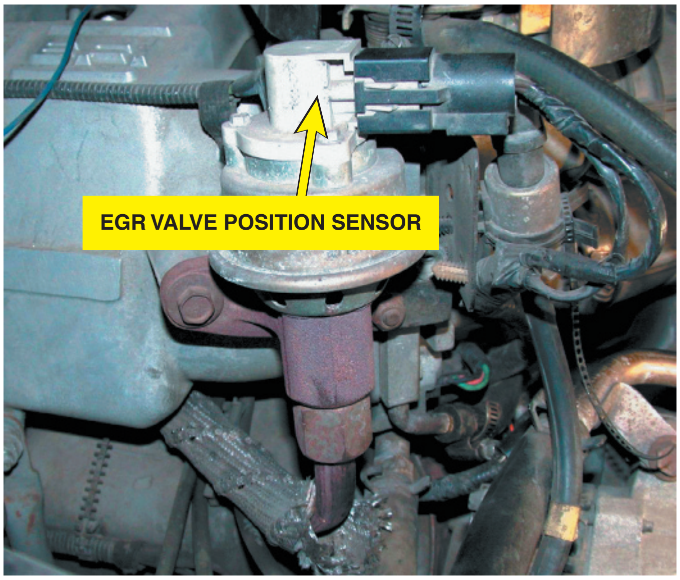

FIGURE 80–19 An EGR valve position sensor on top of an EGR valve.

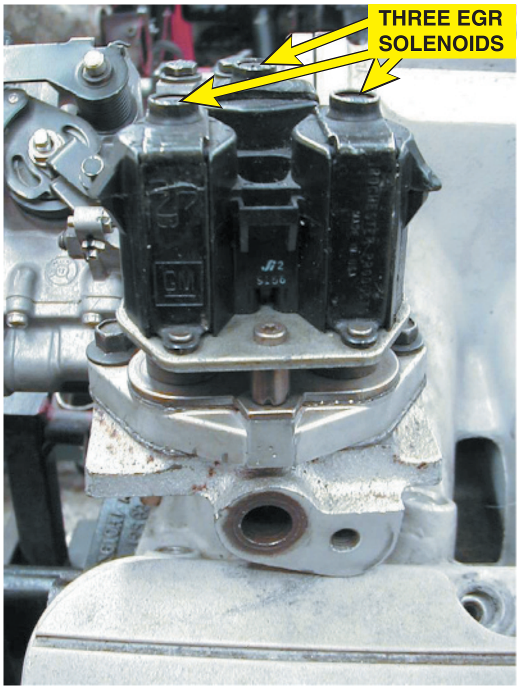

FIGURE 80–20 Digital EGR valve as used on some older General Motors engines.

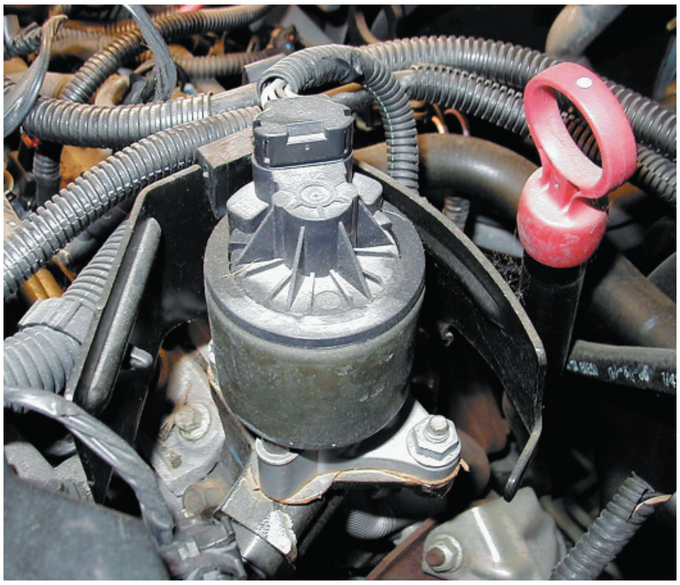

FIGURE 80–21 A General Motors linear EGR valve.

DIGITAL EGR VALVES General Motors used **a digital EGR valve** design on some engines. Unlike vacuum-operated EGR valves, the digital EGR valve consists of three solenoids controlled by the powertrain control module (PCM). Each solenoid controls a different size orifice in the base—small, medium, and large. The PCM controls the ground circuit of each of the solenoids individually. It can produce any of seven different flow rates, using the solenoids to open the three valves in different combinations. The digital EGR valve offers precise control and using a swivel pintle design helps prevent carbon deposit problems. ● **SEE FIGURE 80–20**.

LINEAR EGR Most General Motors and many other vehicles use a **linear EGR valve** that contains a pulse-width modulated solenoid to precisely regulate exhaust gas flow and a feedback potentiometer that signals the PCM regarding the actual position of the valve. ● **SEE FIGURES 80–21 AND 80–22**.

TECH TIP

Find the Root Cause

Excessive back pressure, such as that caused by a partially clogged exhaust system, could cause the plastic sensors on the EGR valve to melt. Always check for a restricted exhaust whenever replacing a failed EGR valve sensor.

OBD-II EGR MONITORING STRATEGIES

PURPOSE AND FUNCTION In 1996, the U.S. Environmental Protection Agency (EPA) began requiring OBD-II systems in all passenger cars and most light-duty trucks. These systems include emission system monitors that alert the driver and the technician if an emission system is malfunctioning. The OBD-II system performs this test by opening and closing the EGR valve. The PCM monitors either the oxygen or MAP sensor for a change in signal voltage. If the EGR system fails, a DTC is set. If the system fails two consecutive times, the MIL is lit.

MONITORING STRATEGIES EGR monitoring strategies include the following:

- Some vehicle manufacturers, such as Chrysler, monitor the difference in the exhaust oxygen sensor's voltage activity as the EGR valve opens and closes. Oxygen in the exhaust decreases when the EGR valve is open and increases when the EGR valve is closed because exhaust gas is inert (contains very little oxygen) and actually displaces oxygen. The PCM sets a DTC if the sensor signal does not change.
- Most Fords use an EGR monitor test sensor called a **delta pressure feedback EGR (DPFE) sensor**. This sensor measures the pressure differential between two sides of a metered orifice positioned just below the EGR valve's exhaust side. Pressure between the orifice and the EGR valve decreases when the EGR opens because it becomes exposed to the lower pressure in the intake. The DPFE sensor recognizes this pressure drop, compares it to the relatively higher pressure on the exhaust side of the orifice, and signals the value of the pressure difference to the PCM. ● **SEE FIGURE 80–23**.
- Many vehicle manufacturers use the manifold absolute pressure (MAP) sensor as the EGR monitor on some applications. After meeting the enable criteria (operating condition requirements), the EGR monitor is run. The PCM monitors the MAP sensor while it commands the EGR valve to open. The MAP sensor signal should change in response to the sudden change in manifold pressure or the fuel trim changes created by a change in the oxygen sensor voltage. If the signal value falls outside the acceptable value in the lookup table, a DTC sets. If the EGR fails on two consecutive trips, the PCM lights the MIL. ● **SEE FIGURE 80–24**.

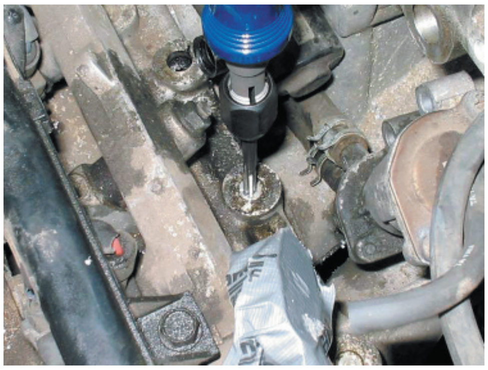

FIGURE 80–25 Removing the EGR passage plugs from the intake manifold on a Honda.

TECH TIP

Watch Out for Carbon Balls!

EGR valves can get stuck partially open by a chunk of carbon, and the valve or solenoid tests as defective. When the valve (or solenoid) is removed, small chunks or balls of carbon often fall into the exhaust manifold passage. When the replacement valve is installed, the carbon balls can be drawn into the new valve again, causing the engine to idle roughly or stall.

To help prevent this problem, start the engine with the EGR valve or solenoid removed. Any balls or chunks of carbon are blown out of the passage by the exhaust. Stop the engine and install the replacement EGR valve or solenoid.

TECH TIP

The Snake Trick

The EGR passages on many intake manifolds become clogged with carbon, which reduces the flow of exhaust and the amount of exhaust gases in the cylinders. This reduction can cause spark knock (detonation) and increased emissions of oxides of nitrogen (NO_X) (especially important in areas with enhanced exhaust emissions testing).

To quickly and easily remove carbon from exhaust passages, cut an approximately 1-foot (30-cm) length from stranded wire, such as garage door guide wire or an old speedometer cable. Flare the end and place the end of the wire into the passage. Set your drill on reverse and turn it on, and the wire pulls its way through the passage, cleaning the carbon as it goes, just like a snake in a drainpipe. Some vehicles, such as Hondas, require that plugs be drilled out to gain access to the EGR passages. ● **SEE FIGURE 80–25**.

DIAGNOSING A DEFECTIVE EGR SYSTEM

SYMPTOMS If the EGR valve is not opening or the flow of the exhaust gas is restricted, then the following symptoms are likely:

- Detonation (spark knock or ping) during acceleration or during cruise (steady-speed driving)
- Excessive oxides of nitrogen (NO_x) exhaust emissions

If the EGR valve is stuck open or partially open, then the following symptoms are likely:

- Rough idle or frequent stalling
- Poor performance/low power, especially at low engine speed

EGR TESTING PROCEDURES The first step in almost any diagnosis is to perform a thorough visual inspection. To check for proper operation of a vacuum-operated EGR valve, follow these steps:

STEP 1 **Check the vacuum diaphragm of the EGR valve to see if it can hold vacuum.** Because many EGR valves require exhaust back pressure to function correctly, the engine should be running at a fast idle during this test.

STEP 2 **Apply vacuum from a hand-operated vacuum pump and check for proper operation.** The valve itself should move when vacuum is applied, and the engine operation should be affected. The EGR valve should be able to hold the vacuum that was applied. If the vacuum drops off, then the valve is likely to be defective.

STEP 3 **Monitor engine vacuum drop.** Connect a vacuum gauge to an intake manifold vacuum source and monitor the engine vacuum at idle (should be 17 to 21 in. Hg at sea level). Raise the speed of the engine to 2,500 RPM and note the vacuum reading (should be 17 to 21 in. Hg or higher).

Activate the EGR valve using a scan tool or vacuum pump, if vacuum-controlled, and observe the vacuum gauge. The results are as follows:

- The vacuum should drop 6 to 8 in. Hg.
- If the vacuum drops less than 6 to 8 in. Hg, the valve or the EGR passages are clogged.
- If the EGR valve is able to hold vacuum, but the engine is not affected when the valve is opened, then the exhaust passage(s) must be checked for restriction.

See the Tech Tip “The Snake Trick.” If the EGR valve does not hold vacuum, the valve itself is likely to be defective and requires replacement.

EGR-RELATED OBD-II DIAGNOSTIC TROUBLE CODES

Diagnostic Trouble Code	Description	Possible Causes
P0400	Exhaust gas recirculation flow problems	■ EGR valve ■ EGR valve hose or electrical connection ■ Defective PCM
P0401	Exhaust gas recirculation flow insufficient	■ EGR valve ■ Clogged EGR ports or passages
P0402	Exhaust gas recirculation flow excessive	■ Stuck-open EGR valve ■ Vacuum hose(s) misrouted ■ Electrical wiring shorted

REVIEW QUESTIONS

1. What components are used in a typical evaporative emission control system?
2. Why is the vent valve subject to rust and corrosion?
3. What are the parameters (enable criteria) that must be met for the evaporative system monitor to run?
4. What causes the formation of oxides of nitrogen?
5. How does the use of exhaust gas reduce NOx exhaust emission?

CHAPTER QUIZ

1. What is the substance used in a vapor canister to absorb volatile organic compounds?
   a. Desiccant
   b. Organic absorber
   c. Pleated paper
   d. Charcoal
2. Which valve(s) is (are) normally closed?
   a. Canister purge valve
   b. Canister vent valve
   c. Both canister purge and canister vent valves
   d. Neither canister purge nor canister vent valve
3. All of the following can increase the pressure in the evaporative emission control system *except* ____________.
   a. fuel temperature
   b. returned fuel from the fuel-injection system
   c. inlet fuel to the fuel pump
   d. volatility of the fuel
4. Inadequate purge flow rate triggers which DTC?
   a. P0440
   b. P0446
   c. P0300
   d. P0440 or P0446
5. Which EVAP valve is subject to rust and corrosion more than all of the others?
   a. Purge valve
   b. Vacuum control valve
   c. Vent valve
   d. Rollover check valve
6. A small leak is detected by the evaporative emission control system monitor that could be caused by a loose gas cap. Which DTC is likely set?
   a. P0440
   b. P0442
   c. P0446
   d. P0440, P0441, or P0442
7. Exhaust gas recirculation (EGR) is generally not needed under all the following conditions *except* ____________.
   a. idle speed
   b. cold engine
   c. cruise speed
   d. wide-open throttle (WOT)
8. EGR is used to control which exhaust emission?
   a. Unburned hydrocarbons (HC)
   b. Oxides of nitrogen (NOx)
   c. Carbon monoxide (CO)
   d. Both NOx and CO
9. When testing an EGR system for proper operation using a vacuum gauge, how much should the vacuum drop when the EGR is commanded on by a scan tool?
   a. 1 to 2 in. Hg
   b. 3 to 5 in. Hg
   c. 6 to 8 in. Hg
   d. 8 to 10 in. Hg
10. A P0401 DTC (exhaust gas recirculation flow insufficient) is being discussed. Technician A says that a defective EGR valve could be the cause. Technician B says that clogged EGR passages could be the cause. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

POSITIVE CRANKCASE VENTILATION AND SECONDARY AIR-INJECTION SYSTEMS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe the purpose and function of the positive crankcase ventilation (PCV) system.
- Discuss PCV system diagnosis.
- Explain the purpose and function of the secondary air-injection (SAI) system.
- Explain how to diagnose faults in the secondary air-injection system.

KEY TERMS:

Air-injection reaction (AIR) 957 • Blowby 954 • Check valve 958 • Positive crankcase ventilation (PCV) 954 • Secondary air injection (SAI) 957 • Smog pump 957 • Thermactor pump 957

CRANKCASE VENTILATION

PURPOSE AND FUNCTION The problem of crankcase ventilation has existed since the beginning of the automobile because no piston ring, new or old, can provide a perfect seal between the piston and the cylinder wall. When an engine is running, the pressure of combustion forces the piston downward. This same pressure also forces gases and unburned fuel from the combustion chamber, past the piston rings, and into the crankcase. This process of gases leaking past the rings is called **blowby**, and the gases form crankcase vapors.

These combustion by-products, particularly unburned hydrocarbons (HC) caused by blowby, must be ventilated from the crankcase. However, the crankcase cannot be vented directly to the atmosphere because the hydrocarbon vapors add to air pollution. **Positive crankcase ventilation (PCV)** systems were developed to ventilate the crankcase and recirculate the vapors to the engine's induction system so they can be burned in the cylinders. PCV systems help reduce HC and CO emissions.

All systems use the following:

1. PCV valve or calibrated orifice, or orifice and separator
2. PCV inlet air filter plus all connecting hoses

● **SEE FIGURE 81–1.**

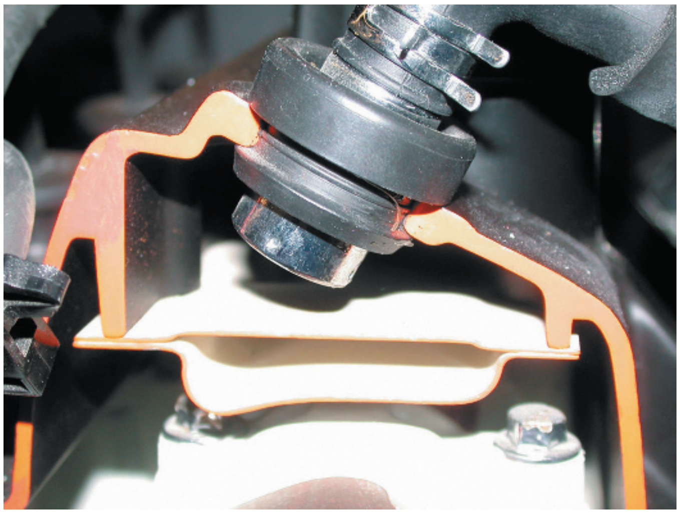

FIGURE 81–1 A PCV valve in a cutaway valve cover, showing the baffles that prevent liquid oil from being drawn into the intake manifold.

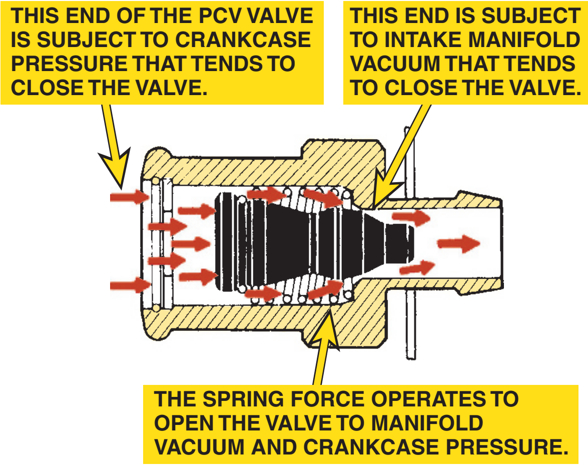
An oil/vapor or oil/water separator is used in some systems instead of a valve or orifice, particularly with turbocharged and fuel-injected engines. The oil/vapor separator lets oil condense and drain back into the crankcase. The oil/water separator



THIS END OF THE PCV VALVE IS SUBJECT TO CRANKCASE PRESSURE THAT TENDS TO CLOSE THE VALVE.
THIS END IS SUBJECT TO INTAKE MANIFOLD VACUUM THAT TENDS TO CLOSE THE VALVE.
THE SPRING FORCE OPERATES TO OPEN THE VALVE TO MANIFOLD VACUUM AND CRANKCASE PRESSURE.

FIGURE 81–2 Spring force, crankcase pressure, and intake manifold vacuum work together to regulate the flow rate through the PCV valve.

accumulates moisture and prevents it from freezing during cold engine starts.

The air for the PCV system is drawn after the air cleaner filter, which acts as a PCV filter.

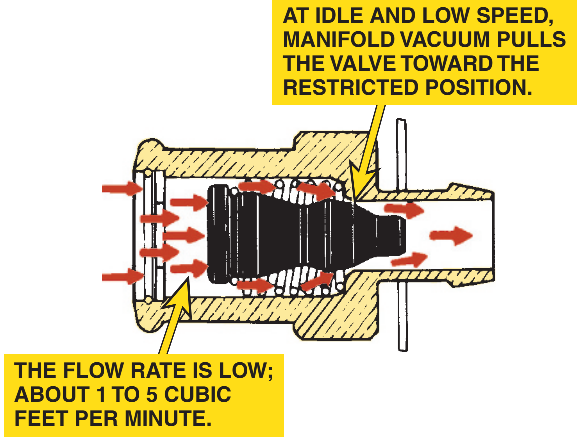
NOTE: Some older designs drew from the dirty side of the air cleaner, where a separate crankcase ventilation filter was used.

PCV VALVES The PCV valve in most systems is a one-way valve containing a spring-operated plunger that controls valve flow rate. ● **SEE FIGURE 81–2**.

Flow rate is established for each engine, and a valve for a different engine should not be substituted. The flow rate is determined by the size of the plunger and the holes inside the valve. PCV valves usually are located in the valve cover or intake manifold.

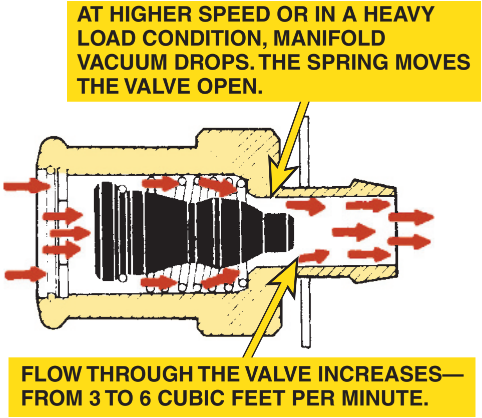
The PCV valve regulates airflow through the crankcase under all driving conditions and speeds. When manifold vacuum is high (at idle, cruising, and light-load operation), the PCV valve restricts the airflow to maintain a balanced air–fuel ratio. ● **SEE FIGURE 81–3**.

It also prevents high intake manifold vacuum from pulling oil out of the crankcase and into the intake manifold. Under high speed or heavy loads, the valve opens and allows maximum airflow. ● **SEE FIGURE 81–4**.



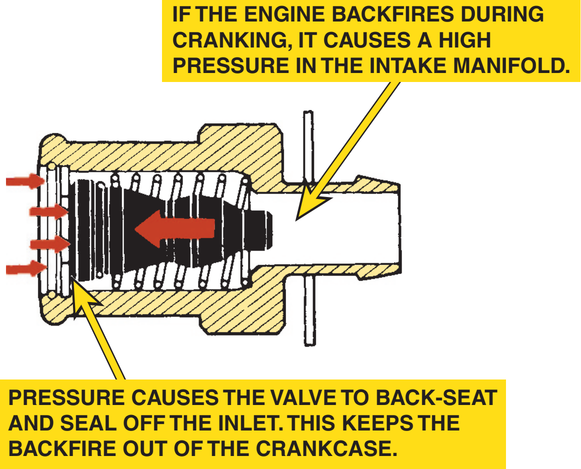
AT IDLE AND LOW SPEED, MANIFOLD VACUUM PULLS THE VALVE TOWARD THE RESTRICTED POSITION.
THE FLOW RATE IS LOW; ABOUT 1 TO 5 CUBIC FEET PER MINUTE.

FIGURE 81–3 Air flows through the PCV valve during idle, cruising, and light-load conditions.



AT HIGHER SPEED OR IN A HEAVY LOAD CONDITION, MANIFOLD VACUUM DROPS. THE SPRING MOVES THE VALVE OPEN.
FLOW THROUGH THE VALVE INCREASES— FROM 3 TO 6 CUBIC FEET PER MINUTE.

FIGURE 81–4 Air flows through the PCV valve during acceleration and when the engine is under a heavy load.



IF THE ENGINE BACKFIRES DURING CRANKING, IT CAUSES A HIGH PRESSURE IN THE INTAKE MANIFOLD.
PRESSURE CAUSES THE VALVE TO BACK-SEAT AND SEAL OFF THE INLET. THIS KEEPS THE BACKFIRE OUT OF THE CRANKCASE.

FIGURE 81–5 PCV valve operation in the event of a backfire.

If the engine backfires, the valve closes instantly to prevent a crankcase explosion. ● **SEE FIGURE 81–5**.

ORIFICE-CONTROLLED SYSTEMS The closed PCV system used on some 4-cylinder engines contains a calibrated orifice instead of a PCV valve. The orifice may be located in the valve cover or intake manifold, or in a hose connected between the valve cover, air cleaner, and intake manifold.

While most orifice flow control systems work the same as a PCV valve system, they may not use fresh air scavenging of the crankcase. Crankcase vapors are drawn into the intake manifold in calibrated amounts, depending on manifold pressure and the orifice size. If vapor availability is low, as during idle, air is drawn in with the vapors. During off-idle operation, excess vapors are sent to the air cleaner.

At idle, PCV flow is controlled by a 0.05-inch (1.3-mm) orifice. As the engine moves off idle, ported vacuum pulls a spring-loaded valve off of its seat, allowing PCV flow to pass through a 0.09-inch (2.3-mm) orifice.

SEPARATOR SYSTEMS Turbocharged and many fuel-injected engines use an oil/vapor or oil/water separator and a calibrated orifice instead of a PCV valve. In the most common applications, the air intake throttle body acts as the source for crankcase ventilation vacuum, and a calibrated orifice acts as the metering device.

CASE STUDY

The Whistling Engine

An older vehicle was being diagnosed for a whistling sound whenever the engine was running, especially at idle. It was finally discovered that the breather in the valve cover was plugged and caused high vacuum in the crankcase. The engine was sucking air from what was likely the rear main seal lip, making the "whistle" noise. After replacing the breather and PCV, the noise stopped.

Summary:

Complaint—The customer stated that the engine made a whistling sound when it was running.
Cause—A clogged PCV breather was found to be the cause of air being drawn into the engine through the rear main seal.
Correction—The PCV breather and check valve were replaced, which corrected the whistling noise concern.

PCV SYSTEM DIAGNOSIS

SYMPTOMS If the PCV valve or orifice is not clogged, intake air flows freely and the PCV system functions properly. Engine design includes the air and vapor flow as a calibrated part of the air–fuel mixture. In fact, some engines receive as much as 30% of the idle air through the PCV system. For this reason, a flow problem in the PCV system results in driveability problems.

A blocked or plugged PCV system may cause the following to occur:

- Rough or unstable idle
- Excessive oil consumption
- Oil in the air filter housing
- Oil leaks due to excessive crankcase pressure

Before attempting expensive engine repairs, check the condition of the PCV system.

TECH TIP

Check for Oil Leaks with the Engine Off

The owner of an older vehicle equipped with a V-6 engine complained to their technician that they smelled burning oil, but only *after* shutting off the engine. The technician found that the rocker cover gaskets were leaking. But why did the owner only notice the smell of hot oil when the engine was shut off? Because of the PCV system, engine vacuum tends to draw oil away from gasket surfaces. When the engine stops, however, engine vacuum disappears, and the oil remaining in the upper regions of the engine tend to flow down and out through any opening. Therefore, a good technician should check an engine for oil leaks, not only with the engine running, but also shortly after shutdown.

PCV SYSTEM PERFORMANCE CHECK A properly operating PCV system should be able to draw vapors from the crankcase and into the intake manifold. If the pipes, hoses, and PCV valve itself are not restricted, vacuum is applied to the crankcase. A slight vacuum is created in the crankcase (usually less than 1 in. Hg if measured at the dipstick) and is also applied to other areas of the engine. Oil drainback holes provide a path for oil to drain back into the oil pan. These holes also allow crankcase vacuum to be applied under the rocker covers and in the valley area of most V-type engines. Several methods can be used to test a PCV system.

RATTLE TEST The rattle test is performed by simply removing the PCV valve and giving it a shake:

- If the PCV valve does *not* rattle, it is definitely defective and must be replaced.
- If the PCV valve *does* rattle, it does not necessarily mean that the PCV valve is good. All PCV valves contain springs that can become weaker with age and with heating and cooling cycles. Replace any PCV valve with the *exact* replacement according to the vehicle manufacturer's recommended intervals.

THE 3 × 5 CARD TEST Remove the oil-fill cap (where oil is added to the engine) and start the engine.

NOTE: Use care on some overhead camshaft engines. With the engine running, oil may be sprayed from the open oil-fill opening.

Hold a 3 × 5 card over the opening (a dollar bill or any other piece of paper can be used for this test):

- If the PCV system, including the valve and hoses, is functioning correctly, the card should be held down on the oil-fill opening by the slight vacuum inside the crankcase.
- If the card does not stay, carefully inspect the PCV valve, hose(s), and manifold vacuum port for carbon buildup (restriction). Clean or replace as necessary.

NOTE: On some 4-cylinder engines, the 3 × 5 card may vibrate on the oil-fill opening when the engine is running at idle speed. This is normal because of the time intervals between intake strokes on a 4-cylinder engine.

SNAP-BACK TEST The proper operation of the PCV valve can be checked by placing a finger over the inlet hole in the valve when the engine is running and removing the finger rapidly. Repeat several times. The valve should "snap back." If the valve does not snap back, replace the valve.

CRANKCASE VACUUM TEST Sometimes the PCV system can be checked by testing for a weak vacuum at the oil dipstick tube using an inches-of-water manometer or gauge, as follows:

STEP 1 Remove the oil-fill cap or vent PCV opening and cover the opening.

STEP 2 Remove the oil dipstick (oil level indicator).

STEP 3 Connect a water manometer or gauge to the dipstick tube.

STEP 4 Start the engine and observe the gauge at idle and at 2,500 RPM. ● **SEE FIGURE 81–6**.

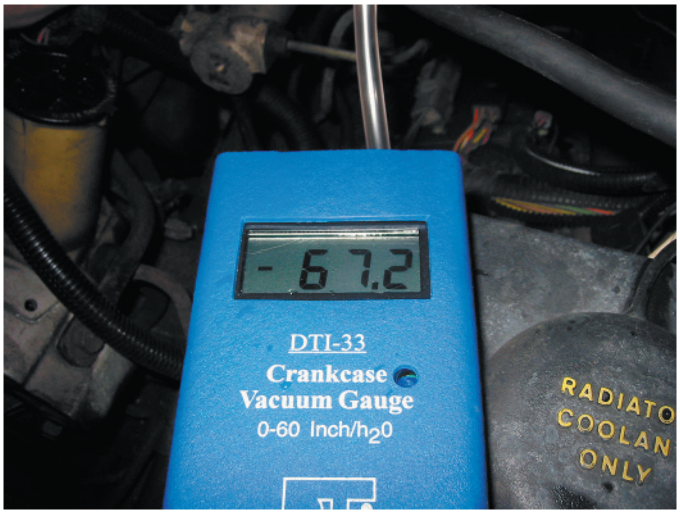


FIGURE 81–6 Using a gauge that measures vacuum in units of inches of water to test the vacuum at the dipstick tube, being sure that the PCV system is capable of drawing a vacuum on the crankcase (28 inches $H_2O = 1$ PSI, or about 2 in. Hg of vacuum).

FREQUENTLY ASKED QUESTION

What Are the Wires for at the PCV Valve?

Ford uses an electric heater to prevent ice from forming inside the PCV valve and causing blockage.

Water is a by-product of combustion, and resulting moisture can freeze when the outside air temperature is low. General Motors and others clip a heater hose to the PCV hose to provide the heat needed to prevent an ice blockage.

The gauge should show some vacuum, especially at 2,500 RPM. If not, carefully inspect the PCV system for blockages or other faults.

PCV MONITOR Starting with 2004 and newer vehicles, all vehicle PCMs monitor the PCV system for proper operation as part of the OBD-II system. The PCV monitor fails if the PCM detects an opening between the crankcase and the PCV valve or between the PCV valve and the intake manifold. ● **SEE FIGURE 81–7**.

PCV-RELATED DIAGNOSTIC TROUBLE CODES

Diagnostic Trouble Code	Description	Possible Causes
P0101	MAF or airflow circuit range problem	■ Defective PCV valve or hose/connections or MAF circuit fault
P0505	Idle control system problem	■ Defective PCV valve or hose/connections

SECONDARY AIR-INJECTION SYSTEM

PURPOSE AND FUNCTION The **secondary air-injection (SAI)** system provides the air necessary for the oxidizing process either at the exhaust manifold or inside the catalytic converter.

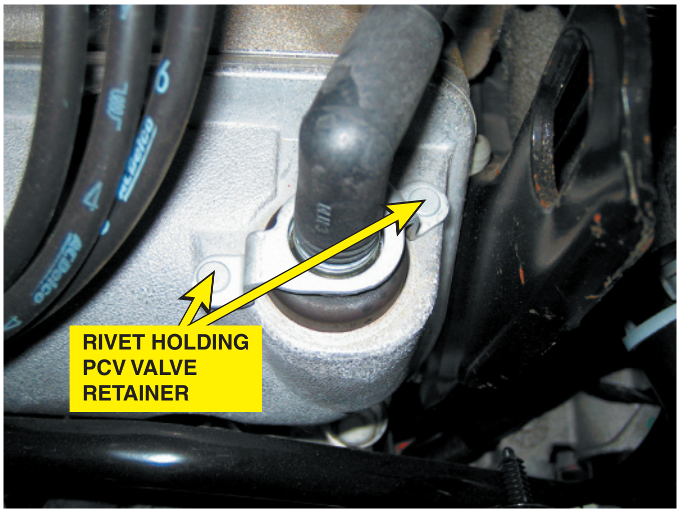

FIGURE 81–7 Most PCV valves used on newer vehicles are secured with fasteners, making it more difficult to disconnect, and thereby less likely to increase emissions.

NOTE: This system is commonly called AIR, meaning air-injection reaction. Therefore, an AIR pump does pump air.

PARTS AND OPERATION The SAI pump, also called an AIR pump, a **smog pump**, or **thermactor pump**, is mounted at the front of the engine and can be driven by a belt from the crankshaft pulley. It pulls fresh air in through an external filter and pumps the air under slight pressure to each exhaust port through connecting hoses or a manifold. The typical SAI system includes the following components:

- A belt-driven pump with inlet air filter (older models) (● **SEE FIGURE 81–8**.)
- An electrically driven air pump (newer models)
- One or more air distribution manifolds and nozzles
- One or more exhaust check valves
- Connecting hoses for air distribution
- Air management valves and solenoids on all newer applications

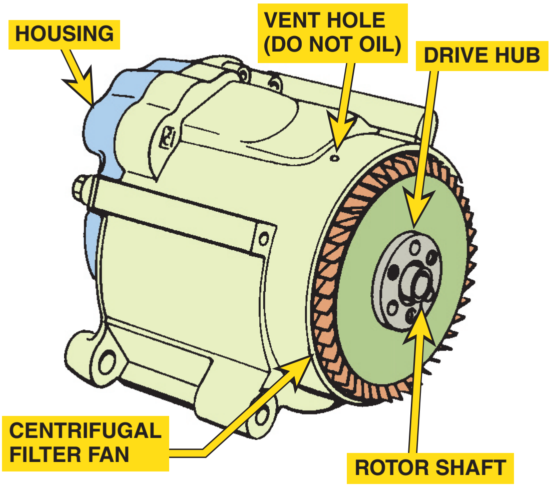

FIGURE 81–8 A typical belt-driven AIR pump. Air enters through the revolving fins behind the drive pulley. The fins act as an air filter because dirt is heavier than air and, therefore, the dirt is deflected off of the fins at the same time air is being drawn into the pump.

With the introduction of NOx reduction converters (also called dual-bed, three-way converters, or TWC), the output of the SAI pump is sent to the center of the converter, where the extra air can help oxidize unburned hydrocarbons (HC) and carbon monoxide (CO) into water vapor (H_2O) and carbon dioxide (CO_2).

The computer controls the airflow from the pump by switching on and off various solenoid valves.

AIR DISTRIBUTION MANIFOLDS AND NOZZLES The secondary air-injection system sends air from the pump to a nozzle installed near each exhaust port in the cylinder head. This provides equal air injection for the exhaust from each cylinder and makes it available at a point in the system where exhaust gases are the hottest.

Air is delivered to the exhaust system in one of two ways:

1. An external air manifold, or manifolds, distributes the air through injection tubes with stainless-steel nozzles. The nozzles are threaded into the cylinder heads or exhaust manifolds close to each exhaust valve. This method is used primarily with smaller engines.
2. An internal air manifold distributes the air to the exhaust ports near each exhaust valve through passages cast in the cylinder head or the exhaust manifold. This method is used mainly with larger engines.

EXHAUST CHECK VALVES All air-injection systems use one or more one-way check valves to protect the air pump and other components from reverse exhaust flow. A **check valve** contains a spring-type metallic disc or reed that closes under exhaust back pressure. Check valves are located between the air manifold and the switching valve(s). If exhaust pressure exceeds injection pressure or if the air pump fails, the check valve spring closes the valve to prevent reverse exhaust flow. ● **SEE FIGURE 81–9**.

NOTE: These check valves commonly fail, resulting in excessive exhaust emissions (CO, especially). When the check valve fails, hot exhaust can travel up to and destroy the switching valve(s) and air pump itself.

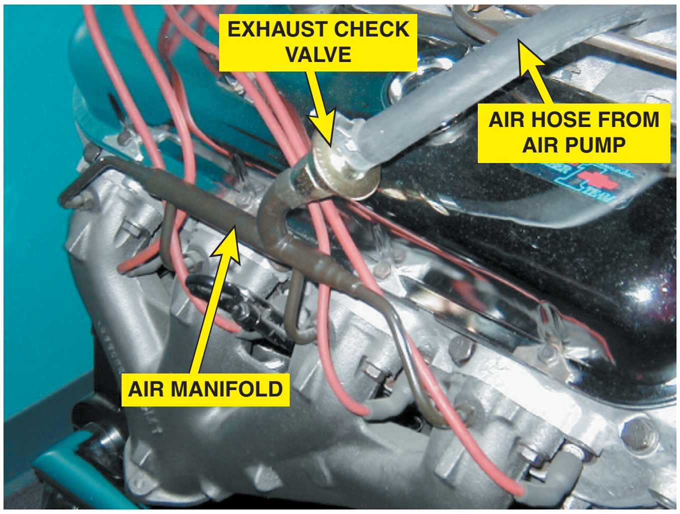

FIGURE 81–9 The external air manifold and exhaust check valve on a restored muscle car engine.

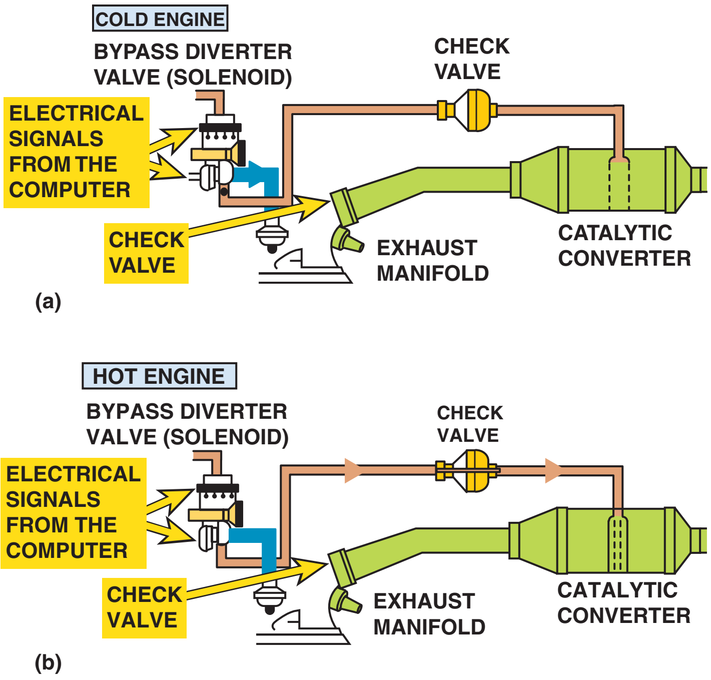

FIGURE 81–10 (a) When the engine is cold and before the oxygen sensor is hot enough to achieve closed loop, the airflow from the air pump is directed to the exhaust manifold(s) through the one-way check valves, which keep the exhaust gases from entering the switching solenoids and the pump itself. (b) When the engine achieves closed loop, the air is directed to the catalytic converter.

BELT-DRIVEN AIR PUMPS The belt-driven air pump uses a centrifugal filter just behind the drive pulley. As the pump rotates, underhood air is drawn into the pump and slightly compressed. The system uses either vacuum- or solenoid-controlled diverter valves to air directed to the following:

- The exhaust manifold, when the engine is cold to help oxidize CO and unburned HCs into CO_2 and H_2O vapor
- The catalytic converter when the engine is warm on some models to help provide the extra oxygen needed for the efficient conversion of CO and HC into CO_2 and H_2O
- The air cleaner, during deceleration or wide-open throttle (WOT) engine operation. ● **SEE FIGURE 81–10**.

ELECTRIC MOTOR–DRIVEN AIR PUMPS This style of pump is generally used only during cold engine operation and is computer controlled. The SAI system helps reduce HCs and CO. The air flowing to the exhaust manifold also helps to warm the three-way catalytic converters quickly on engine start-up so conversion of exhaust gases may occur sooner:

- The SAI pump solenoids are controlled by the PCM. The PCM turns on the SAI pump by providing the ground to complete the circuit, which energizes the SAI pump solenoid relay. When air to the exhaust ports is desired, the PCM energizes the relay in order to turn on the solenoid and the SAI pump. ● **SEE FIGURE 81–11**.
- The PCM turns on the SAI pump during start-up any time the engine coolant temperature is above 32°F (0°C). A typical electric SAI pump operates for a maximum of four minutes or until the system enters closed-loop operation.

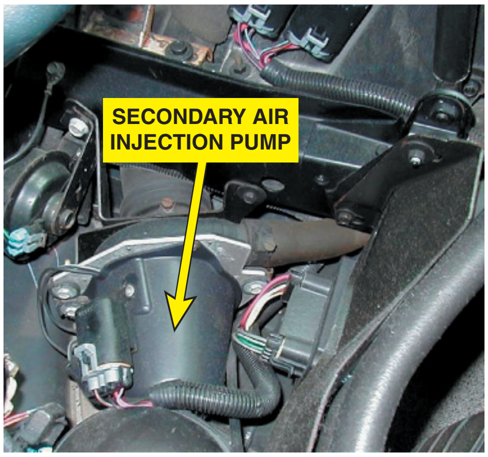

FIGURE 81–11 A typical electric motor-driven SAI pump. This unit is on a Chevrolet Corvette and only works when the engine is cold.

SECONDARY AIR-INJECTION SYSTEM DIAGNOSIS

SYMPTOMS The air pump system should be inspected if an exhaust emissions test failure occurs. In severe cases, the exhaust enters the air cleaner assembly, resulting in a horribly running engine, because the extra exhaust displaces the oxygen needed for proper combustion. With the engine running, check for normal operation. ● **SEE CHART 81–1**.

ENGINE OPERATION	NORMAL OPERATION OF A TYPICAL SAI SYSTEM
Cold engine (open-loop operation)	Air is diverted to the exhaust manifold(s) or cylinder head
Warm engine (closed-loop operation)	Air is diverted to the catalytic converter
Deceleration	Air is diverted to the air cleaner assembly
Wide-open throttle	Air is diverted to the air cleaner assembly

CHART 81–1

Typical SAI system operation showing location of airflow from the pump.

VISUAL INSPECTION Carefully inspect all parts of the SAI system, including the following:

- Hoses and pipes (Any that have holes and leak air or exhaust require replacement.)
- Check valve(s), when a pump has become inoperative
- Exhaust gases, which could have gotten past the check valve and damaged the pump (Look for signs of overheated areas upstream from the check valves. In severe cases, the exhaust can enter the air cleaner assembly, destroying the air filter and greatly reducing engine power.)
- Drive belt on an engine-driven pump, for wear and proper tension (If the belt is worn or damaged, check that the AIR pump rotates.)

FOUR-GAS EXHAUST ANALYSIS An SAI system can be easily tested using an exhaust gas analyzer and the following steps:

1. Start the engine and allow it to run until normal operating temperature is achieved.
2. Connect the analyzer probe to the tailpipe and observe the exhaust readings for HCs and CO.
3. Using the appropriate pinch-off pliers, shut off the airflow from the SAI system. Observe the HC and CO readings. If the SAI system is working correctly, the HC and CO levels should increase when the SAI system is shut off.
4. Record the O_2 reading with the SAI system still inoperative. Unclamp the pliers and watch the O_2 readings. If the system is functioning correctly, the O_2 level should increase by 1% to 4%.

SAI-RELATED DIAGNOSTIC TROUBLE CODE

Diagnostic Trouble Code	Description	Possible Causes
P0410	SAI solenoid circuit fault	■ Defective SAI solenoid ■ Loose or corroded electrical connections ■ Loose, missing, or defective rubber hose(s)

REVIEW QUESTIONS

1. What exhaust emissions do the PCV valve and the SAI system control?
2. How does a PCV valve work?
3. What prevents a backfire in the intake manifold from causing the fumes in the crankcase from exploding?
4. Why do some PCV valves have an electric heater?
5. What keeps the exhaust gases from flowing up from the exhaust manifold and into the secondary air injection (SAI) pump?

CHAPTER QUIZ

1. The PCV system controls which exhaust emission(s)?
a. HC
b. CO
c. NO_x
d. Both HC and CO

2. How much of the air needed by the engine flows through the PCV system when the engine is at idle speed?
a. 1% to 3%
b. 5% to 10%
c. 10% to 20%
d. Up to 30%

3. Technician A says that if the PCV value is defective or clogged, the engine could idle rough. Technician B says that the engine may stall. Which technician is correct?
a. Technician A only
b. Technician B only
c. Both Technicians A and B
d. Neither Technician A nor B

4. Technician A says that if a PCV valve rattles, then it is okay and does not need to be replaced. Technician B says that if a PCV valve does not rattle, it should be replaced. Which technician is correct?
a. Technician A only
b. Technician B only
c. Both Technicians A and B
d. Neither Technician A nor B

5. Technician A says that the PCV system should create a slight pressure in the crankcase at idle. Technician B says that the PCV system should create a slight vacuum in the crankcase at 2,500 RPM. Which technician is correct?
a. Technician A only
b. Technician B only
c. Both Technicians A and B
d. Neither Technician A nor B

6. The SAI system is used to reduce which exhaust emission(s)?
a. HC
b. CO
c. NO_x
d. Both HC and CO

7. Two technicians are discussing exhaust check valves used in SAI systems. Technician A says that they are used to prevent the output from the SAI pump from entering the intake manifold. Technician B says the check valves are used to keep the exhaust from entering the AIR pump. Which technician is correct?
a. Technician A only
b. Technician B only
c. Both Technicians A and B
d. Neither Technician A nor B

8. Where is the output of the AIR pump directed when the engine is cold?
a. Exhaust manifold
b. Catalytic converter
c. Air cleaner assembly
d. To the atmosphere

9. The switching valves on the AIR pump have failed several times. Technician A says that a defective exhaust check valve could be the cause. Technician B says that a leaking exhaust system at the muffler could be the cause. Which technician is correct?
a. Technician A only
b. Technician B only
c. Both Technicians A and B
d. Neither Technician A nor B

10. When checking for the proper operation of the AIR system using an exhaust gas analyzer, how much should the oxygen (O_2) levels increase when the pump is allowed to function?
a. 1% to 4%
b. 5% to 10%
c. 10% to 20%
d. Up to 30%

Chapter 82

CATALYTIC CONVERTERS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain the purpose, function, construction, and operation of catalytic converters.
- Describe catalytic converter performance in OBD-II vehicles.
- Discuss the diagnosis of catalytic converters.
- Discuss the replacement of catalytic converters.

KEY TERMS:

Catalysts 961 • Catalytic converter 961 • Cerium 962 • Light-off temperature 962 • Light-off converter (LOC) 963 • Oxygen storage capacity (OSC) 963 • Palladium 962 • Platinum 962 • Preconverter 963 • Pup (mini) converter 963 • Rhodium 962 • Tap test 964 • Three-way converter (TWC) 962 • Washcoat 962

CATALYTIC CONVERTERS

PURPOSE AND FUNCTION A **catalytic converter** is an after-treatment device used to reduce exhaust emissions outside of the engine. The catalytic converter uses a *catalyst:*

- A **catalyst** is a chemical that helps start a chemical reaction, but does not enter into the chemical reaction.
- The catalyst materials on the surface of the material inside the converter help create a chemical reaction.
- The chemical reaction changes harmful exhaust emissions into nonharmful exhaust emissions.
- The *converter*, therefore, converts harmful exhaust gases into water vapor (H_2O) and carbon dioxide (CO_2).

This device is installed in the exhaust system between the exhaust manifold and the muffler and usually is positioned beneath the passenger compartment. The location of the converter is important since as much of the exhaust heat as possible must be retained for effective operation. The nearer it is to the engine, the better. ● **SEE FIGURE 82–1**.

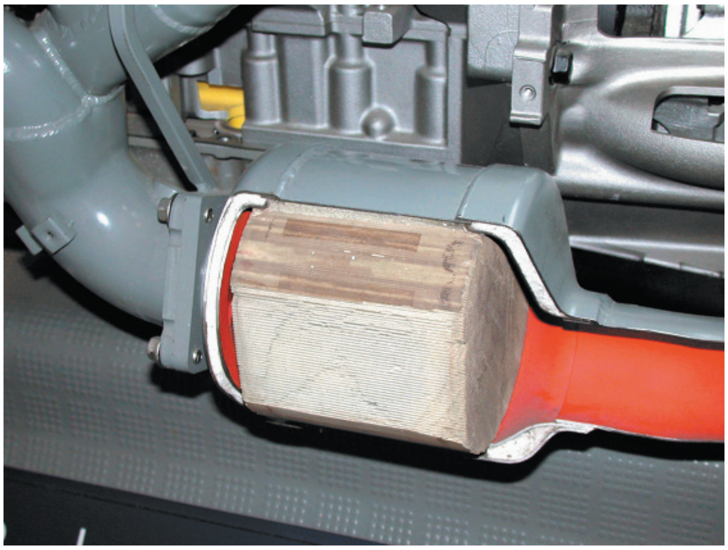

FIGURE 82–1 Most catalytic converters are located as close to the exhaust manifold as possible, as seen in this display of a Chevrolet Corvette.

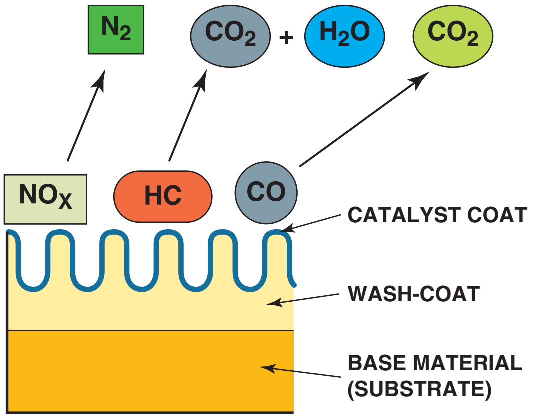

FIGURE 82–2 The base material, called the substrate, is used to support the wash coat, which is a porous material that is used to hold the catalyst materials.

CATALYTIC CONVERTER CONSTRUCTION

Most catalytic converters are constructed of a ceramic material in a honeycomb shape with square openings for the exhaust gases:

- There are approximately 400 openings per square inch (62 per sq. cm), and the wall thickness is about 0.006 inch (1.5 mm).
- The substrate is then coated with a porous aluminum material called the **washcoat**, which makes the surface rough.
- The catalytic materials are then applied on top of the washcoat. The substrate is contained within a round or oval shell made by welding together two stamped pieces of alumina or stainless steel. ● **SEE FIGURE 82–2.**

The ceramic substrate in monolithic converters is not restrictive; however, the converter can be physically broken if exposed to shock or severe jolts. Monolithic converters can be serviced only as a unit.

An exhaust pipe is connected to the manifold or header to carry gases through a catalytic converter and then to the muffler or silencer. V-type engines can use dual converters or route the exhaust into one catalytic converter by using a Y-exhaust pipe.

CATALYTIC CONVERTER OPERATION

The converter substrate contains small amounts of **rhodium**, **palladium**, and **platinum**. These elements act as catalysts. As mentioned, a catalyst is an element that starts a chemical reaction without becoming a part of, or being consumed in, the process. In a **three-way (catalytic) converter (TWC)** all three exhaust emissions (NO_x, HC, and CO) are converted to carbon dioxide (CO_2) and water (H_2O). As the exhaust gas passes through the catalyst, oxides of nitrogen (NO_x) are chemically reduced (i.e., nitrogen and oxygen are separated) in the first section of the catalytic converter. In the second section of the catalytic converter, most of the HCs and CO remaining in the exhaust gas are oxidized to form harmless CO_2 and H_2O. ● **SEE FIGURE 82–3.**

Since the early 1990s, many converters also contain **cerium**, an element that can store oxygen. The purpose of the cerium is to provide oxygen to the oxidation bed of the converter when the exhaust is rich and lacks enough oxygen for proper oxidation. When the exhaust is lean, the cerium absorbs the extra oxygen. For the most efficient operation, the converter should have a 14.7:1 air–fuel ratio, but can use a mixture that varies slightly:

- A rich exhaust is required for reduction—stripping the oxygen (O_2) from the nitrogen in NO_x.
- A lean exhaust is required to provide the oxygen necessary to oxidize HC and CO (combining oxygen with HC and CO to form H_2O and CO_2).

If the catalytic converter is not functioning correctly, ensure that the air–fuel mixture being supplied to the engine is correct and that the ignition system is free of defects.

CONVERTER LIGHT-OFF TEMPERATURE

The catalytic converter does not work when cold, so it must be heated to its **light-off temperature** of close to 500°F (260°C) before it starts working at 50% effectiveness. When fully effective, the converter reaches a temperature range of 900°F to 1,600°F (482°C to 871°C). In spite of the intense heat, however, catalytic reactions do not generate a flame associated with a simple burning reaction. Because of the extreme heat (almost as hot as combustion chamber temperatures), a converter remains hot long after the engine is shut off. Most vehicles use a series of heat shields to protect the passenger compartment

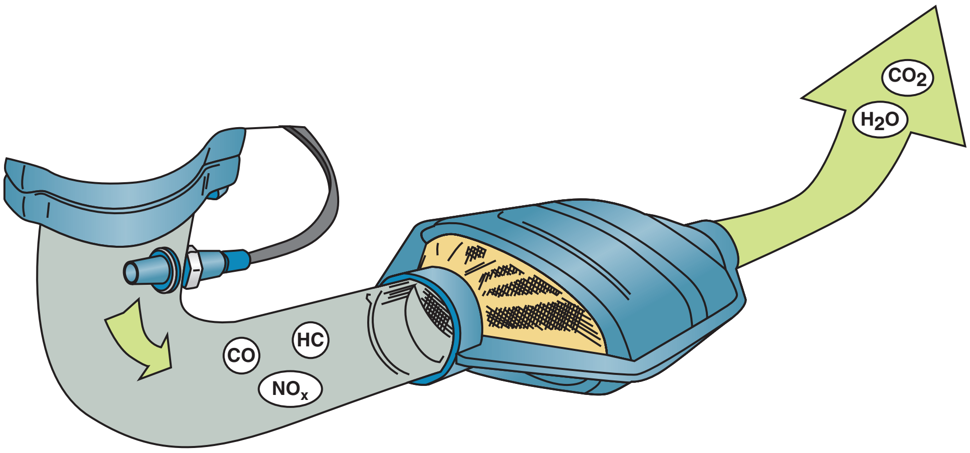

FIGURE 82–3 The three-way catalytic converter first separates the NO_x into nitrogen and oxygen and then converts the HC and CO into harmless water (H_2O) and carbon dioxide (CO_2). The nitrogen (N) passes through the converter and exits the tailpipe and enters the atmosphere, which is about 78% nitrogen.

and other parts of the chassis from excessive heat. Vehicles have been known to start fires because of the hot converter causing tall grass or dry leaves beneath the just-parked vehicle to ignite, especially if the engine is idling. This is most likely to occur if the heat shields have been removed from the converter.

CONVERTER USAGE A catalytic converter must be located as close as possible to the exhaust manifold to work effectively. The farther back the converter is positioned in the exhaust system, the more the exhaust gases cool before they reach the converter. Since positioning in the exhaust system affects the oxidation process, vehicle manufacturers that use only an oxidation converter generally locate it underneath the front of the passenger compartment.

Some vehicles have used a small, quick heating oxidation converter, called a **preconverter** or a **pup (mini) converter**, that connects directly to the exhaust manifold outlet. These have a small catalyst surface area close to the engine that heats up rapidly to start the oxidation process more quickly during cold engine warm-up. For this reason, they were often called **light-off converters (LOCs)**. The larger main converter, under the passenger compartment, completes the oxidation reaction started in the LOC.

Most older vehicles used a catalytic converter that had the reduction section first to separate the oxygen from the nitrogen in NOx. The oxygen released during this action helps provide extra oxygen to help oxidize the HC and CO into harmless H_2O and CO_2. However, since 2007, emission standards for oxides of nitrogen are stricter and, therefore, a larger reduction section is often needed. Therefore, the reduction section is now often after the oxidation section, which is the opposite of the way it was in converters for older models. ● **SEE FIGURE 82–4**.

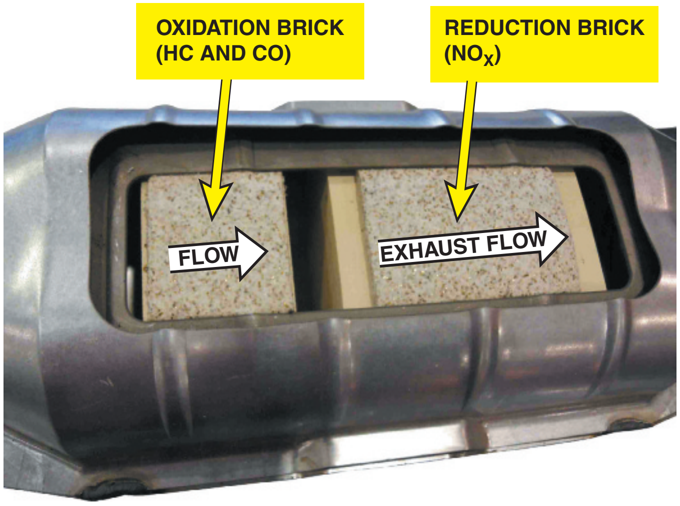

FIGURE 82–4 The small oxidation section of the converter helps build heat for the reduction section to reduce NO_x emissions in the rear brick on most newer vehicles. Older catalytic converters had the reduction brick first then the oxidation brick. Since about 2007, the allowable NO_x levels were greatly reduced and the engines became more efficient at controlling HC and CO and that was when the position of the bricks were changed.

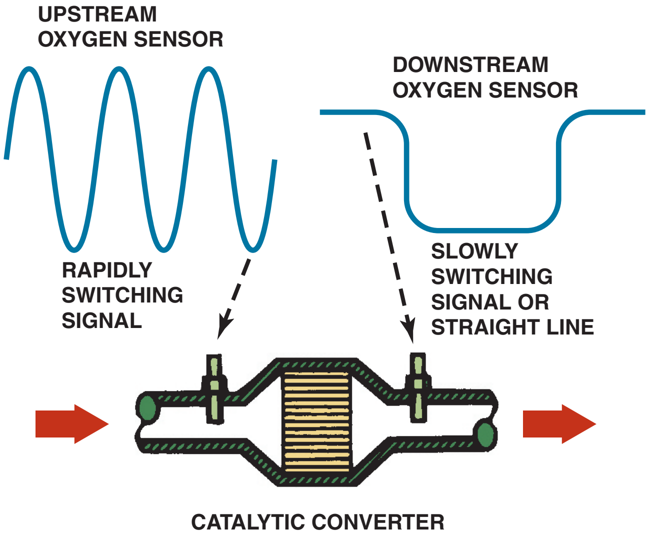

FIGURE 82–5 The OBD-II catalytic converter monitor compares the signals of upstream and downstream oxygen sensors to determine converter efficiency.

OBD-II CATALYTIC CONVERTER PERFORMANCE

With OBD-II-equipped vehicles, catalytic converter performance is monitored by a heated oxygen sensor (HO_2S) both before and after the converter. ● **SEE FIGURE 82–5**.

The converters used on these vehicles have **oxygen storage capacity (OSC)**, due mostly to the cerium coating in the catalyst rather than the precious metals used. When the three-way converter (TWC) is operating as it should, the postconverter HO_2S is far less active than the preconverter sensor. The converter stores, then releases, the oxygen during normal reduction and oxidation of the exhaust gases, smoothing out the variations in oxygen being released.

The PCM determines if the catalytic converter is ready for testing based on the following conditions, which may vary by vehicle make, model, and year:

- Closed-loop status achieved
- IAT sensor temperature higher than 32°F (0°C)
- ECT sensor temperature higher than 165°F (18°C)
- MAF sensor input from 15 to 32 g/sec
- Engine load less than 65% and steady
- Engine speed less than 4,000 RPM
- All of the above conditions met for at least four minutes

These factors are the enable criteria that must be achieved before the OBD-II catalyst monitor runs.

Where a cycling sensor voltage output is expected before the converter, because of the converter action, the postconverter HO_2S should read a steady signal with little fluctuation. ● **SEE FIGURE 82–6**.

CONVERTER-DAMAGING CONDITIONS Since converters have no moving parts, they require no periodic service. Under federal law, catalyst effectiveness is warranted for 80,000 miles or eight years.

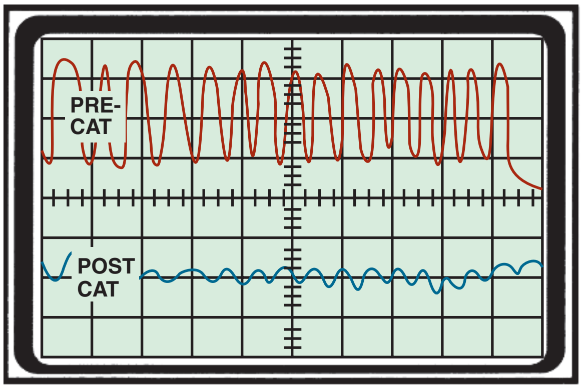

FIGURE 82–6 The waveform of a downstream O2S sensor from a properly functioning converter shows little, if any, activity.

The three main causes of premature converter failure are the following:

- **Contamination.** Substances that can destroy the converter include exhaust that contains excess engine oil, antifreeze, sulfur (from poor fuel), and various other chemical substances.
- **Excessive temperatures.** Although a converter operates at high temperatures, it can be destroyed by excessive temperatures. This most often occurs either when too much unburned fuel enters the converter, or with excessively lean mixtures. Excessive temperatures may be caused by long idling periods on some vehicles since more heat develops at those times than when driving at normal highway speeds. Severe high temperatures can cause the converter to melt down, leading to the internal parts breaking apart and either clogging the converter or moving downstream to plug the muffler. In either case, the restricted exhaust flow severely reduces engine power.
- **Improper air–fuel mixtures.** Rich mixtures or raw fuel in the exhaust can be caused by engine misfiring or an excessively rich air–fuel mixture resulting from a defective coolant temp sensor or defective fuel injectors. Lean mixtures are commonly caused by intake manifold leaks. When either of these circumstances occurs, the converter can become a catalytic furnace, causing the previously described damage. For most efficient catalytic converter operation, the air–fuel mixture should be near 14.7:1. ● **SEE FIGURE 82–7**.

To avoid excessive catalyst temperatures and the possibility of fuel vapors reaching the converter, observe the following rules:

1. Do not use fuel additives or cleaners that are not converter safe.
2. Do not crank an engine for more than 40 seconds when it is flooded or misfiring.
3. Do not turn off the ignition switch when the vehicle is in motion.
4. Do not disconnect a spark plug wire for more than 30 seconds.
5. Repair engine problems, such as dieseling, misfiring, or stumbling, as soon as possible.

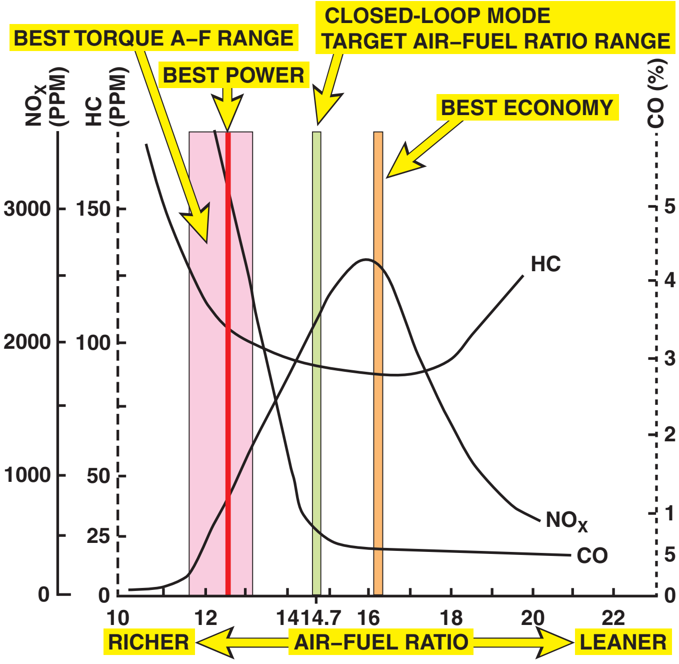

FIGURE 82–7 The highest catalytic converter efficiency occurs when the air–fuel mixture is about 14.7:1.

FREQUENTLY ASKED QUESTION

Can a Catalytic Converter Be Defective without Being Clogged?

Yes. Catalytic converters can fail by being chemically damaged or poisoned without being mechanically clogged. Therefore, the catalytic converter should be tested not only for physical damage (clogging) by performing a back pressure or vacuum test and a rattle test, but also for temperature rise, usually with a pyrometer or propane test, to check the efficiency of the converter.

DIAGNOSING CATALYTIC CONVERTERS

TAP TEST The simple **tap test** involves tapping (not pounding) on the catalytic converter using a rubber mallet. If the substrate inside the converter is broken, the converter rattles when hit. If the converter rattles, a replacement converter is required. ● **SEE FIGURE 82–8**.

TESTING BACK PRESSURE WITH A PRESSURE GAUGE

Exhaust system back pressure can be measured directly by installing a pressure gauge in an exhaust opening. This can be accomplished in one of the following ways:

1. To test backpressure, remove the inside of an old, discarded oxygen sensor and thread in an adapter to convert it to a vacuum or pressure gauge.

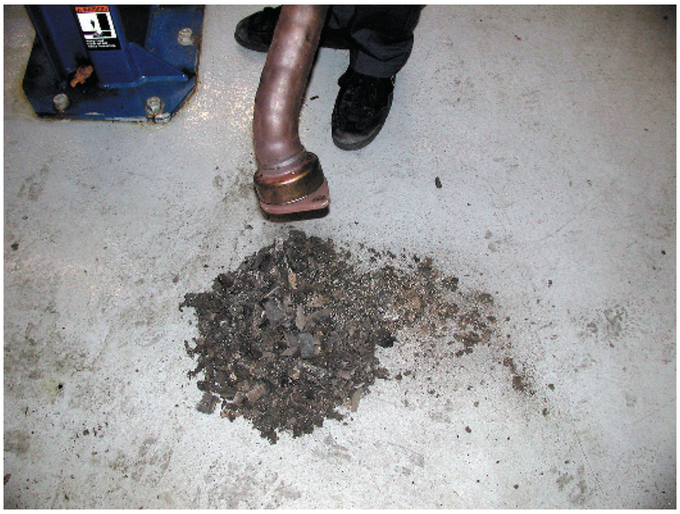

FIGURE 82–8 A catalytic converter that rattles when tapped was removed, and the substrate, or what was left of it, fell out. This converter has to be replaced and the root cause of why it failed found and corrected.

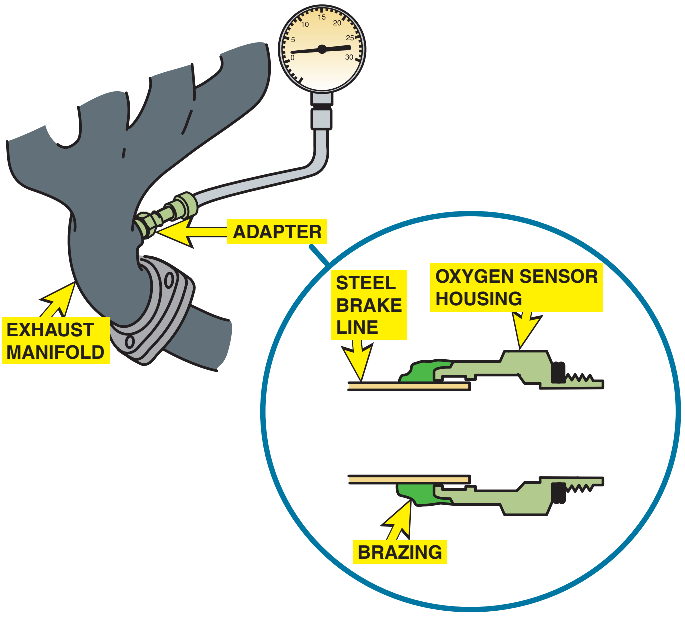

FIGURE 82–9 A back pressure tool can be made by using an oxygen sensor housing and epoxy or braze to hold the tube to the housing.

NOTE: An adapter can be easily made by inserting a metal tube or pipe into an old oxygen sensor housing. A short section of brake line works great. The pipe can be brazed to the oxygen sensor housing, or it can be glued with epoxy. An 18-mm compression gauge adapter can also be adapted to fit into the oxygen sensor opening. ● **SEE FIGURE 82–9**.

2. To test the exhaust back pressure at the exhaust gas recirculation (EGR) valve, remove the EGR valve and fabricate a plate equipped with a fitting for a pressure gauge.
3. To test at the secondary air-injection (SAI) check valve, remove the check valve from the exhaust tubes leading to the exhaust manifold. Use a rubber cone with a tube inside to seal against the exhaust tube. Connect the tube to a pressure gauge.

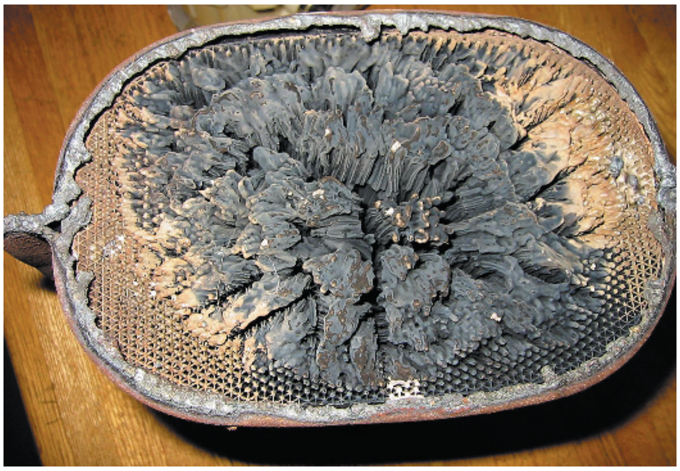

FIGURE 82–10 This partially melted catalytic converter tested okay at idle, but had excessive back pressure at higher engine speeds.

At idle, the maximum back pressure should be less than 1.5 PSI (10 kPa), and it should be less than 2.5 PSI (15 kPa) at 2,500 RPM. Pressure readings higher than these indicate that the exhaust system is restricted, and further testing is needed to determine the location of the restriction. ● **SEE FIGURE 82–10**.

TESTING FOR BACK PRESSURE USING A VACUUM GAUGE

An exhaust restriction can be tested indirectly by checking the intake manifold vacuum with the engine operating at a fast idle speed (about 2,500 RPM). If the exhaust is restricted, some exhaust can pass, and the effect may not be noticeable when the engine is at idle speed. However, when the engine is operating at a higher speed, the exhaust gases build up behind the restriction and eventually are not able to leave the combustion chamber. When some of the exhaust is left behind at the end of the exhaust stroke, the resulting pressure in the combustion chamber reduces engine vacuum. To test for an exhaust restriction using a vacuum gauge, perform the following steps:

STEP 1 Attach a vacuum gauge to an intake manifold vacuum source.

STEP 2 Start the engine. Record the engine manifold vacuum reading. The engine vacuum should read 17 to 21 in. Hg when the engine is at idle speed.

STEP 3 Increase the engine speed to 2500 RPM and hold that speed for 60 seconds while looking at the vacuum gauge.

Results

- If the vacuum reading is equal to or higher than the vacuum reading when the engine was at idle speed, the exhaust system is *not* restricted.
- If the vacuum reading is lower than the vacuum reading when the engine was at idle speed, then the exhaust *is* restricted. Further testing is needed to determine the location of the restriction.

TESTING A CATALYTIC CONVERTER FOR TEMPERATURE RISE

A properly working catalytic converter should be able to reduce NO_x exhaust emissions into nitrogen (N) and oxygen (O_2)

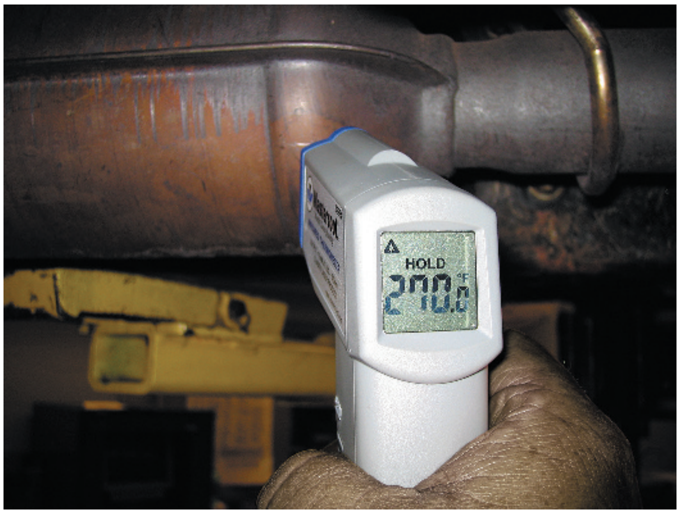

FIGURE 82–11 The temperature of the outlet should be at least 10% hotter than the temperature of the inlet. If a converter is not working, the inlet temperature is hotter than the outlet temperature.

TECH TIP

Aftermarket Catalytic Converters

Some replacement aftermarket (nonfactory) catalytic converters do not contain the same amount of cerium as the original part. Cerium is the element that is used in catalytic converters to store oxygen. As a result of the lack of cerium, the correlation between the oxygen storage and the conversion efficiency may be affected enough to set a false diagnostic trouble code (P0422).

NOTE: If an aftermarket converter is being installed, be sure that the distance between the rear of the catalyst block is the same distance from the rear oxygen sensor as the factory converter to be ensured of proper operation. Always follow the instructions that come with the replacement converter. ● **SEE FIGURE 82–12**.

TECH TIP

Catalytic Converters

Catalytic converters start a chemical reaction, but do not enter into the chemical reaction. Therefore, catalytic converters neither wear out nor die of old age. If a catalytic converter is found to be defective (nonfunctioning or clogged), look for the *root* cause.

Items that should be checked when a defective catalytic converter is discovered include all components of the ignition and fuel systems. Excessive unburned fuel can cause the catalytic converter to overheat and fail. The oxygen sensor must be working and fluctuating from 0.5 to 5 Hz (times per second) to provide the necessary air–fuel mixture variations for maximum catalytic converter efficiency.

and oxidize unburned HC and CO into harmless CO_2 and H_2O vapor. During these chemical processes, the catalytic converter should increase in temperature at least 10% if the converter is working properly. To test the converter, operate the engine at 2,500 RPM for at least two minutes to fully warm the converter. Measure the inlet and the outlet temperatures using an infrared pyrometer, as shown in ● **FIGURE 82–11**.

NOTE: If the engine is extremely efficient, the converter may not have any excessive unburned HCs or CO to convert! In this case, a spark plug wire could be grounded out using a vacuum hose and a test light to create some unburned HC in the exhaust. Do not ground out a cylinder for longer than 10 seconds, or the excessive amount of unburned HC could overheat and damage the converter.

CATALYTIC CONVERTER EFFICIENCY TESTS The efficiency of a catalytic converter can be determined using an exhaust gas analyzer:

- **Oxygen level test.** With the engine warm and in closed loop, check the O_2 and CO levels. A good converter should be able to oxidize the extra HCs caused by the rapid acceleration:
  - If O_2 is zero, go to the snap-throttle test.
  - If O_2 is greater than zero, check the CO level.

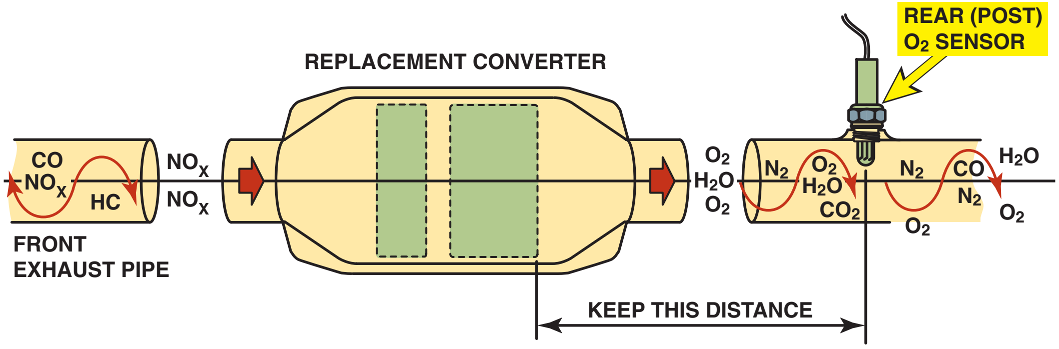

FIGURE 82–12 Whenever replacing a catalytic converter with a universal unit, first measure the distance between the rear brick and the center of the rear oxygen sensor. Be sure that the replacement unit is installed to the same dimension.

    - If CO is greater than zero, the converter is *not* functioning correctly.
- **Snap-throttle test.** With the engine warm and in closed loop, snap the throttle to wide-open throttle (WOT) in park or neutral and observe the oxygen reading:
    - The O_2 reading should not exceed 1.2%; if it does, the converter is *not* working.
    - If the O_2 rises to 1.2%, the converter may have low efficiency.
    - If the O_2 remains below 1.2%, then the converter is okay.

CATALYTIC CONVERTER–RELATED DIAGNOSTIC TROUBLE CODE

Diagnostic Trouble Code	Description	Possible Causes
P0422	Catalytic converter efficiency failure	■ Engine mechanical fault ■ Exhaust leaks ■ Fuel contaminants, such as engine oil, coolant, or sulfur

CATALYTIC CONVERTER REPLACEMENT GUIDELINES

Because a catalytic converter is a major exhaust gas emission control device, the U.S. Environmental Protection Agency (EPA) has strict guidelines for its replacement, including the following:

- If a converter is replaced on a vehicle with less than 80,000 miles or eight years, depending on the year of the vehicle, an original equipment catalytic converter *must* be used as a replacement.
- The replacement converter must be of the same design as the original. If the original had an AIR pump fitting, so must the replacement.
- The old converter must be kept for possible inspection by the authorities for 60 days.
- A form must be completed and signed by both the vehicle owner and a representative from the service facility. This form must state the cause of the converter failure and must remain on file for two years.

REVIEW QUESTIONS

1. What are the three most commonly used catalysts in a catalytic converter?
2. How does a catalytic converter reduce NO_x to nitrogen and oxygen?
3. Why must a catalytic converter be mounted close to the exhaust ports of the engine?
4. How does the computer monitor catalytic converter performance?
5. What tests can be performed by a service technician to test the catalytic converter?

CHAPTER QUIZ

1. What is applied to the ceramic substrate to make the surface porous?
    a. Honeycomb filler
    b. Washcoat
    c. Aluminum
    d. Cerium
2. Two technicians are discussing catalytic converters. Technician A says that the exhaust mixture should be 14.7:1 for the best efficiency. Technician B says that the air–fuel mixture must be leaner than 14.7:1 for best performance from a three-way catalytic converter. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B
3. A catalytic converter has to be at least how hot before it starts to work?
    a. 500°F (260°C)
    b. 1,000°F (540°C)
    c. 1,500°F (815°C)
    d. 2,000°F (1,100°C)
4. What two primary sensors does the PCM use to check the catalytic converter?
    a. Catalytic converter temperature sensor and rear oxygen sensor
    b. Precat and postcat oxygen sensor
    c. Precat oxygen sensor and MAF
    d. MAP and TP
5. A catalytic converter can be harmed by ___________.
    a. excessive engine oil
    b. antifreeze
    c. sulfur from poor-quality fuel
    d. Any of the above
6. Two technicians are discussing testing a catalytic converter. Technician A says that a vacuum gauge can be used and observed to see if the vacuum drops with the engine at 2,500 RPM for 30 seconds. Technician B says that a pressure gauge can be used to check for back pressure. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B
7. A catalytic converter is being tested with an infrared pyrometer. Which is an acceptable (good converter) result?
    a. The inlet should be hotter than the outlet by 10%.
    b. The outlet should be hotter than the inlet by 10%.
    c. Both the inlet and the outlet should be the same temperature after the converter reaches operating temperature.
    d. The temperature of a catalytic converter is the best test to perform to locate a restricted (clogged) unit.

8. Which exhaust gas reading indicates a good catalytic converter?
   - **a.** O_2 is zero
   - **b.** CO is zero
   - **c.** Both a and b
   - **d.** Neither a nor b

9. A P0422 (catalytic converter efficiency failure) is set. What is a possible cause?
   - **a.** Engine mechanical fault
   - **b.** Exhaust leak
   - **c.** Fuel contamination
   - **d.** Any of the above

10. Technician A says that the catalytic converter is warranted for eight years or 80,000 miles, whichever comes first. Technician B says that after replacing the catalytic converter, the old converter must be kept for possible inspection for 60 days. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B

Chapter 83

ONBOARD DIAGNOSIS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain the purpose and function of OBD systems.
- Discuss the diagnostic executive.
- List the various continuous and noncontinuous monitors.
- Discuss OBD-II monitor information.
- Explain enabling criteria.
- Explain the numbering designation of OBD-II diagnostic trouble codes.
- Explain the information captured by freeze-frame.
- Describe the criteria to enable an OBD monitor.
- Describe PCM tests related to OBD systems.
- List the operation modes of a global scan tool.
- Describe mode six diagnosis.

KEY TERMS:

California Air Resources Board (CARB) 969 • Component identification (CID) 976 • Comprehensive component monitor (CCM) 970 • Diagnostic executive 970 • Enable criteria 972 • Exponentially weighted moving average (EWMA) monitor 972 • Federal Test Procedure (FTP) 970 • Freeze-frame 970 • Functionality 971 • Malfunction indicator lamp (MIL) 969 • On-Board Diagnostics (OBD) 969 • Parameter identification (PID) 976 • Rationality 971 • Society of Automotive Engineers (SAE) 972 • Task manager 970 • Test identification (TID) 976

ON-BOARD DIAGNOSTICS GENERATION-II (OBD-II) SYSTEMS

PURPOSE AND FUNCTION OF OBD II During the 1980s, most manufacturers began equipping their vehicles with full-function control systems capable of alerting the driver of a malfunction and of allowing the technician to retrieve codes that identify circuit faults. These early diagnostic systems were meant to reduce emissions and speed up vehicle repair.

The automotive industry calls these systems **On-Board Diagnostics (OBD)**. The **California Air Resources Board (CARB)** developed the first regulation requiring manufacturers selling vehicles in that state to install OBD. OBD Generation I (OBD I) applies to all vehicles sold in California beginning with the 1988 model year. It specifies the following requirements:

1. An instrument panel warning lamp able to alert the driver of certain control system failures, now called a **malfunction indicator lamp (MIL)**. ● **SEE FIGURE 83–1**.
2. The system's ability to record and transmit diagnostic trouble codes (DTCs) for emission-related failures.

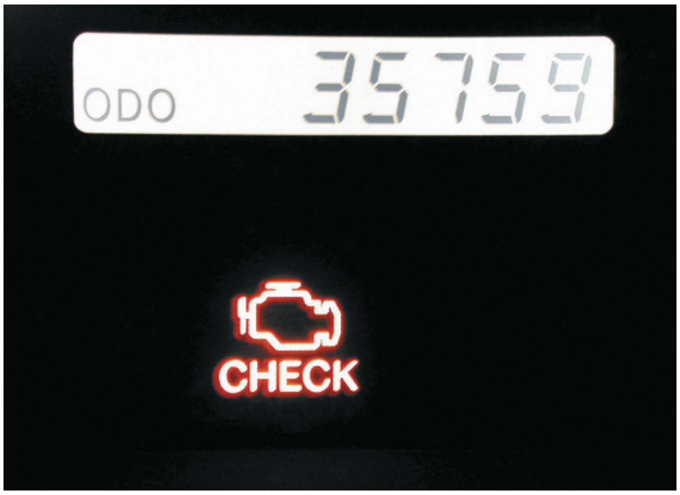

FIGURE 83–1 A typical malfunction indicator lamp (MIL) often labeled "check engine" or "service engine soon" (SES).

All light-duty vehicles (less than 8,500 pounds) sold in North America since 1996, as well as medium-duty vehicles (8,500–14,000 pounds) beginning in 2005, and heavy-duty vehicles (greater than 14,000 pounds) beginning in 2010, are required to support OBD-II diagnostics, using a standardized data link connector, and a subset of the SAE J/1979 defined PIDs (or SAE J1939 as applicable for medium/heavy-duty vehicles), primarily for state-mandated emissions inspections.

OBD-II OBJECTIVES Generally, the CARB defines an OBD-II-equipped vehicle by its ability to do the following:

1. Detect component degradation or a faulty emission-related system that prevents compliance with federal emission standards.
2. Alert the driver of needed emission-related repair or maintenance.
3. Use standardized DTCs and accept a generic scan tool.

These requirements apply to all 1996 and later-model light-duty vehicles. The Clean Air Act of 1990 directed the Environmental Protection Agency (EPA) to develop new regulations for OBD. The primary purpose of OBD II is emission-related, whereas the primary purpose of OBD I (1988) was to detect faults in sensors or sensor circuits. OBD-II regulations require that not only sensors be tested, but also all exhaust emission-control devices, and that they be verified for proper operation.

All new vehicles must pass the **Federal Test Procedure (FTP)** for exhaust emissions while being tested for 1874 seconds on dynamometer rollers that simulate the urban drive cycle around downtown Los Angeles.

NOTE: IM 240 is simply a shorter 240-second version of the 505-second federal test procedure.

The regulations for OBD-II vehicles state that the vehicle powertrain control module (PCM) must be capable of testing for, and determining, if the exhaust emissions are within 1.5 times the FTP limits. To achieve this goal, the PCM must do the following:

1. Test all exhaust emission system components for correct operation.
2. Actively operate the system and measure the results.
3. Continuously monitor all aspects of the engine operation to be certain that the exhaust emissions do not exceed 1.5 times the FTP.
4. Check engine operation for misfire.
5. Turn on the MIL (check engine) if the computer senses a fault in a circuit or system.
6. Record a **freeze-frame**, which is a snapshot of important engine data at the time the DTC was set.
7. Flash the MIL if an engine misfire occurs that could damage the catalytic converter.

DIAGNOSTIC EXECUTIVE AND TASK MANAGER

On OBD-II systems, the powertrain control module (PCM) incorporates a special segment of software. On Ford and GM systems, this software is called the **diagnostic executive**. On Chrysler systems, it is called the **task manager**. This software program is designed to manage the operation of all OBD-II monitors by controlling the sequence of steps necessary to execute the diagnostic tests and monitors.

MONITORS

PURPOSE AND FUNCTION A monitor is an organized method of testing a specific part of the system. Monitors are simply tests that the computer performs to evaluate components and systems. If a component or system failure is detected while a monitor is running, a DTC is stored and the MIL illuminated during the second trip. The two types of monitors are continuous and noncontinuous.

CONTINUOUS MONITORS As required conditions are met, continuous monitors begin to run. These continuous monitors run for the remainder of the vehicle drive cycle. The three continuous monitors are as follows:

- **Comprehensive component monitor (CCM).** This monitor watches the sensors and actuators in the OBD-II system. Sensor values are constantly compared with known-good values stored in the PCM's memory.

  The CCM is an internal program in the PCM designed to monitor a failure in any electronic component or circuit (including emission-related and non-emission-related circuits) that provide input or output signals to the PCM. The PCM considers that an input or output signal is inoperative when a failure exists due to an open circuit, out-of-range value, or if an on-board rationality check fails. If an emission-related fault is detected, the PCM sets a code and activates the MIL (requires two consecutive trips).

  Many PCM sensors and output devices are tested at key-on or immediately after engine start-up. However, some devices are only tested by the CCM after the engine meets certain engine conditions. The number of times the CCM must detect a fault before it activates the MIL depends upon the manufacturer, but most require two consecutive trips to activate the MIL. The components tested by the CCM include

  Four-wheel-drive low switch
  Brake switch
  Camshaft position (CMP) and crankshaft position (CKP) sensors
  Clutch switch (manual transmissions/transaxles only)
  Cruise servo switch
  Engine coolant temperature (ECT) sensor
  EVAP purge sensor or switch
  Fuel composition sensor
  Intake air temperature (IAT) sensor
  Knock sensor (KS)
  Manifold absolute pressure (MAP) sensor
  Mass airflow (MAF) sensor
  Throttle-position (TP) sensor
  Transmission temperature sensor
  Transmission turbine speed sensor
  Vacuum sensor
  Vehicle speed (VS) sensor
  EVAP canister purge and EVAP purge vent solenoid
  Idle air control (IAC)
  Ignition control system
  Transmission torque converter clutch solenoid
  Transmission shift solenoids

- **Misfire monitor.** This monitor watches for engine misfire. The PCM uses the information received from the crankshaft position sensor (CKP) to calculate the time between the edges of the reluctor, as well as the rotational speed and acceleration. By comparing the acceleration of each firing event, the PCM can determine if a cylinder is not firing correctly.

Misfire type A. Upon detection of a misfire type A (200 revolutions), which causes catalyst damage, the MIL blinks once per second during the actual misfire, and a DTC is stored.

Misfire type B. Upon detection of a misfire type B (1,000 revolutions), which exceeds 1.5 times the EPA federal test procedure (FTP) standard or causes a vehicle to fail an inspection and maintenance tailpipe emissions test, the MIL illuminates and a DTC is stored.

The DTC associated with multiple cylinder misfire for a type A or type B misfire is DTC P0300. The DTCs associated with an individual cylinder misfire for a type A or type B misfire are DTCs P0301, P0302, P0303, P0304, P0305, P0306, P0307, P0308, P0309, and P0310.

- **Fuel trim monitor.** The PCM continuously monitors short- and long-term fuel trim. Constantly updated adaptive fuel tables are stored in long-term memory (KAM), and used by the PCM for compensation due to wear and aging of the fuel system components. The MIL illuminates when the PCM determines the fuel trim values have reached and stayed at their limits for too long a period of time.

NONCONTINUOUS MONITORS

Noncontinuous monitors run (at most) once per vehicle drive cycle. The noncontinuous monitors are as follows:

O2S monitor
O2S heater monitor
Catalyst monitor
EGR monitor
EVAP monitor
Secondary AIR monitor
Transmission monitor
PCV system monitor
Thermostat monitor

Once a noncontinuous monitor has run to completion, it does not run again until the conditions are met during the next vehicle drive cycle. Also, after a noncontinuous monitor has run to completion, the readiness status on the scan tool shows "complete" or "done" for that monitor. Monitors that have not run to completion show up on the scan tool as "incomplete."

OBD-II MONITOR INFORMATION

COMPREHENSIVE COMPONENT MONITOR

The circuits and components covered by the comprehensive component monitor (CCM) do not include those directly monitored by another monitor.

However, OBD II also requires that inputs from powertrain components to the PCM be tested for **rationality**, and that outputs to powertrain components from the PCM be tested for **functionality**. Both inputs and outputs are to be checked *electrically*. Rationality checks refer to a PCM comparison of input values to values from other sensors to determine if they make sense and are normal (rational).

Example:

TPS	3 V
MAP	18 in. Hg
RPM	700 RPM
PRNDL	Park

NOTE: Comprehensive component monitors are continuous. Therefore, enabling conditions do not apply.

- Monitor runs continuously
- Monitor includes sensors, switches, relays, solenoids, and PCM hardware
- All are checked for opens, shorts-to-ground, and shorts-to-voltage
- Inputs are checked for rationality
- Outputs are checked for functionality
- Most are one-trip DTCs
- Freeze-frame is priority 3
- Three consecutive good trips are used to extinguish the MIL
- Forty warm-up cycles are necessary to self-erase the DTC and freeze-frame
- Two minutes run time without reoccurrence of the fault constitutes a "good trip"

CONTINUOUS RUNNING MONITORS

Continuous monitors run continuously and only stop if they fail and include

- Fuel system: rich/lean
- Misfire: catalyst damaging/FTP (emissions)
- Two-trip faults (except early-generation catalyst damaging misfire)
- MIL, DTC, freeze-frame after two consecutive faults
- Freeze-frame is priority 2 on first trip
- Freeze-frame is priority 4 on maturing trip
- Three consecutive good trips in a similar condition window are used to extinguish the MIL
- Forty warm-up cycles are used to erase DTC and freeze-frame (80 to erase one-trip failure, if similar conditions cannot be met)

ONCE PER TRIP MONITORS

- Monitor runs once per trip, pass or fail
- O_2 response, O_2 heaters, EGR, purge flow EVAP leak, secondary air, catalyst
- Two-trip DTCs
- MIL, DTC, freeze-frame after two consecutive faults
- Freeze-frame is priority 1 on first trip
- Freeze-frame is priority 3 on maturing trip
- Three consecutive good trips are used to extinguish the MIL
- Forty warm-up cycles are used to erase DTC and freeze-frame

EXPONENTIALLY WEIGHTED MOVING AVERAGE (EWMA) MONITORS The **exponentially weighted moving average (EWMA) monitor** is a mathematical method used to determine performance.

This method smooths out any variables in the readings over time and results in a running average. This method is used by some vehicle manufacturers for two monitors.

1. Catalyst monitor
2. EGR monitor

ENABLING CRITERIA

With so many different tests (monitors) to run, the PCM needs an internal director to keep track of when each monitor should run. As mentioned, different manufacturers have different names for this director, such as the diagnostic executive or the task manager. Each monitor has enabling criteria. These criteria are a set of conditions that must be met before the task manager gives the go-ahead for each monitor to run. Most enabling criteria follow simple logic, for example:

- The task manager does not authorize the start of the O2S monitor until the engine has reached operating temperature and the system has entered closed loop.
- The task manager does not authorize the start of the EGR monitor when the engine is at idle, because the EGR is always closed at this time.

Because each monitor is responsible for testing a different part of the system, the enabling criteria can differ greatly from one monitor to the next. The task manager must decide when each monitor should run, and in what order, to avoid confusion.

There may be a conflict if two monitors run at the same time. The results of one monitor might also be tainted if a second monitor runs simultaneously. In such cases, the task manager decides which monitor has a higher priority. Some monitors also depend on the results of other monitors before they can run.

A monitor may be classified as pending if a failed sensor or other system fault is keeping it from running on schedule.

The task manager may suspend a monitor if the conditions are not correct to continue. For example, if the catalyst monitor is running during a road test and the PCM detects a misfire, the catalyst monitor is suspended for the duration of the misfire.

TRIP A trip is defined as a key-on condition that contains the necessary conditions for a particular test to be performed, followed by a key-off. These conditions are called the **enable criteria**. For example, for the EGR test to be performed, the engine must be at normal operating temperature and decelerating for a minimum amount of time. Some tests are performed when the engine is cold, whereas others require that the vehicle be cruising at a steady highway speed.

WARM-UP CYCLE Once a MIL is deactivated, the original code remains in memory until 40 warm-up cycles are completed without the fault reappearing. A warm-up cycle is defined as a trip with an engine temperature increase of at least 40°F and where engine temperature reaches at least 160°F (71°C).

MIL CONDITION: OFF This condition indicates that the PCM has not detected any faults in an emissions-related component or system, or that the MIL circuit is not working.

MIL CONDITION: ON STEADY This condition indicates a fault in an emissions-related component or system that could affect the vehicle emission levels.

MIL CONDITION: FLASHING This condition indicates a misfire or fuel control system fault that could damage the catalytic converter.

NOTE: In a misfire condition with the MIL on steady, if the driver reaches a vehicle speed and load condition with the engine misfiring at a level that could cause catalyst damage, the MIL starts flashing. It continues to flash until engine speed and load conditions cause the level of misfire to subside. Then, the MIL goes back to the on-steady condition. This situation might result in a customer complaint of a MIL with an intermittent flashing condition.

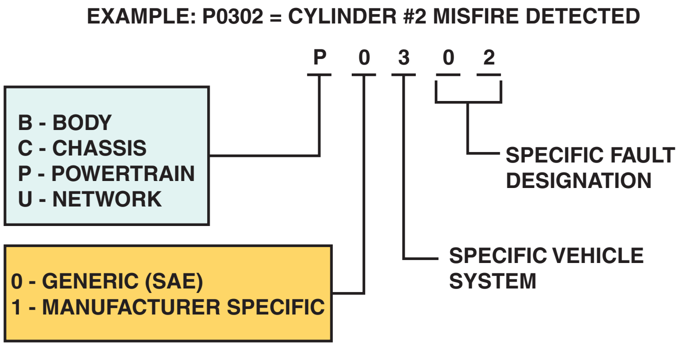
MIL: OFF The PCM turns off the MIL if any of the following actions or conditions occur:

- The codes are cleared with a scan tool.
- Power to the PCM is removed at the battery or with the PCM power fuse for an extended period of time (may be up to several hours or longer).
- A vehicle is driven on three consecutive trips with a warm-up cycle and meets all code set conditions without the PCM detecting any faults.

The PCM sets a code if a fault is detected that could cause tailpipe emissions to exceed 1.5 times the FTP standard; however, the PCM does not deactivate the MIL until the vehicle has been driven on three consecutive trips with vehicle conditions similar to actual conditions present when the fault was detected. This is not merely three vehicle start-ups and trips. It means three trips during which certain engine operating conditions are met, so that the OBD-II monitor that found the fault can run again and pass the diagnostic test.

OBD-II DTC NUMBERING DESIGNATION

A scan tool is required to retrieve DTCs from an OBD-II vehicle. Every OBD-II scan tool is able to read all generic **Society of Automotive Engineers (SAE)** DTCs from any vehicle. ● **SEE FIGURE 83–2** for definitions and explanations of OBD alphanumeric DTCs. The DTCs are grouped into major



EXAMPLE: P0302 = CYLINDER #2 MISFIRE DETECTED
P 0 3 0 2
B - BODY
C - CHASSIS
P - POWERTRAIN
U - NETWORK
0 - GENERIC (SAE)
1 - MANUFACTURER SPECIFIC
SPECIFIC FAULT DESIGNATION
SPECIFIC VEHICLE SYSTEM

FIGURE 83–2 OBD-II DTC identification format.

FREQUENTLY ASKED QUESTION

What Is a Drive Cycle?

A drive cycle is a vehicle being driven under specified speed and times that allows all monitors to run. In other words, the PCM is looking at a series of data points representing speed and time and determines from these data points when the conditions are right to perform a monitor or a test of a component. These data points and, therefore, the drive cycle are vehicle-specific and are not the same for each vehicle. Some common conditions for a drive cycle to successfully run all of the monitors include

1. Cold start with intake air temperature (IAT) and engine coolant temperature (ECT) close to each other, indicating that the engine has cooled to the temperature of the surrounding air temperature.
2. Fuel level within a certain range, usually between 15% and 85%.
3. Vehicle speed within a certain speed range for certain amount of time, usually 4 to 12 minutes.
4. Stop and idle for a certain time.

Each monitor requires its own set of parameters needed to run the test, and sometimes these conditions cannot be met. For example, some evaporate emissions control (EVAP) systems require a temperature that may not be possible in winter months in a cold climatic area.

A typical universal drive cycle that works for many vehicles includes the following steps.

MIL must be off.
No DTCs present.
Fuel fill between 15% and 85%.
Cold start—Preferred = 8-hour soak at 68°F to 86°F.
Alternative = ECT below 86°F.

STEP 1 With the ignition off, connect scan tool.
STEP 2 Start engine and drive between 20 and 30 mph for 22 minutes, allowing speed to vary.
STEP 3 Stop and idle for 40 seconds, gradually accelerate to 55 mph.
STEP 4 Maintain 55 mph for 4 minutes using a steady throttle input.
STEP 5 Stop and idle for 30 seconds, then accelerate to 30 mph.
STEP 6 Maintain 30 mph for 12 minutes.
STEP 7 Repeat steps 4 and 5 four times.

Using scan tool, check readiness. Always check service information for the exact drive cycle conditions for the vehicle being serviced for best results.

categories, depending on the location of the fault on the system involved.

Pxxx codes—powertrain DTCs (engine, transmission-related faults)

Bxxx codes—body DTCs (accessories, interior-related faults)

Cxxx codes—chassis DTCs (suspension and steering-related faults)

Uxxx codes—network DTCs (module communication-related faults)

DTC NUMBERING EXPLANATION The number in the hundredth position indicates the specific vehicle system or subgroup that failed. This position should be consistent for P0xxx and P1xxx type codes. The following numbers and systems were established by SAE:

- P0100—Air metering and fuel system fault
- P0200—Fuel system (fuel injector only) fault
- P0300—Ignition system or misfire fault
- P0400—Emission control system fault
- P0500—Idle speed control, vehicle speed (VS) sensor fault
- P0600—Computer output circuit (relay, solenoid, etc.) fault
- P0700—Transaxle, transmission faults

NOTE: The tens and ones numbers indicate the part of the system at fault.

TYPES OF DTCS Not all OBD-II DTCs are of the same importance for exhaust emissions. Each type of DTC has different requirements for it to set, and the computer only turns on the MIL for emissions-related DTCs.

TYPE A CODES A type A DTC is emission-related and causes the MIL to be turned on the first trip if the computer has detected a problem. Engine misfire or a very rich or lean air–fuel ratio, for example, causes a type A DTC. These codes alert the driver to an emission problem that may cause damage to the catalytic converter.

TYPE B CODES A type B code is stored and the MIL is turned on during the second consecutive trip, alerting the driver to the fact that a diagnostic test was performed and failed.

NOTE: Type A and B codes are emission-related codes that cause the lighting of the MIL, usually labeled "check engine" or "service engine soon."

TYPE C AND D CODES Type C and D codes are for use with non-emission-related diagnostic tests; they cause the lighting of a "service" lamp (if the vehicle is so equipped). Type C codes are also called type C1 codes and D codes are also called type C0 codes.

DIAGNOSTIC TROUBLE CODE PRIORITY CARB has also mandated that all diagnostic trouble codes (DTCs) be stored according to individual priority. DTCs with a higher priority overwrite those with a lower priority. The OBD-II System DTC Priority is listed below.

Priority 0—Non-emission-related codes

Priority 1—One-trip failure of two-trip fault for non-fuel, non-misfire codes

Priority 2—One-trip failure of two-trip fault for fuel or misfire codes

Priority 3—Two-trip failure or matured fault of non-fuel, non-misfire codes

Priority 4—Two-trip failure or matured fault for fuel or misfire codes

OBD-II FREEZE-FRAME

To assist the service technician, OBD II requires the computer to take a “snapshot” or freeze-frame of all data at the instant an emission-related DTC is set. A scan tool is required to retrieve this data.

NOTE: Although OBD II requires that just one freeze-frame of data be stored, the instant an emission-related DTC is set, vehicle manufacturers usually provide expanded data about the DTC beyond that required. However, retrieving this enhanced data usually requires the use of the vehicle-specific scan tool.

Freeze-frame items include

- Calculated load value
- Engine speed (RPM)
- Short-term and long-term fuel trim percent
- Fuel system pressure (on some vehicles)
- Vehicle speed (mph)
- Engine coolant temperature
- Intake manifold pressure
- Closed-open-loop status
- Fault code that triggered the freeze-frame
- If a misfire code is set, identify which cylinder is misfiring

A DTC should not be cleared from the vehicle computer memory unless the fault has been corrected and the technician is so directed by the diagnostic procedure. If the problem that caused the DTC to be set has been corrected, the computer automatically clears the DTC after 40 consecutive warm-up cycles with no further faults detected. It requires 80 warm-up cycles to erase the pending fault if similar conditions cannot be met. The codes can also be erased by using a scan tool. ● **SEE CHART 83–1**.

FREQUENTLY ASKED QUESTION

What Are Pending Codes?

Pending codes are set when operating conditions are met and the component or circuit is not within the normal range, yet the conditions have not yet been met to set a DTC. For example, a sensor may require two consecutive faults before a DTC is set. If a scan tool displays a pending code or a failure, a driveability concern could also be present. The pending code can help the technician to determine the root cause before the customer complains of a check engine light indication.

NOTE: Disconnecting the battery may not erase OBD-II DTCs or freeze-frame data. Most vehicle manufacturers recommend using a scan tool to erase DTCs, rather than disconnecting the battery, because the memory for the radio, seats, and learned engine operating parameters is lost if the battery is disconnected.

ENABLING CONDITIONS

These are the exact engine operating conditions required for a diagnostic monitor to run.

Example:

Specific RPM
Specific ECT, MAP, run time, etc.

PENDING Under some situations, the PCM does not run a monitor if the MIL is illuminated and a fault is stored from

MONITOR NAME	MONITOR TYPE (HOW OFTEN IT COMPLETES)	NUMBER OF FAULTS ON SEPARATE TRIPS TO SET A PENDING DTC	NUMBER OF SEPARATE CONSECUTIVE TRIPS TO LIGHT MIL, STORE A DTC	NUMBER OF TRIPS WITH NO FAULTS TO ERASE A MATURING DTC	NUMBER OF TRIPS WITH NO FAULT TO TURN THE MIL OFF	NUMBER OF WARM-UP CYCLES TO ERASE DTC AFTER MIL IS TURNED OFF
CCM	Continuous (when trip conditions allow it)	1	2	1–Trip	3–Trips	40
Catalyst	Once per drive cycle	1	3	1–Trip	3–OBD-II drive cycle	40
Misfire Type A	Continuous		1		3–Similar conditions	80
Misfire Type B	Continuous	1	2	1–Trip	3–Similar conditions	80
Fuel System	Continuous	1	2	1–Trip	3–Similar conditions	80
Oxygen Sensor	Once per trip	1	2	1–Trip	3–Trips	40
EGR	Once per trip	1	2	1–Trip	3–Trips	40
EVAP	Once per trip	1	1	1–Trip	3–Trips	40
AIR	Once per trip	1	2	1–Trip	3–Trips	40

CHART 83–1

PCM Determination of faults chart.

another monitor. In these situations, the PCM postpones monitors pending a resolution of the original fault. The PCM does not run the test until the problem is remedied.

For example, when the MIL is illuminated for an oxygen sensor fault, the PCM does not run the catalyst monitor until the oxygen sensor fault is remedied. Since the catalyst monitor is based on signals from the oxygen sensor, running the test produces inaccurate results.

CONFLICT There are also situations when the PCM does not run a monitor if another monitor is in progress. In these situations, the effects of another monitor running could result in an erroneous failure. If this conflict is present, the monitor is not run until the conflicting condition passes. Most likely, the monitor runs later, after the conflicting monitor has passed.

For example, if the fuel system monitor is in progress, the PCM does not run the EGR monitor. Since both tests monitor changes in air–fuel ratio and adaptive fuel compensation, the monitors conflict with each other.

SUSPEND Occasionally, the PCM may not allow a two-trip fault to mature. The PCM suspends the maturing fault if a condition exists that may induce erroneous failure. This prevents illuminating the MIL for the wrong fault and allows more precise diagnosis.

For example, if the PCM is storing a one-trip fault for the oxygen sensor and the EGR monitor, the PCM may still run the EGR monitor, but suspends the results until the oxygen sensor monitor either passes or fails. At that point, the PCM can determine if the EGR system is actually failing or if an oxygen sensor is failing.

PCM TESTS

RATIONALITY TEST While input signals to the PCM are constantly being monitored for electrical opens and shorts, they are also tested for rationality. This means that the input signal is compared against other inputs and information to see if it makes sense under the current conditions.

PCM sensor inputs that are checked for rationality include

- MAP sensor
- O_2 sensor
- ECT
- Camshaft position (CMP) sensor
- VS sensor
- Crankshaft position (CKP) sensor
- IAT sensor
- TP sensor
- Ambient air temperature sensor
- Power steering switch
- O_2 sensor heater
- Engine controller
- Brake switch
- P/N switch (range switch)
- Transmission controls

FUNCTIONALITY TEST A functionality test refers to PCM inputs checking the operation of the outputs.

Example

PCM commands the IAC open; expected change in engine RPM is not seen
IAC 60 counts
RPM 700 RPM
PCM outputs that are checked for functionality include

- EVAP canister purge solenoid
- EVAP purge vent solenoid
- Cooling fan
- Idle air control solenoid
- Ignition control system
- Transmission torque converter clutch solenoid
- Transmission shift solenoids (A, B, 1–2, etc.)

ELECTRICAL TEST Refers to the PCM check of both input and outputs for the following:

- Open
- Shorts
- Ground

Example:

ECT

Shorted high (input to PCM) above capable voltage, that is, 5-volt sensor with 12-volt input to PCM indicates a short to voltage.

Monitor Type	Conditions to Set DTC and Illuminate MIL	Extinguish MIL	Clear DTC Criteria	Applicable DTC
Continuous 1-trip monitor	(See note below) Input and output failure-rationally, functionally, electrically	3 consecutive pass trips	40 warm-up cycles	P0123

NOTE: The number of times the comprehensive component monitor must detect a fault depends on the vehicle manufacturer. On some vehicles, the comprehensive component monitor activates the MIL as soon as it detects a fault. On other vehicles, the comprehensive component monitor must fail two times in a row.

- Freeze-frame captured on first-trip failure.
- Enabling conditions: Many PCM sensors and output devices are tested at key-on or immediately after engine start-up. However, some devices (ECT, idle speed control) are only tested by the comprehensive component monitor after the engine meets particular engine conditions.
- Pending: No pending condition
- Conflict: No conflict conditions
- Suspend: No suspend conditions

GLOBAL OBD-II

All OBD-II vehicles must be able to display data on a global (also called *generic*) scan tool under nine different modes of operation. These modes include

Mode One	Current powertrain data (**parameter identification** display or **PID**)
Mode Two	Freeze-frame data
Mode Three	DTCs
Mode Four	Clear and reset DTCs, freeze-frame data, and readiness status monitors for noncontinuous monitors only
Mode Five	Oxygen sensor monitor test results
Mode Six	Onboard monitoring of test results for noncontinuously monitored systems
Mode Seven	Onboard monitoring of test results for continuously monitored systems
Mode Eight	Bidirectional control of onboard systems
Mode Nine	Module identification
Mode 10 ($0A)	Permanent DTCs

The global (generic) data is used by most state emission programs. Global OBD-II displays often use hexadecimal numbers, which use 16 numbers instead of 10. The numbers 0 to 9 (zero counts as a number) make up the first 10 and then capital letters A to F complete the 16 numbers. To help identify the number as being in a hexadecimal format, a dollar sign ($) is used in front of the number or letter. See the conversion chart below:

Decimal Number	Hexadecimal Code
0	$0
1	$1
2	$2
3	$3
4	$4
5	$5
6	$6
7	$7
8	$8
9	$9
10	$A
11	$B
12	$C
13	$D
14	$E
15	$F

Hexadecimal coding is also used to identify tests (**test identification [TID]** and **component identification [CID]**).

FREQUENTLY ASKED QUESTION

How Can You Tell Generic from Factory?

When using a scan tool on an OBD-II-equipped vehicle, if the display asks for make, model, and year, then the factory or enhanced part of the PCM is being accessed. If the generic or global part of the PCM is being scanned, then there is no need to know the vehicle identification details.

DIAGNOSING PROBLEMS USING MODE SIX

Mode six information can be used to diagnose faults by following three steps:

1. Check the monitor status before starting repairs. This step shows how the system failed.
2. Look at the component or parameter that triggered the fault. This step helps pin down the root cause of the failure.
3. Look to the monitor enable criteria, which shows what it takes to fail or pass the monitor.

REVIEW QUESTIONS

1. What does the PCM do during a trip to test emission-related components?
2. What is the difference between a type A and type B OBD-II DTC?
3. What is the difference between a trip and a warm-up cycle?
4. What could cause the MIL to flash?
5. What modes are available using Mode $06?

CHAPTER QUIZ

1. A freeze-frame is generated on an OBD-II vehicle __________.
   a. when a type C or D diagnostic trouble code is set
   b. when a type A or B diagnostic trouble code is set
   c. every other trip
   d. when the PCM detects a problem with the O2S
2. An ignition misfire or fuel mixture problem is an example of what type of DTC?
   a. Type A
   b. Type C
   c. Type B
   d. Type D

3. The comprehensive component monitor checks computer-controlled devices for __________.
   - **a.** opens
   - **b.** shorts-to-ground
   - **c.** rationality
   - **d.** All of the above

4. A freeze-frame is a __________ of all data at the instant an emission-related DTC is set.
   - **a.** comprehensive component monitor
   - **b.** failure record
   - **c.** snapshot
   - **d.** trip

5. Which is a continuous monitor?
   - **a.** Fuel system monitor
   - **b.** EGR monitor
   - **c.** Oxygen sensor monitor
   - **d.** Catalyst monitor

6. DTC P0302 is a(n) __________.
   - **a.** generic DTC
   - **b.** vehicle manufacturer-specific DTC
   - **c.** idle speed-related DTC
   - **d.** transmission/transaxle-related DTC

7. Enable criteria means __________.
   - **a.** the same thing as a trip
   - **b.** conditions for a particular test to be performed
   - **c.** a drive cycle
   - **d.** a warm-up cycle

8. By looking at the way diagnostic trouble codes are formatted, which DTC could indicate that the gas cap is loose or defective?
   - **a.** P0221
   - **b.** P1301
   - **c.** P0442
   - **d.** P1603

9. The computer automatically clears a DTC if there are no additional detected faults after __________.
   - **a.** forty consecutive warm-up cycles
   - **b.** eighty warm-up cycles
   - **c.** two consecutive trips
   - **d.** four key-on/key-off cycles

10. A global scan tool can display data under __________ modes of operation.
    - **a.** dual
    - **b.** nine
    - **c.** only three
    - **d.** fifteen

Chapter

MODULE REPROGRAMMING

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- List the benefits of module reprogramming over previous methods of update.
- Describe the regulatory requirements of J2534.
- List the hardware used for programming.
- List the software used for programming.
- Describe the methods of module reprogramming.
- Explain the need for a battery maintainer during reprogramming.
- Describe the concerns of programming in the shop.
- Describe aftermarket reprogramming.

KEY TERMS:

Application programming interface (API) 980 • Battery maintainer 981 • PROM 978 • Electronically erasable programmable read only memory (EEPROM) 978 • Locksmith ID 980 • NASTF 980 • Over-the-air (OTA) 982 • Pass-through device 980 • SAE J2534 979 • SAE J2534-1 979 • SAE J2534-2 979 • SAE J2534 version 5.00 979

MODULE SOFTWARE UPDATE

HISTORY OF MODULE PROGRAMMING Software programming has been used by the engine control module to meet air quality and emission standards since fuel injection replaced carburetors. The method of updating the software calibration has changed as technology has evolved. On early fuel-injected vehicles, it was necessary to change the computer when the calibration needed to be updated. ● **SEE FIGURE 84–1**.

In the early 1980s, the replacement **PROM** (programmable read only memory) was introduced. Instead of replacing the entire module, the technician would remove the PROM and install a replacement chip. Several versions of replaceable PROMs were used. ● **SEE FIGURE 84–2A AND B**.

In 1990, General Motors introduced flash reprogramming. This process allowed the technician to download the replacement software calibration from the manufacturer and to install it in the vehicles computer **EEPROM** (electronically erasable programmable read only memory). This eliminated the need to stock any parts which decreased the cost and the time needed for the repair.

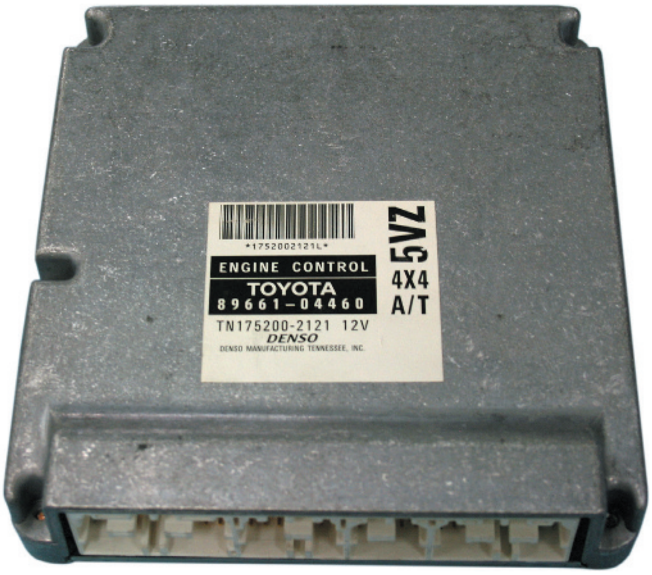

FIGURE 84–1 The Toyota engine control module pictured in the figure is an example of a module that must be replaced to update the programming memory.

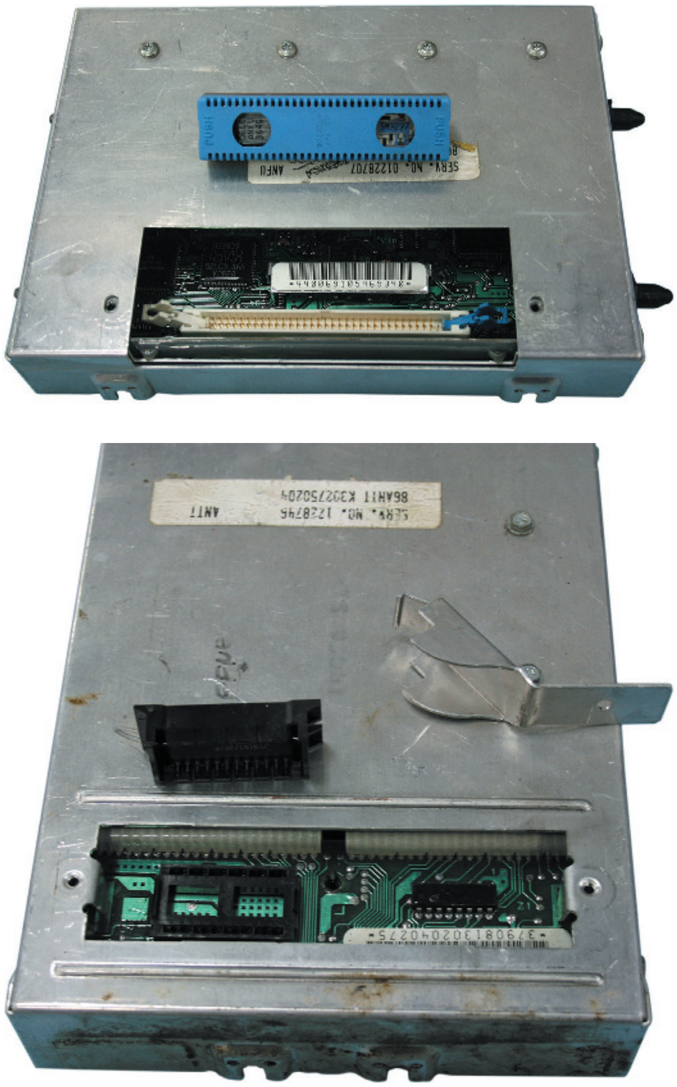

FIGURE 84–2A AND B The two General Motors engine control modules above are examples of two styles of removable PROMs used to update programmable memory.

In 1996 as part of the OBDII requirements, all modules that were responsible for emissions control were required to have EEPROM. The main purpose of this regulation was to make it more difficult for the technician to install a software calibration that would take the vehicle out of emission compliance. During this time period, module programming could typically only be performed by the dealer or by someone who had purchased manufacturer-specific tools. ● **SEE FIGURE 84–3**.

In 2004, it was mandated by CARB and the EPA that all vehicles manufactured after that point must be J2534 compliant, allowing for the reprogramming of emission-related modules. This mandate allowed for all individuals engaged in repair of emission-related failures the ability to update the software of these modules.

PURPOSE Designing a program that allows an engine to meet strict air quality and fuel economy standards while providing excellent performance is no small feat. However, this is only part of the challenge facing engineers assigned with the task of developing OBD-II software. The reason for this is the countless variables involved with running diagnostic monitors. Although programmers do their best to factor in any and all operating conditions when writing this complex code, periodic revisions are often required. Reprogramming consists of downloading new calibrations from the manufacturer into the PCM's electronically erasable programmable read only memory (EEPROM).

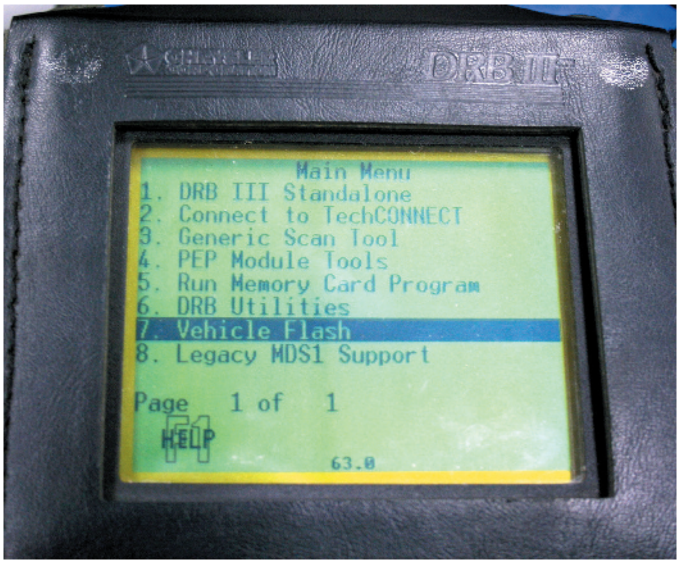

FIGURE 84–3 The manufacturer scan tool is being used to reprogram the engine control module via the data link connector.

SAE STANDARDS

J2534 SAE created the standard **SAE J2534** for communications between a computer and a vehicle. The original standard was introduced in February of 2002, and was identified as version 02.02. The EPA and CARB regulations require all automakers to provide a J2534 service to everyone in the United States for re-flashing emission-related controllers. If the technician has a SAE J2534 pass-through device, they can re-flash and, in some cases, diagnose vehicles with factory functionality. The EPA documentation requires OEMs to comply with SAE J2534 for pass-through reprogramming beginning with model year 2004. Reprogramming information also had to be made available within three months of vehicle introduction for new models. The original version of the standard was found to have some errors.

This original standard was updated in December of 2004. The new standard was identified as version 04.04 or more commonly as **SAE J2534-1**. The changes in the second version of the standard supported specific requirements of Ford and Chrysler that were not addressed in the first standard that related to J1850 class 2 communication protocols. It also defined specifics for the design of the vehicle communication interface device.

The standard was updated again and referred to as **SAE J2534-2**. These changes addressed issues related to single wire CAN BUS communication and issues related to the GM UART communication protocol. The new standard also provided a method for manufacturers to add optional features in a uniform way. An example of this is the ability to flash program modules that were not emission related.

The current standard is referred to as **SAE J2534 version 5.00**. The newest standard includes all the changes required in the previous updates and serves to improve the communication through the J1962 connector. It is important to have the most current equipment to ensure that that the flash reprogramming process will be completed without any malfunctions.

PROGRAMMING HARDWARE

MANUFACTURER SPECIFIC Each manufacturer has developed their own J2534 **pass-through device** or **application programming interface (API)** that is specific to the brands the manufacturer sells. A pass-through device or API serves as a connection point that makes all the hardware look the same, and allows the computer with the reprogramming software to communicate with the vehicles control module through the data link connector (DLC). Generally, these tools are not designed with the functionality to support competitive brands. In many cases, these pass-through devices are designed to support the manufacturer scan tool in addition to providing reprogramming capabilities. The GM MDI and Ford VCI are both examples of this type of technology. ● **SEE FIGURE 84–4**.

GENERIC The generic J2534 pass-through device is designed to support multiple manufacturers. These tools typically do not have the same level of scan tool diagnostics as a manufacturer-specific tool. These tools are more often found outside of the dealership environment in the independent repair facilities. The Drew Technologies CarDAQ-Plus series of J2534 pass-through devices is an example of a generic tool. ● **SEE FIGURE 84–5**.

PROGRAMMING SOFTWARE

NASTF (NATIONAL AUTOMOTIVE SERVICE TASK FORCE) The **NASTF** is a cooperative effort of the automotive service industry, the tool industry, and the original equipment manufacturers to ensure that automotive professionals employed outside of the OEMs have all the information, training, and tools they need to diagnose and repair modern automobiles. The NASTF has created a portal for all automotive service professionals to access manufacturer-specific reprogramming information. This includes where to access the information, the tools needed, and in many cases a short video on how to complete the task. ● **SEE FIGURE 84–6**.

VEHICLE SECURITY PROFESSIONAL – LOCKSMITH ID Many times when a module must be reprogrammed or programmed upon replacement, the security codes or key specific information must be re-entered during the process. In order to obtain this information, the shop or service technician must be a registered vehicle security professional and have a **locksmith ID** number. The National Automotive Service Task Force (NASTF), in conjunction with automotive manufacturers, insurance industry, independent repair, and law enforcement communities, has developed this system to allow the aftermarket repair industry to access to this sensitive data. The forms and instructions needed to apply for this identification number can be found on the NASTF website (www.nasft.org) under Locksmith/Vehicle Security. ● **SEE FIGURE 84–7**.

REPROGRAMMING

ON-BOARD On-board reprogramming of the controller is defined as having the module connected to the vehicle during the process. The module uses its normal connection points to provide the power, ground, communication links, and any other needed support. This is the type of programming that typically occurs in a service facility. ● **SEE FIGURE 84–8**.

Learn how to get key codes from OEM Technical service websites. www.lockmanlocksmiths.com/nastf-website-guides/

What is the VSP Registry?

The NASTF Vehicle Security Professional (VSP) Registry is a service created from the NASTF Secure Data Release Model (SDRM), a project of the NASTF Vehicle Security Committee. SDRM is a data exchange system (see graphic below) conceived and designed cooperatively by automakers, the independent repair, insurance and law enforcement communities; it allows the aftermarket to access security sensitive information related to automobiles, i.e. key codes, PIN numbers, immobilizer reset information, and similar types of information. The NASTF VSP Registry program allows access to security-related information while protecting the safety and security of consumers and the integrity of automobile security systems.

Who should use the NASTF VSP Registry and why?

USA-resident* locksmiths and service technicians qualified in vehicle security system repairs need a subscription to the NASTF VSP Registry in order to purchase security codes and VIN-specific computer files directly from the OEM/automaker. Most automakers/OEMs make this information available instantly from their websites 24/7/365. See a list of the OEMs and the model year ranges available in this pdf file (click HERE).

*Canadian VSPs may be eligible to participate in the Canadian program. Email John Norris in BC. NASTF is unaware of any similar registry in other countries. Contact local automaker agents.

OFF-BOARD
COMPUTER
PROGRAMMING
STATION

FIGURE 84–9 The engine control module can be programmed at an off-board location.

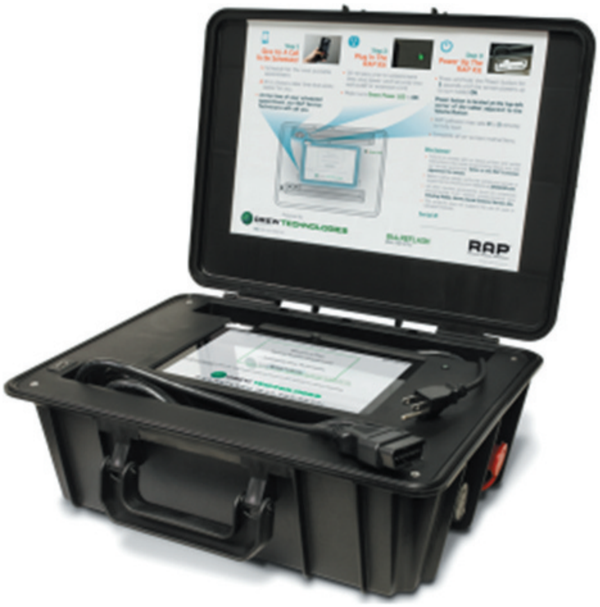

FIGURE 84–10 The Drew Technologies remote programming tool is an example of a tool that is connected to the vehicle and used remotely.

OFF-BOARD Off-board programming of the controller is defined as having the module programmed someplace other than in the vehicle. This could be anywhere that there is a computer and the needed power, ground and communication links. The purchase and programming of a module at a local parts store is an example of off-board programming. ● **SEE FIGURE 84–9**.

REMOTE Remote programming is a relatively new process. The servicing facility does not perform the reprogramming of the vehicle. Instead, the shop simply plugs in the equipment and follows the instructions of someone who is at a distant location. This process still requires an Internet connection and equipment. However, it relies on a third party who has the manufacturer subscription for the software. This option has become increasingly popular for shops that perform very few reprogramming events or lack the technical expertise to complete the task. ● **SEE FIGURE 84–10**.

BATTERY VOLTAGE

BATTERY MAINTAINER In order to provide a stable vehicle voltage throughout the reprogramming process, it is recommended that a **battery maintainer** be connected to the vehicle during the repair. A battery maintainer is designed to hold the vehicle at a specific voltage throughout the duration of the repair. A unique feature of the battery maintainer is that it accomplishes this task without wide fluctuations in voltage or amperage. ● **SEE FIGURES 84–11 AND 84–12**. Currently there are very few battery maintainers in the marketplace and they are more expensive than a battery charger. It is recommended that the maintainer be only used for the purpose of voltage stabilization during a reprogramming event, and they not be used for any other general shop use to ensure their proper operation.

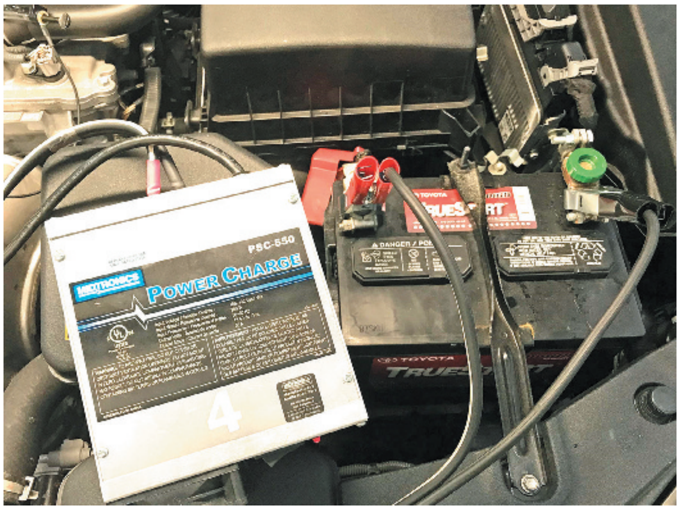

FIGURE 84–11 The Midtronics PSC-550 is an example of battery maintainer that meets the voltage and current requirements for reprogramming.

PROGRAMMING PROBLEMS AND CONCERNS

PROBLEMS AND CONCERNS IN THE FIELD The reprogramming of computers is relatively new to the automotive industry, and, as a result, there are many concerns related to the failure of the process and the damaging of the vehicle's module. The items listed below are some of the reasons some shops are hesitant to perform this type of repair.

- Are not plug-and-play technology.
- PC-based scan tools may host J2534 operations, but are not J2534 hardware.
- IT skills (owner or technician) will need to improve.
- Different OEMs use different interfaces and some tools can be difficult to use with some models.
- Software, Java, browser settings, and PC requirements are critical to proper operation.

AFTERMARKET REPROGRAMMING

COMPLIANCE CONCERNS There are many aftermarket programmers or "tuners" available in the marketplace today. The primary purpose of the programs is to increase torque and horsepower or to defeat emission control devices. These programs take the vehicle out of emission compliance because they do not meet the EPA/CARB requirements and are therefore illegal for on- or off-road use. It is likely that the change in torque and horsepower will lead to physical failures of the powertrain due to the increased numbers. The changes in software may also lead to a failure at the emission test lane due to monitor failures or omissions. ● **SEE FIGURE 84–13**.

FREQUENTLY ASKED QUESTION

How Does Over-The-Air Software Update Work?

Over-the-air (OTA) updates refers to the process of updating the software wirelessly by the manufacturer, eliminating the need to take the vehicle to the dealership. The vehicle is connected to the Internet via onboard cellular equipment (either 4G or 5G) or by Wi-Fi (if the owner allows access to their home Internet). The software is downloaded when the vehicle is updated while parked during a period of non-use. The process allows the manufacturer to update many vehicles in a very short period. ● **SEE FIGURE 84–14**.

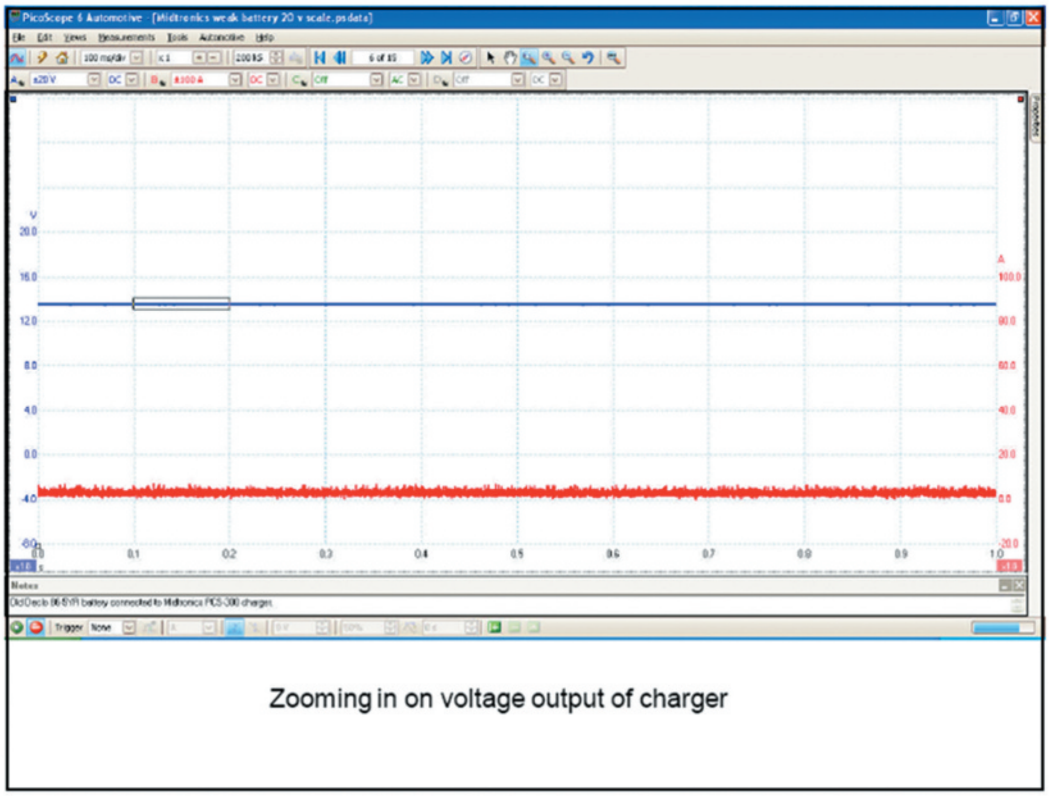

FIGURE 84–12 The scope patterns show stable voltage and current traces.

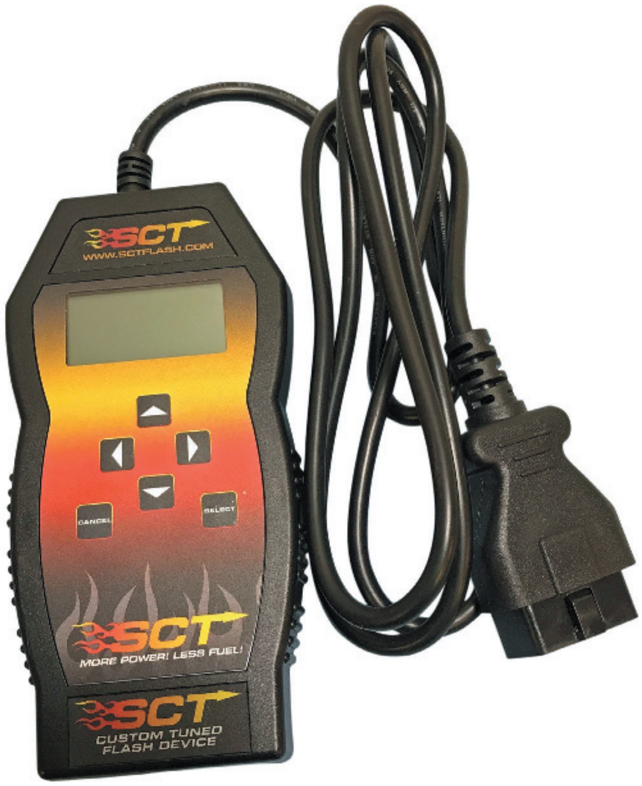

FIGURE 84–13 The SCT aftermarket tuner is an example of device that takes the vehicle out of compliance when reprogramming the module.

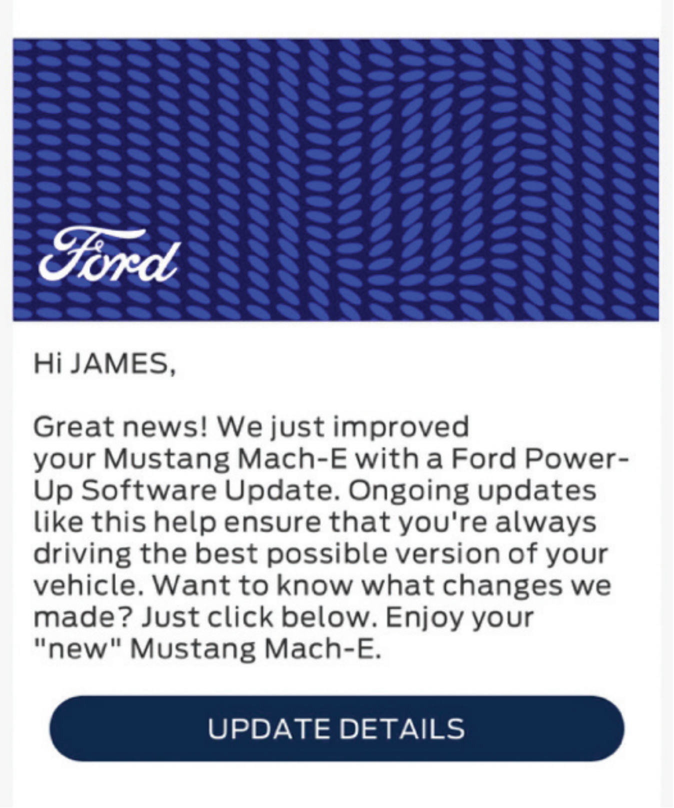


Hi JAMES,

Great news! We just improved your Mustang Mach-E with a Ford Power-Up Software Update. Ongoing updates like this help ensure that you're always driving the best possible version of your vehicle. Want to know what changes we made? Just click below. Enjoy your "new" Mustang Mach-E.

FIGURE 84–14 The vehicle owner receives a message from the manufacturer acknowledging the software update.

REVIEW QUESTIONS

1. Why did the manufacturers begin using EEPROM in 1996?
2. What is the SAE J2534 standard used for?
3. What are the differences between on-board, off-board, and remote programming?
4. Why is it important to use a battery maintainer when reprogramming a module?
5. Why do some aftermarket programmers or "tuners" cause a failure at the emission test lane?

CHAPTER QUIZ

1. Technician A says that reprogramming an engine control module using the J2534 system requires a factory scan tool. Technician B says that reprogramming an engine control module using the J2534 system requires Internet access. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
2. Which method can be used to reprogram an engine control module?
   a. On-board
   b. Off-board
   c. Remote
   d. Any of the above
3. A battery maintainer is used during reprogramming to ______________.
   a. make sure the OBDII data is not lost
   b. make sure the customer's radio stations are not lost
   c. make sure the system voltage does not drop during the reprogramming event
   d. All of the above
4. What is *not* required to reprogram a vehicle's engine control module?
   a. A good Internet connection
   b. A manufacturer's scan tool
   c. A pass-through device
   d. A computer that meets the minimum specifications
5. SAE J2534 is a mandated specification to all automakers who sell vehicles in the United States after 2004 to ______________.
   a. have standard data link connectors
   b. support reprogramming of the EEPROM
   c. make service information available to all who service vehicle emissions
   d. All of the above
6. How was programming updated before 1996?
   a. A new computer had to be installed
   b. A replaceable PROM was used
   c. The control cable was replaced
   d. The instrument panel cluster (IPC) was updated

7. What type of battery charger is specified when reprogramming?
- **a.** Must be a low-voltage, high-amperage charger
- **b.** Must use a battery charger that produces little, if any, voltage fluctuations
- **c.** Must be able to communicate with the J2534 unit
- **d.** Needs to be OBD/CARB approved

8. What organization created the J2534 standard?
- **a.** EPA
- **b.** CARB
- **c.** SAE
- **d.** OBD

9. What does a pass-through device do?
- **a.** It is used between the vehicle and the scan tool.
- **b.** It passes data between the DLC and the computer used to program a vehicle.
- **c.** It is used only for off-board programming.
- **d.** It is used to monitor the data being transferred.

10. Aftermarket programmers may create an issue of ___________.
- **a.** noncompliance
- **b.** excessive cost to the vehicle owner
- **c.** not being certified by EPA/CARB
- **d.** Both a and c

Chapter 85

STRATEGY-BASED DIAGNOSIS

LEARNING OBJECTIVES:

After studying this chapter, the reader will be able to:

- List the steps of the diagnostic process.
- Discuss the types of scan tools that are used to assess vehicle components.
- Explain how to retrieve diagnostic information and how to use DTCs.
- Explain the troubleshooting procedures to follow if a diagnostic trouble code has been set.
- Explain manufacturer's diagnostic routines.
- Discuss completing system repairs, including resetting the PCM and road test (drive cycle).

KEY TERMS:

Data link connector (DLC) 988 • Drive cycle 994 • Pending code 988 • Smoke machine 988 • Technical service bulletins (TSBs) 988

THE EIGHT-STEP DIAGNOSTIC PROCEDURE

STRATEGY-BASED DIAGNOSIS The diagnostic process is a strategy that eliminates known good components or systems in order to find the root cause of automotive engine performance problems. All vehicle manufacturers recommend a diagnostic procedure, and the plan suggested in this chapter combines most of the features of these plans plus additional steps developed over years of real-world problem solving.

Many different things can cause an engine performance problem or concern. The service technician has to narrow the possibilities to find the cause of the problem and correct it. A funnel is a way of visualizing a diagnostic procedure. ● **SEE FIGURE 85–1**. At the wide top are the symptoms of the problem; the funnel narrows as possible causes are eliminated until the root cause is found and corrected at the bottom of the funnel.

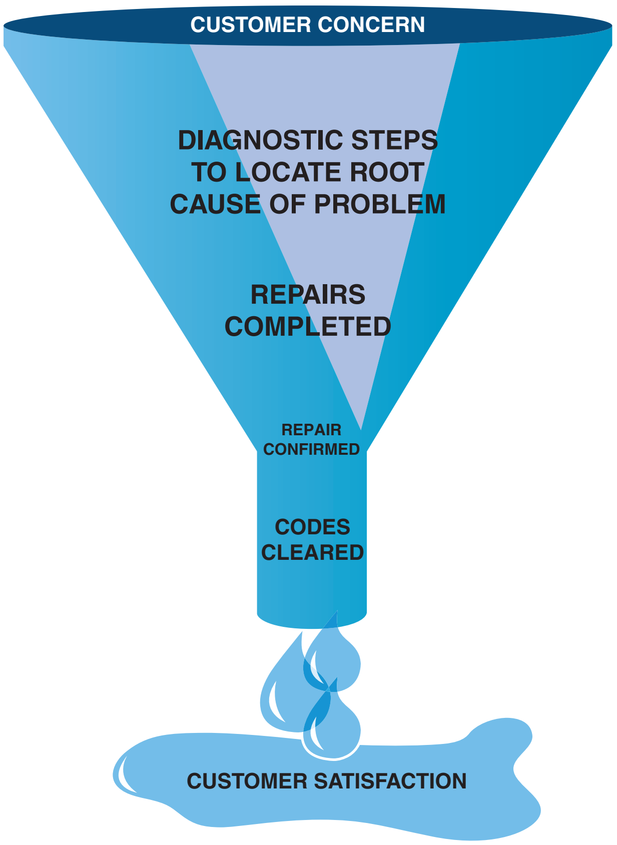
All problem diagnosis deals with symptoms that could be the result of many different causes. The wide range of possible solutions must be narrowed to the most likely and these must eventually be further narrowed to the actual cause. The following section describes eight steps the service technician can take to narrow the possibilities to one cause. ● **SEE FIGURE 85–2**.

STEP 1—VERIFY THE PROBLEM (CONCERN) Before a minute is spent on diagnosis, be certain that a problem exists. If the problem cannot be verified, it cannot be solved or tested to verify that the repair was complete.

The driver of the vehicle knows much about the vehicle and how it is driven. *Before* diagnosis, always ask the following questions:

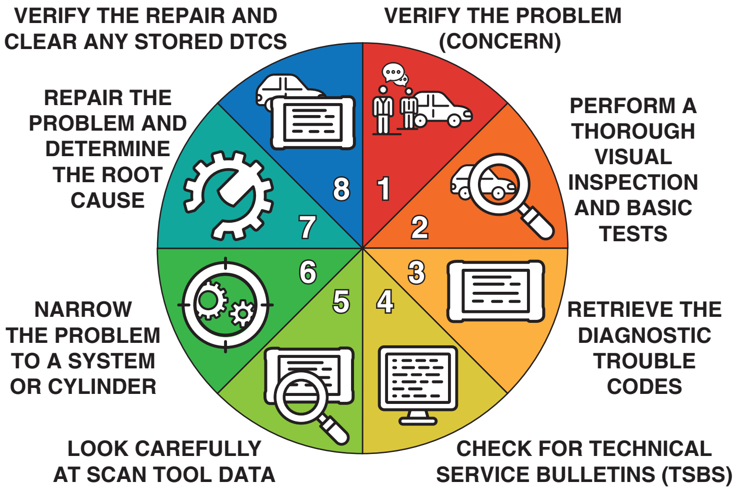
- Is the malfunction indicator light (check engine) on?
- What was the temperature outside?
- Was the engine warm or cold?
- Was the problem during starting, acceleration, cruise, or some other condition?
- How far had the vehicle been driven?
- Were any dash warning lights on? If so, which one(s)?
- Has there been any service or repair work performed on the vehicle lately?

NOTE: This last question is very important. Many engine performance faults are often the result of something being knocked loose or a hose falling off during repair work. Knowing that the vehicle was just serviced before the problem began may be an indicator as to where to look for the solution to a problem.



CUSTOMER CONCERN
DIAGNOSTIC STEPS TO LOCATE ROOT CAUSE OF PROBLEM
REPAIRS COMPLETED
REPAIR CONFIRMED
CODES CLEARED
CUSTOMER SATISFACTION

FIGURE 85–1 A funnel is one way to visualize the diagnostic process. The purpose is to narrow the possible causes of a concern until the root cause is determined and corrected.



VERIFY THE REPAIR AND CLEAR ANY STORED DTCS
VERIFY THE PROBLEM (CONCERN)
REPAIR THE PROBLEM AND DETERMINE THE ROOT CAUSE

8

FIGURE 85–2 Another way to visualize the diagnostic process is in a circle.

After the nature and scope of the problem are determined, the complaint should be verified before further diagnostic tests are performed. A sample form that customers could fill out with details of the problem is shown in ● **FIGURE 85–3**.

NOTE: Because drivers differ, it is sometimes the best policy to take the customer on the test-drive to verify the concern.

STEP 2—PERFORM A THOROUGH VISUAL INSPECTION AND BASIC TESTS The visual inspection is the most important aspect of diagnosis! Most experts agree that between 10% and 30% of all engine performance, problems can be found simply by performing a *thorough* visual inspection. The inspection should include the following:

- **Check for obvious problems (basics, basics, basics).**
  Fuel leaks
  Vacuum hoses that are disconnected or split
  Corroded connectors
  Unusual noises, smoke, or smell
  Check the air cleaner and air duct (squirrels and other small animals can build nests or store dog food in them). ● **SEE FIGURE 85–4**.
- **Check everything that does and does not work.** This step involves turning things on and observing that everything is working properly.
- **Look for evidence of previous repairs.** Any time work is performed on a vehicle, there is always a risk that something will be disturbed, knocked off, or left disconnected.
- **Check oil level and condition.** Another area for visual inspection is oil level and condition.
  Oil level. Oil should be to the proper level.
  Oil condition. Using a match or lighter, try to light the oil on the dipstick; if the oil flames up, gasoline is present in the engine oil. Drip some engine oil from the dipstick onto the hot exhaust manifold. If the oil bubbles or boils, coolant (water) is present in the oil. Check for grittiness by rubbing the oil between your fingers.

NOTE: Gasoline in the oil will cause the engine to run rich by drawing fuel through the positive crankcase ventilation (PCV) system.

- **Check coolant level and condition.** Many mechanical engine problems are caused by overheating. The proper operation of the cooling system is critical to the life of any engine.

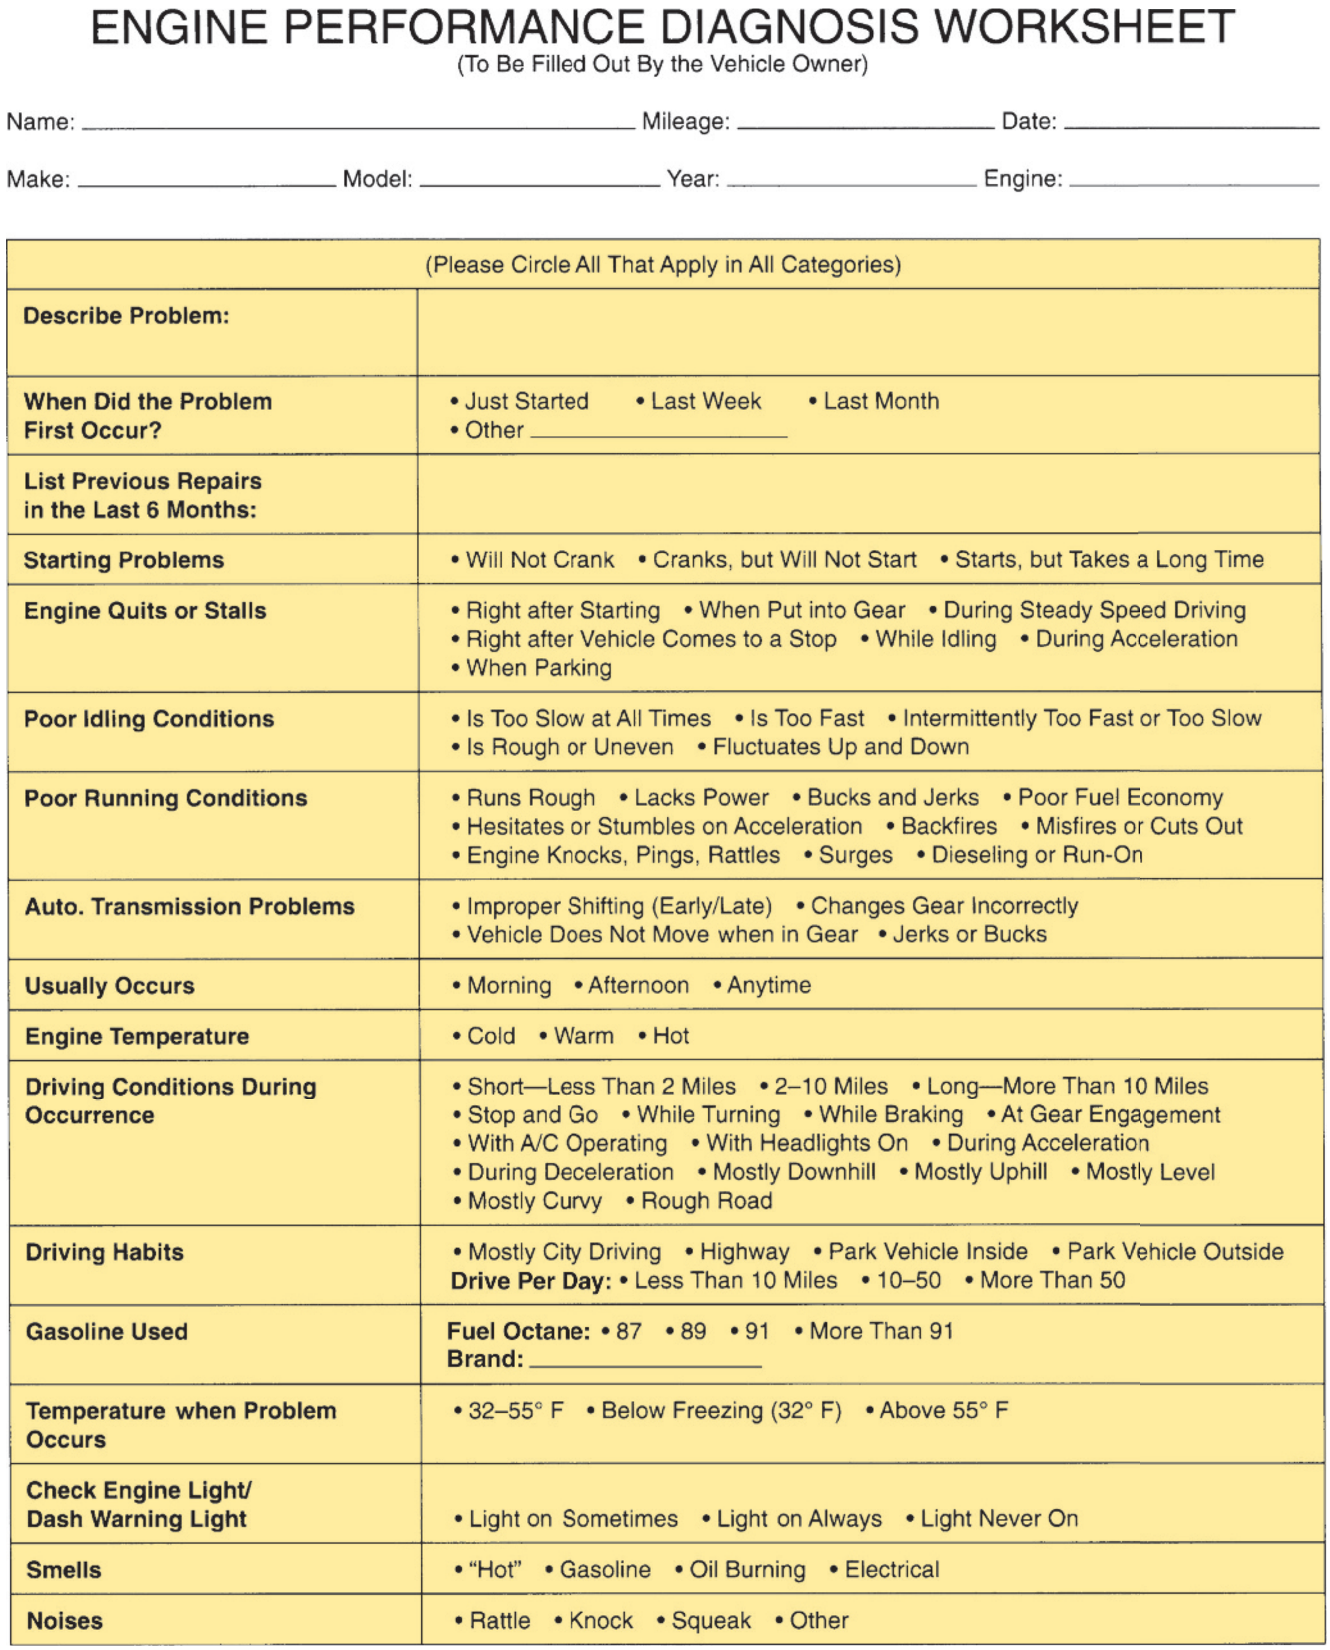
NOTE: Check the coolant level in the radiator only if the radiator is cool. If the radiator is hot and the radiator cap is removed, the drop in pressure above the coolant will cause the coolant to boil immediately, which can cause severe burns because the coolant expands explosively upward and outward from the radiator opening.

TECH TIP

"Original Equipment" Is Not a Four-Letter Word

To many service technicians, an original-equipment part is considered to be only marginal, and to get the really "good stuff" an aftermarket (renewal market) part has to be purchased. However, many problems can be traced to the use of an aftermarket part that has failed early in its service life. Technicians who work at dealerships usually go immediately to an aftermarket part that is observed during a visual inspection. It has been their experience that simply replacing the aftermarket part with the factory original-equipment (OE) part often solves the problem.

Original equipment parts are *required* to pass quality and durability standards and tests at a level not required of aftermarket parts. The technician should be aware that the presence of a new part does not necessarily mean that the part is good.



ENGINE PERFORMANCE DIAGNOSIS WORKSHEET

(To Be Filled Out By the Vehicle Owner)

Name: ____________ Mileage: ____________ Date: ____________

Make: ____________ Model: ____________ Year: ____________ Engine: ____________

(Please Circle All That Apply in All Categories)

Describe Problem:	
When Did the Problem First Occur?	• Just Started • Last Week • Last Month • Other ____________
List Previous Repairs in the Last 6 Months:	
Starting Problems	• Will Not Crank • Cranks, but Will Not Start • Starts, but Takes a Long Time
Engine Quits or Stalls	• Right after Starting • When Put into Gear • During Steady Speed Driving • Right after Vehicle Comes to a Stop • While Idling • During Acceleration • When Parking
Poor Idling Conditions	• Is Too Slow at All Times • Is Too Fast • Intermittently Too Fast or Too Slow • Is Rough or Uneven • Fluctuates Up and Down
Poor Running Conditions	• Runs Rough • Lacks Power • Bucks and Jerks • Poor Fuel Economy • Hesitates or Stumbles on Acceleration • Backfires • Misfires or Cuts Out • Engine Knocks, Pings, Rattles • Surges • Dieseling or Run-On
Auto. Transmission Problems	• Improper Shifting (Early/Late) • Changes Gear Incorrectly • Vehicle Does Not Move when in Gear • Jerks or Bucks
Usually Occurs	• Morning • Afternoon • Anytime
Engine Temperature	• Cold • Warm • Hot
Driving Conditions During Occurrence	• Short—Less Than 2 Miles • 2–10 Miles • Long—More Than 10 Miles • Stop and Go • While Turning • While Braking • At Gear Engagement • With A/C Operating • With Headlights On • During Acceleration • During Deceleration • Mostly Downhill • Mostly Uphill • Mostly Level • Mostly Curvy • Rough Road
Driving Habits	• Mostly City Driving • Highway • Park Vehicle Inside • Park Vehicle Outside **Drive Per Day:** • Less Than 10 Miles • 10–50 • More Than 50
Gasoline Used	**Fuel Octane:** • 87 • 89 • 91 • More Than 91 **Brand:** ____________
Temperature when Problem Occurs	• 32–55° F • Below Freezing (32° F) • Above 55° F
Check Engine Light/ Dash Warning Light	• Light on Sometimes • Light on Always • Light Never On
Smells	• "Hot" • Gasoline • Oil Burning • Electrical
Noises	• Rattle • Knock • Squeak • Other

FIGURE 85–3 A form that the customer should fill out if there is a driveablilty concern to help the service technician more quickly find the root cause.

- **Ensure adequate fuel level.** Make certain that the fuel tank is at least one-fourth to one-half full; if the fuel level is low, it is possible that any water or alcohol at the bottom of the fuel tank is more concentrated and can be drawn into the fuel system.
- **Check the battery voltage.** The voltage of the battery should be at least 12.4 volts and the charging voltage (engine running) should be 13.5 to 15.0 volts at 2000 RPM. Low battery voltage can cause a variety of problems including reduced fuel economy and incorrect (usually too high) idle speed. Higher-than-normal battery voltage can also cause the PCM problems and could cause damage to electronic modules.
- **Check the spark using a spark tester.** Remove one spark plug wire and attach the removed plug wire to the spark tester. Attach the grounding clip of the spark tester to a

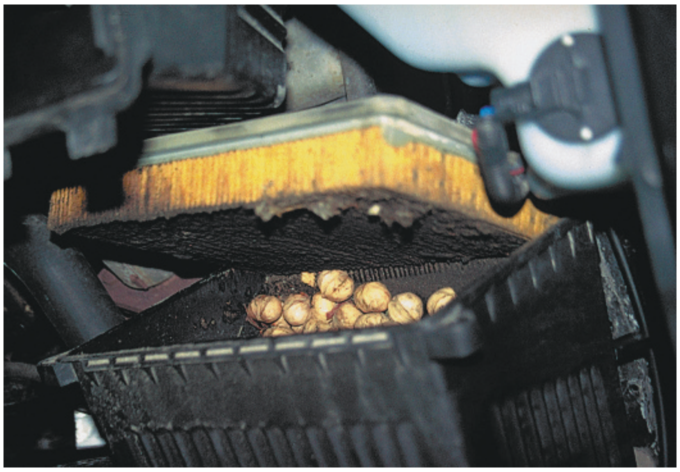


FIGURE 85–4 This is what was found when removing an air filter from a vehicle that had a lack-of-power concern. Obviously, the nuts were deposited by squirrels or some other animal, blocking a lot of the airflow into the engine.

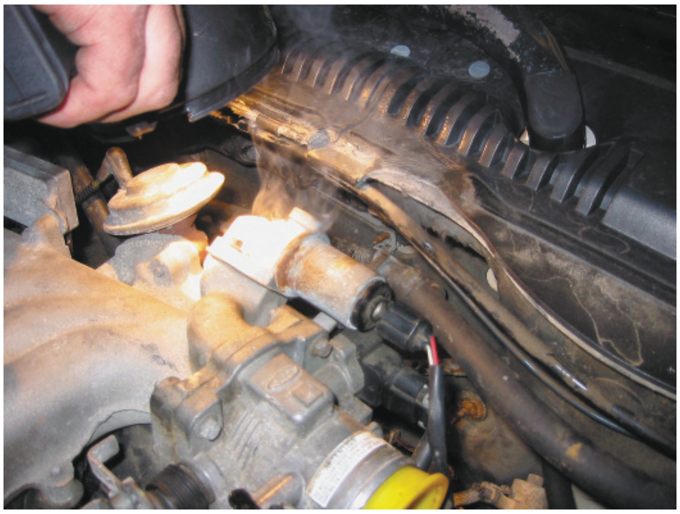

FIGURE 85–5 Using a bright light makes seeing where the smoke is coming from easier. In this case, smoke was added to the intake manifold with the inlet blocked with a yellow plastic cap and smoke was seen escaping past a gasket at the idle air control.

TECH TIP

Smoke Machine Testing

Vacuum (air) leaks can cause a variety of driveability problems and are often difficult to locate. One good method is to use a machine that generates a stream of smoke. Connecting the outlet of the **smoke machine** to the hose that was removed from the vacuum brake booster allows smoke to enter the intake manifold. Any vacuum leaks will be spotted by observing smoke coming out of the leak. ● **SEE FIGURE 85–5**.

good clean engine ground, start or crank the engine, and observe the spark tester. ● **SEE FIGURE 85–6**. The spark at the spark tester should be steady and consistent. If an intermittent spark occurs, then this condition should be treated as a no-spark condition. If this test does not show satisfactory spark, carefully inspect and test all components of the primary and secondary ignition systems.

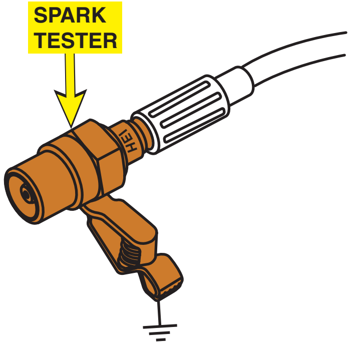

FIGURE 85–6 A spark tester connected to a spark plug wire or coil output. A typical spark tester will fire only if at least 25,000 volts is available from the coil, making a spark tester a useful tool. Do not use one that just lights when a spark is present, because it does not require more than about 2,000 volts to light.

NOTE: Do not use a standard spark plug to check for proper ignition system voltage. An electronic ignition spark tester is designed to force the spark to jump about 0.75 inch (19 mm). This amount of gap requires between 25,000 and 30,000 volts (25 to 30 kV) at atmospheric pressure, which is enough voltage to ensure that a spark can occur under compression inside an engine.

- **Check the fuel-pump pressure.** Checking the fuel-pump pressure is relatively easy on many port fuel-injected engines. Often the cause of intermittent engine performance is due to a weak electric fuel pump or clogged fuel filter. Checking fuel pump pressure early in the diagnostic process eliminates low fuel pressure as a possibility.

STEP 3—RETRIEVE THE DIAGNOSTIC TROUBLE CODES (DTCS)

If a diagnostic trouble code (DTC) is present in the computer memory, it may be signaled by illuminating a malfunction indicator lamp (MIL), commonly labeled “check engine” or “service engine soon.” ● **SEE FIGURE 85–7**. Any code(s) that is displayed when the MIL is *not* on is called a **pending code**. Because the MIL is not on, this indicates that the fault has not repeated to cause the PCM to turn on the MIL. Although this pending code is helpful to the technician to know that a fault has, in the past, been detected, further testing will be needed to find the root cause of the problem.

STEP 4—CHECK FOR TECHNICAL SERVICE BULLETINS (TSBS)

Check for corrections in **technical service bulletins (TSBs)** that match the symptoms. ● **SEE FIGURE 85–8**. According to studies performed by automobile manufacturers, as many as 30% of vehicles can be repaired following the information, suggestions, or replacement parts found in a service bulletin. DTCs must be known before searching for service bulletins, because bulletins often include information on solving problems that involve a stored diagnostic trouble code.

STEP 5—LOOK CAREFULLY AT SCAN TOOL DATA

Vehicle manufacturers have been giving the technician more and more data on a scan tool connected to the **data link connector (DLC)**. ● **SEE FIGURE 85–9**. Beginning technicians are often observed scrolling through scan data without a real clue about what they

FIGURE 85–7 Step 3 in the diagnostic process is to retrieve any stored diagnostic trouble codes.

FIGURE 85–8 After checking for stored diagnostic trouble codes (DTCs), the wise technician checks service information for any technical service bulletins that may relate to the vehicle being serviced.

TECH TIP

Look at the Freeze Frame

Whenever a DTC is set, a freeze frame is stored. The freeze frame includes data showing how the engine was being operated at the time the code was set. The wise service technician saves the freeze frame information to help determine not only what might have caused the code to set but also to allow the technician to drive the vehicle under similar conditions to verify that the problem has been corrected.

FIGURE 85–9 Looking carefully at the scan tool data is very helpful in locating the source of a problem.

are looking for. When asked, they usually reply that they are looking for something unusual, as if the screen will flash a big message "LOOK HERE—THIS IS NOT CORRECT." That statement does not appear on scan tool displays. The best way to look at scan data is in a definite sequence and with specific, selected bits of data that can tell the most about the operation of the engine, such as the following:

- Engine coolant temperature (ECT) is the same as intake air temperature (IAT) after the vehicle sits for several hours.
- Idle air control (IAC) valve is being commanded to an acceptable range.
- Oxygen sensor (O2S) is operating properly:
  1. Readings below 200 mV at times
  2. Readings above 800 mV at times
  3. Rapid transitions between rich and lean

The oxygen sensor data is used by the PCM to make any necessary adjustments to the fuel delivery to ensure that the catalytic converter is receiving an air–fuel ratio that can be most efficient not only for driveability but also for the lowest possible exhaust emissions. The correction is called fuel trim, and this represents the percentage of fuel either added or subtracted from the amount that was programmed as being the required. ● **SEE CHART 85–1**.

STEP 6—NARROW THE PROBLEM TO A SYSTEM OR CYLINDER

Narrowing the focus to a system or individual cylinder is the hardest part of the entire diagnostic process.

- Perform a cylinder power balance test.
- If a weak cylinder is detected, perform a compression test and a cylinder leakage test to determine the probable cause.

STEP 7—REPAIR THE PROBLEM AND DETERMINE THE ROOT CAUSE The repair or part replacement must be performed following vehicle manufacturer's recommendations and be certain

Rich/Lean Air–Fuel Ratio

TOTAL FUEL TRIM (LTFT + STFT) AT IDLE	2,500 RPM FUEL TRIM	LOADED FUEL TRIM	DRIVABILITY SYMPTOMS	POSSIBLE CAUSES
0–5%	0–5%	0–5%	No issues	Preferred fuel trim values
6–10%	6–10%	6–10%	No issues	Acceptable fuel trim valves
−10+%	−10+%	−10+%	Poor fuel economy	PCM is reducing fuel do to faults in the fuel system over-fueling the engine
+10%+	+10%+	+10%+	Low power, possible hesitation on acceleration	PCM is increasing fuel delivery do to faults in the air induction system

CHART 85–1

Normal short term fuel trim (STFT and long term fuel trim (LTFT) are considered to be less than +/− 10%.

that the root cause of the problem has been found. Also follow the manufacturer's recommended repair procedures and methods.

STEP 8—VERIFY THE REPAIR AND CLEAR ANY STORED DTCS

● **SEE FIGURE 85–10.**

- Test-drive to verify that the original problem (concern) is fixed.
- Verify that no additional problems have occurred during the repair process.
- Check for and then clear all diagnostic trouble codes. (This step ensures that the computer will not make any changes based on a stored DTC, but should not be performed if the vehicle is going to be tested for emissions because all of the monitors will need to be run and pass.)

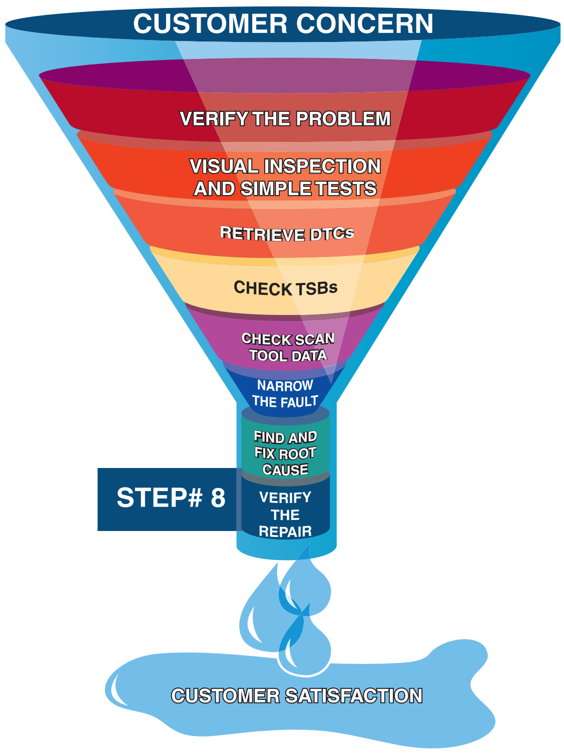

FIGURE 85–10 Step 8 is very important. Be sure that the customer's concern has been corrected.

- Return the vehicle to the customer and double-check the following:
  1. The vehicle is clean.
  2. The radio is turned off.
  3. The clock is set to the right time and the radio stations have been restored if the battery was disconnected during the repair procedure.

SCAN TOOLS

Scan tools are the workhorse for any diagnostic work on all vehicles. Scan tools can be divided into two basic groups

1. **Factory scan tools.** These are the scan tools required by all dealers that sell and service the brand of vehicle. Examples of factory scan tools include
   - **General Motors**—Tech 2, MDI (Multiple Diagnostic Interface), MDI 2, or GDS2 (global diagnostic system 2).
   - **Ford**—New Generation Star (NGS), IDS (Integrated Diagnostic System), VCM, VCM2, or VCM3.
   - **Chrysler**—DRB-III, Star Scan, wiTECH, or wiTECH 2.
   - **Honda**—HDS or Master Tech
   - **Toyota**—Master Tech, or Techstream ADVi.

TECH TIP

One Test Is Worth 1,000 "Expert" Opinions

Whenever any vehicle has an engine performance or driveability concern, certain people always say:

"Sounds like it's a bad injector."

"I'll bet you it's a bad computer."

"I had a problem just like yours yesterday and it was a bad EGR valve."

Regardless of the skills and talents of those people, it is still more accurate to perform tests on the vehicle than to rely on feelings or opinions of others who have not even seen the vehicle. Even your own opinion should not sway your thinking. Follow a plan, perform tests, and the test results will lead to the root cause.

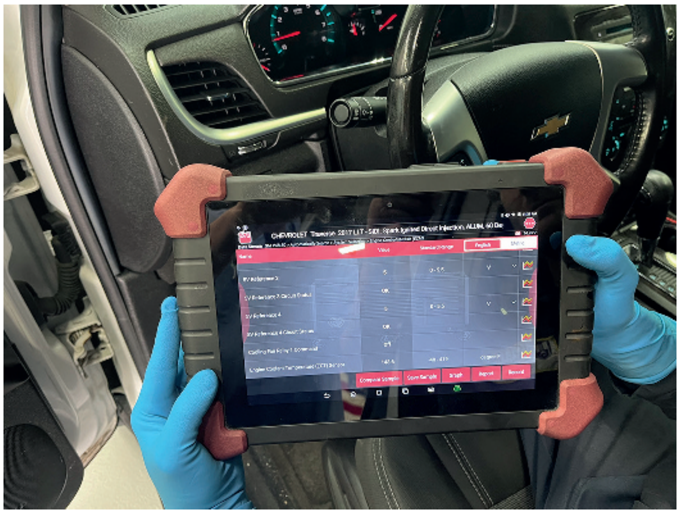

FIGURE 85–11 An enhanced aftermarket scan tool being used to diagnose an engine performance issue.

All factory scan tools are designed to provide bidirectional capability that allows the service technician the opportunity to operate components using the scan tool thereby confirming that the component is able to work when commanded. Also all factory scan tools are capable of displaying all factory parameters.

2. **Aftermarket scan tools.** These scan tools are designed to function on more than one brand of vehicle. Examples of aftermarket scan tools include

   - **Snap-on** (various models including the Solus and Vantage Ultra and Modis)
   - **OTC** (various models including Genisys and Task Master Evo and Evolve)
   - **Autel** (various models) ● **SEE FIGURE 85–11**.

While many aftermarket scan tools can display most if not all of the parameters of the factory scan tool, there can be a difference when trying to troubleshoot some faults. ● **SEE FIGURE 85–12**.

RETRIEVAL OF DIAGNOSTIC INFORMATION

To retrieve diagnostic information from the powertrain control module (PCM), a scan tool is needed. If a factory or factory-level scan tool is used, then all of the data can be retrieved. If a global (generic) only type scan tool is used, only the emissions-related data can be retrieved. To retrieve diagnostic information from the PCM, use the following steps:

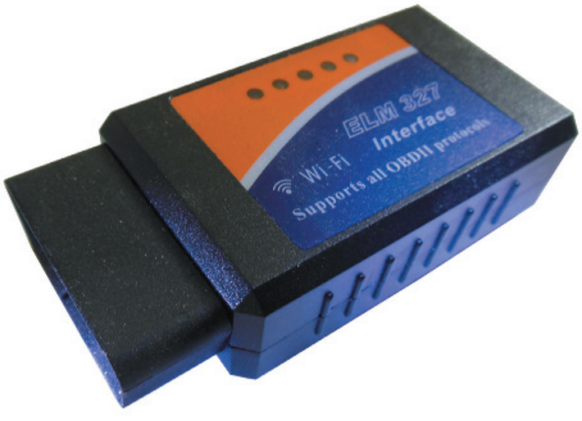

FIGURE 85–12 A Bluetooth adapter that plugs into the DLC and transmits global OBD II information to a smart phone that has a scan tool app installed.

STEP 1 Locate and gain access to the data link connector (DLC). ● **SEE FIGURES 85–13, 85–14, AND 85–15**.

STEP 2 Connect the scan tool to the DLC and establish communication.

NOTE: If no communication is established, follow the vehicle manufacturer's specified instructions.

STEP 3 Follow the on-screen instructions of the scan tool to correctly identify the vehicle.

STEP 4 Observe the scan data, as well as any diagnostic trouble codes.

STEP 5 Follow vehicle manufacturer's instructions if any DTCs are stored. If no DTCs are stored, compare all sensor values with a factory acceptable range chart to see if any sensor values are out of range. ● **SEE CHART 85–2**.

TROUBLESHOOTING USING DIAGNOSTIC TROUBLE CODES

Pinning down causes of the actual problem can be accomplished by trying to set the opposite code. For example, if a code indicates an open throttle position (TP) sensor (high resistance), clear the code and create a shorted (low-resistance) condition. This can be accomplished by using a jumper wire and connecting the signal terminal to the 5-volt reference terminal. This should set a diagnostic trouble code.

- **If the opposite code sets,** this indicates that the wiring and connector for the sensor is okay and the sensor itself is defective (open).
- **If the same code sets,** this indicates that the wiring or electrical connection is open (has high resistance) and is the cause of the setting of the DTC.

DIAGNOSING INTERMITTENT MALFUNCTIONS Of all the different types of conditions that you will see, the hardest to accurately diagnose and repair are intermittent malfunctions. These conditions may be temperature related (only occur when the vehicle is hot or cold), or humidity related (only occur when it is raining). Regardless of the conditions that will cause the malfunction to occur, you must diagnose and correct the condition.

When dealing with an intermittent concern, you should determine the conditions when the malfunction occurs, and then try to duplicate those conditions. If a cause is not readily apparent to you, ask the customer when the symptom occurs. Ask if there are any conditions that seem to be related to, or cause the concern.

Another consideration when working on an OBD-II-equipped, vehicle is whether a concern is intermittent, or if it only occurs when a specific diagnostic test is performed by the PCM. Since OBD-II systems conduct diagnostic tests only under very precise conditions, some tests may only be run once during an ignition cycle. Additionally, if the requirements needed to perform the

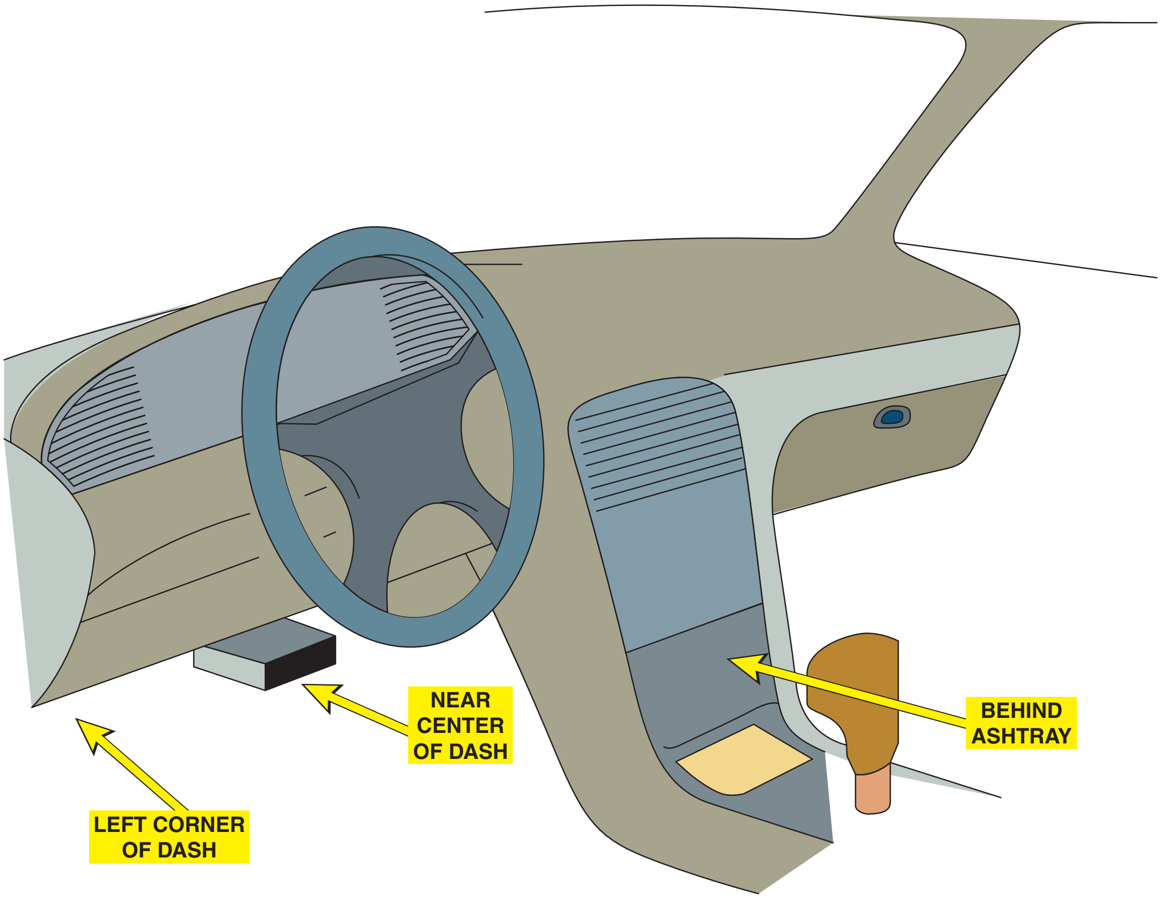

FIGURE 85–13 The data link connector (DLC) can be located in various locations.

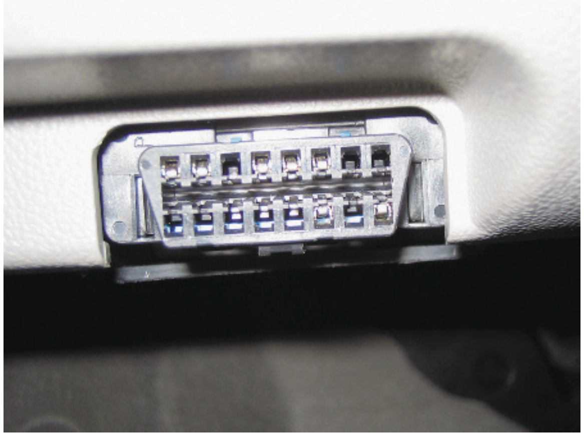

FIGURE 85–14 A typical OBD-II data link connector (DLC). The location varies with make and model and may even be covered, but a tool is not needed to gain access. Check service information for the exact location if needed.

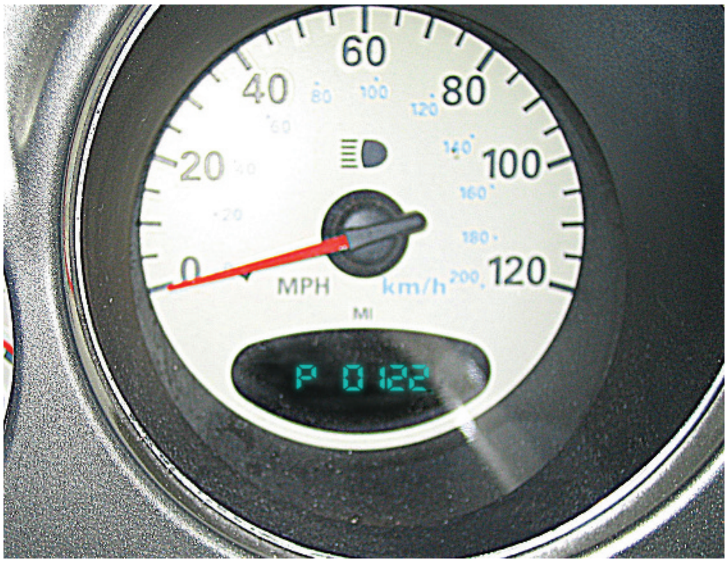

FIGURE 85–15 Diagnostic trouble codes (DTCs) from Chrysler and Dodge vehicles can be retrieved by turning the ignition switch to on and then off three times.

test are not met, the test will not run during an ignition cycle. This type of onboard diagnostics could be mistaken as "intermittent" when, in fact, the tests are only infrequent (depending on how the vehicle is driven). Examples of this type of diagnostic test are HO2S heaters, evaporative canister purge, catalyst efficiency, and EGR flow. When diagnosing intermittent concerns on an OBD-II-equipped vehicle, a logical diagnostic strategy is essential. The use of stored freeze-frame information can also be very useful when diagnosing an intermittent malfunction if a code has been stored.

MANUFACTURER'S DIAGNOSTIC ROUTINES

Each vehicle manufacturer has established their own diagnostic routines and they should be followed. Most include the following steps:

STEP 1 Retrieve diagnostic trouble codes.

Parameter Identification (PID)

Scan Tool Parameter	Units Displayed	Typical Data Value
Engine Idling/Radiator Hose Hot/Closed Throttle/ Park or Neutral/ Closed Loop/Accessories Off/ Brake Pedal Released		
3X Crank Sensor	RPM	Varies
24X Crank Sensor	RPM	Varies
Actual EGR Position	Percent	0
BARO	kPa/volts	65–110 kPa/3.5-4.5 volts
CMP Sensor Signal Present	Yes/No	Yes
Commanded Fuel Pump	On/Off	On
Cycles of Misfire Data	Counts	0–99
Desired EGR Position	Percent	0
ECT	°C/°F	Varies
EGR Duty Cycle	Percent	0
Engine Run Time	Hr: Min: Sec	Varies
EVAP Canister Purge	Percent	Low and Varying
EVAP Fault History	No Fault/ Excess Vacuum/ Purge Valve Leak/ Small Leak/ Weak Vacuum	No Fault
Fuel Tank Pressure	Inches of H_2O/volts	Varies
HO2S Sensor 1	Ready/ Not Ready	Ready
HO2S Sensor 1	Millivolts	0–1,000 and Varying
HO2S Sensor 2	Millivolts	0–1,000 and Varying
HO2S X Counts	Counts	Varies
IAC Position	Counts	15–25 preferred
IAT	°C/°F	Varies
Knock Retard	Degrees	0
Long-Term FT	Percent	0–10
MAF	Grams per second	3–7
MAF Frequency	Hz	1,200–3,000 (depends on altitude and engine load)
MAP	kPa/volts	20–48 kPa/0.75–2 volts (depends on altitude)
Misfire Current Cyl. 1–10	Counts	0
Misfire History Cyl. 1–10	Counts	0

CHART 85–2

Examples of observed scan tool data.

Scan Tool Parameter	Units Displayed	Typical Data Value
Short-Term FT	Percent	0–10
Start-Up ECT	°C/°F	Varies
Start-Up IAT	°C/°F	Varies
Total Misfire Current Count	Counts	0
Total Misfire Failures	Counts	0
Total Misfire Passes	Counts	0
TP Angle	Percent	0
TP Sensor	Volts	0.20–0.74
Vehicle Speed	mph/km/h	0

Note: Viewing the PID screen on the scanner is useful in determining if a problem is occurring at the present time.

CHART 85–2 continued

STEP 2 Check for all technical service bulletins that could be related to the stored DTC.

STEP 3 If there are multiple DTCs, the diagnostic routine may include checking different components or systems instead of when only one DTC was stored.

STEP 4 Perform system checks.

STEP 5 Perform a road test matching the parameters recorded in the freeze-frame to check that the repair has corrected the malfunction.

STEP 6 Repeat the road test to cause the MIL to be extinguished.

NOTE: Do not clear codes (DTCs) unless instructed by the service information.

Following the vehicle manufacturer's specific diagnostic routines will ensure that the root cause is found and the repair verified. This is important for customer satisfaction.

COMPLETING SYSTEM REPAIRS

After the repair has been successfully completed, the vehicle should be driven under similar conditions that caused the original concern. Verify that the problem has been corrected. To perform this test-drive, it is helpful to have a copy of the freeze-frame parameters that were present when the DTC was set. By driving under similar conditions, the PCM may perform a test of the system and automatically extinguish the MIL. This is the method preferred by most vehicle manufacturers. The DTC can be cleared using a scan tool, but then that means that monitors will have to be run and the vehicle may fail an emissions inspection if driven directly to the testing station.

PROCEDURES FOR RESETTING THE PCM The PCM can be reset or cleared of previously set DTCs and freeze-frame data in the following ways:

1. **Driving the Vehicle.** Drive the vehicle under similar conditions that were present when the fault occurred. If the

conditions are similar and the PCM performed the noncontinuous monitor test and it passed three times, then the PCM will extinguish the MIL. This is the method preferred by most vehicle manufacturers; however, this method could be time consuming. If three passes cannot be achieved, the owner of the vehicle will have to be told that even though the check engine light (MIL) is on, the problem has been corrected and the MIL should go out in a few days of normal driving.

2. **Clear DTCs Using a Scan Tool.** A scan tool can be used to clear the diagnostic trouble code (DTC), which will also delete all of the freeze-frame data. The advantage of using a scan tool is that the check engine (MIL) will be out and the customer will be happy that the problem (MIL on) has been corrected. Do not use a scan tool to clear a DTC if the vehicle is going to be checked soon at a test station for state-mandated emissions tests.
3. **Battery Disconnect.** Disconnecting the negative battery cable will clear the DTCs and freeze-frame on many vehicles but not all. Besides clearing the DTCs, disconnecting the battery for about 20 minutes will also erase radio station presets and other memory items in many cases. Most vehicle manufacturers do not recommend that the battery be disconnected to clear DTCs and it may not work on some vehicles.

ROAD TEST (DRIVE CYCLE)

Use the freeze-frame data and test-drive the vehicle so that the vehicle is driven to match the conditions displayed on the freeze-frame. If the battery has been disconnected, then the vehicle may have to be driven under conditions that allow the PCM to conduct monitor tests. This drive pattern is called a **drive cycle**. The drive cycle is different for each vehicle manufacturer but a universal drive cycle may work in many cases. In many cases, performing a universal drive cycle will reset most monitors in most vehicles.

UNIVERSAL DRIVE CYCLE

Preconditioning: Phase I.

MIL must be off.
No DTCs present.
Fuel fill between 15% and 85%.
Cold start–Preferred = eight – hour soak at 68°F to 86°F.
Alternative = ECT below 86°F.

1. With the ignition off, connect scan tool.
2. Start engine and drive between 20 and 30 mph for 22 minutes, allowing speed to vary.
3. Stop and idle for 40 seconds, gradually accelerate to 55 mph.
4. Maintain 55 mph for 4 minutes using a steady throttle input.
5. Stop and idle for 30 seconds, then accelerate to 30 mph.
6. Maintain 30 mph for 12 minutes.
7. Repeat steps 4 and 5 four times.

Using scan tool, check readiness. If insufficient readiness set, continue to universal drive trace phase II.

Important: (Do not shut off engine between phases). Phase II:

1. Bring vehicle to a stop and idle for 45 seconds, then accelerate to 30 mph.
2. Maintain 30 mph for 22 minutes.
3. Repeat steps 1 and 2 three times.
4. Bring vehicle to a stop and idle for 45 seconds, then accelerate to 35 mph.
5. Maintain speed between 30 and 35 mph for 4 minutes.
6. Bring vehicle to a stop and idle for 45 seconds, then accelerate to 30 mph.
7. Maintain 30 mph for 22 minutes.
8. Repeat steps 6 and 7 five times.
9. Using scan tool, check readiness.

TECH TIP

The Brake Pedal Trick

If the vehicle manufacturer recommends that battery power be disconnected, first disconnect the negative battery cable and then depress the brake pedal. Because the brake lights are connected to battery power, depressing the brake pedal causes all of the capacitors in the electrical system and computer(s) to discharge through the brake lights.

TECH TIP

Drive the Light Out

If working on a vehicle that is subject to state emissions testing, it is best to not clear codes. When diagnostic trouble codes are cleared, all of the monitors have to be rerun and this can be a time-consuming job. Instead of clearing the code, simply drive the vehicle until the PCM clears the code. This will likely take less time compared to trying to drive the vehicle under varying conditions to run all of the monitors.

REVIEW QUESTIONS

1. Explain the procedure to follow when diagnosing a vehicle with stored DTCs using a scan tool.
2. Discuss what the PCM does during a drive cycle to test emissions-related components.
3. Where is the DLC typically located?
4. List three things that should be checked as part of a thorough visual inspection.
5. Explain why a bulletin search should be performed after stored DTCs are retrieved.

CHAPTER QUIZ

1. Technician A says that the first step in the diagnostic process is to verify the problem (concern). Technician B says the second step is to perform a thorough visual inspection. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
2. Which item is *not* important to know before starting the diagnosis of an engine performance problem?
   - **a.** List of previous repairs
   - **b.** The brand of engine oil used
   - **c.** The type of gasoline used
   - **d.** The temperature of the engine when the problem occurs
3. After completing repairs the technician should perform a ___________ to allow the PCM to conduct monitor tests.
   - **a.** battery disconnect
   - **b.** DTC survey
   - **c.** drive cycle
   - **d.** fuel mileage test
4. Which step should be performed *last* when diagnosing an engine performance problem?
   - **a.** Checking for any stored diagnostic trouble codes
   - **b.** Checking for any technical service bulletins (TSBs)
   - **c.** Performing a thorough visual inspection
   - **d.** Verifying the repair
5. Technician A says that if the opposite DTC can be set, the problem is the component itself. Technician B says if the opposite DTC cannot be set, the problem is with the wiring or grounds. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
6. The preferred method to clear diagnostic trouble codes (DTCs) is to ___________.
   - **a.** disconnect the negative battery cable for 10 seconds
   - **b.** use a scan tool
   - **c.** remove the computer (PCM) power feed fuse
   - **d.** cycle the ignition key on and off 40 times
7. Which is the factory scan tool for Chrysler brand vehicles?
   - **a.** wiTECH
   - **b.** Tech 2
   - **c.** NGS
   - **d.** Master Tech
8. Which of these is *not* part of a visual inspection?
   - **a.** Check oil level
   - **b.** Check coolant condition
   - **c.** Check battery voltage
   - **d.** Check DTCs
9. Technician A says that knowing if there are any stored diagnostic trouble codes (DTCs) may be helpful when checking for related technical service bulletins (TSBs). Technician B says that only a factory scan tool should be used to retrieve DTCs. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
10. To help the technician verify the customer's concern, a ___________ should be used.
    - **a.** scope
    - **b.** diagnosis worksheet
    - **c.** vibration monitor
    - **d.** digital camera

HYBRID AND ELECTRIC VEHICLE SAFETY

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss high-voltage safety, electric shock potential, and EV/HEV service areas.
- Discuss electric shock potential.
- Discuss EV/HEV service areas.
- Describe the personal protective equipment (PPE) recommended for working on EV/HEV systems.
- Explain the tools and equipment needed for working on high-voltage electrical systems.
- Explain the purpose of the safety interlock system.
- Describe the process for depowering the high-voltage system.
- Discuss precautions that are needed when hoisting an EV/HEV in the shop.
- Discuss precautions that are needed when moving an EV/HEV in the shop.

KEY TERMS:

Acoustic vehicle alerting system (AVAS) 1003 • American National Standards Institute (ANSI) 999 • American Society for Testing and Materials (ASTM) 999 • Category three (CAT III) 1001 • Digital multimeter (DMM) 1001 • High voltage (HV) 996 • International Electrotechnical Commission (IEC) 1001 • Occupational Safety and Health Administration (OSHA) 999 • System main relays (SMRs) 998

HIGH-VOLTAGE SAFETY

NEED FOR CAUTION Electrical systems have been used on vehicles for more than a century. Technicians have been repairing vehicle electrical systems without fear of serious injury or electrocution. However, when working with electric or hybrid electric vehicles, this is no longer true. It is now possible to be seriously injured or electrocuted (killed) if proper safety procedures are not followed.

Electric and hybrid electric vehicles use **high-voltage (HV)** circuits that if touched with an unprotected hand could cause serious burns or even death.

PRECAUTIONS FOR ELECTRONIC MEDICAL DEVICES

- Electronic medical devices include cardiac pacemakers and cardioverter defibrillators.
- Technicians who rely on cardiac pacemakers should not service or repair electric or hybrid electric vehicles because of strong magnetic fields.
- Technicians who rely on implanted cardiac pacemakers or implanted cardioverter defibrillators should check with the manufacturer of the device before being in or around a charging vehicle.

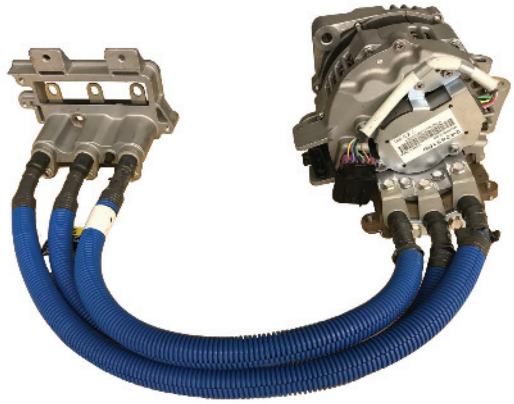

FIGURE 86–1A When the belt starter alternator assembly is installed, the three blue cables run between the inverter assembly and the alternator.

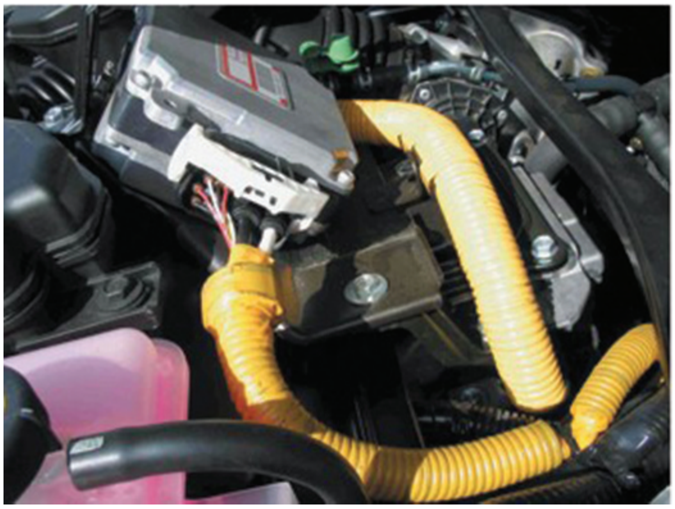

FIGURE 86–1B The yellow cable is part of the electric power steering system on a Toyota/Lexus vehicle.

IDENTIFYING HIGH-VOLTAGE CIRCUITS HV components are identified with warning labels. HV cables are identified by color of the plastic conduit and are indicated by the following colors:

- **Blue or yellow**—Up to 60 volts (not a shock hazard, but an arc will be maintained if a circuit is opened). ● **SEE FIGURE 86–1A AND 86–1B**.
- **Orange**—Above 60 volts. ● **SEE FIGURE 86–2**.

Follow all precautions when working on or near HV wiring or components.

ELECTRIC SHOCK POTENTIAL

LOCATIONS WHERE SHOCK CAN OCCUR Accidental and unprotected contact with any electrically charged ("hot" or "live") HV component can cause serious injury or death. However, receiving an electric shock from a hybrid vehicle is highly unlikely because of the following:

1. Contact with the battery module or other components inside the battery box can occur only if the box is damaged and the

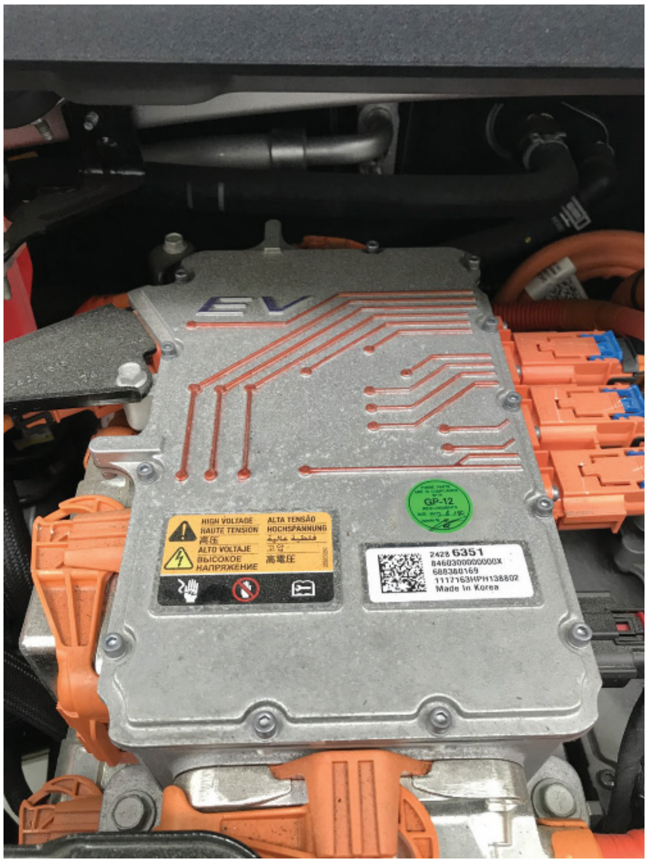

FIGURE 86–2 The orange cables connect to the high power distribution module (HPDM) on the Chevrolet Bolt.

FREQUENTLY ASKED QUESTION

How Much Current Is Too Much?

Low voltage, such as the 12–14 volts used in conventional vehicles, does not represent a shock hazard and it is safe to handle. The only concern would be a possible burn could occur if a 12-volt wire were to touch ground causing the wiring to overheat. Voltages between 14 and 60 volts do not present a shock hazard, but an arc can occur if a connector carrying current is opened. High voltage, over 60 volts, does create a shock hazard and all precautions must be adhered to prevent personal injury. Typical current and how it affects the body are given as follows:

- 1 milliamp—May be noticeable as a slight tingle.
- 2–5 milliamps—May be noticeable as a light shock forcing the technician to let go.
- 6–25 milliamps—Noticed by pain and the technician cannot let go of the wires or component.
- 26–150 milliamps—Severe pain and possibly fatal.
- 1,000 milliamps—One ampere across the heart can stop the heart (fatal).

Also, always wear HV gloves for protection whenever working on or near a potential HV circuit or component. To help prevent an electric current from flowing through the body, always place one hand in a pocket and use only one hand when measuring a potential HV circuit or disconnecting a potential HV circuit.

contents are exposed, or the box is opened without following proper precautions.

2. Contact with the electric motor can occur only after one or more components are removed.
3. The HV cables can be easily identified by their distinctive orange color, and contact with them can be avoided.
4. The **system main relays (SMRs)** or contactors disconnect power from the cables the moment the ignition is turned off.

ELECTRIC VEHICLES IN THE SERVICE AREA

For a safe working environment:

- Be sure the work area is clean and dry.
- Care should be taken that HV warnings and safety cones are posted.
- Additional precautions, such as a roof cone or warning tape, are also recommended.

They are used to establish a safety zone around the vehicles so that other technicians will know that a possible shock hazard may be present. ● **SEE FIGURE 86–3.**

TECH TIP

Silence Is NOT Golden

Never assume the vehicle is shut off just because the engine is off. When working with a hybrid electric vehicle, always look for the READY indicator status on the dash display. The vehicle is shut off when the READY indicator is off.

The vehicle may be powered by

1. The electric motor only.
2. The gasoline engine only.
3. A combination of both the electric motor and the gasoline engine.

The vehicle computer determines the mode in which the vehicle operates to improve fuel economy and reduce emissions. The driver cannot manually select the mode. ● **SEE FIGURE 86–4.**

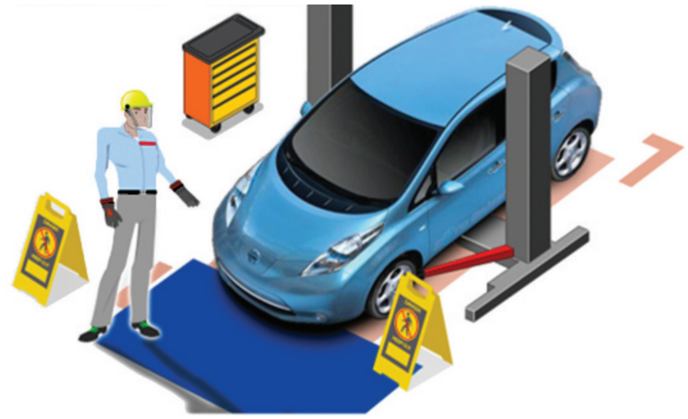

FIGURE 86–3 A clearly defined safety zone needs to be established in the area where a hybrid or electric vehicle is being repaired.

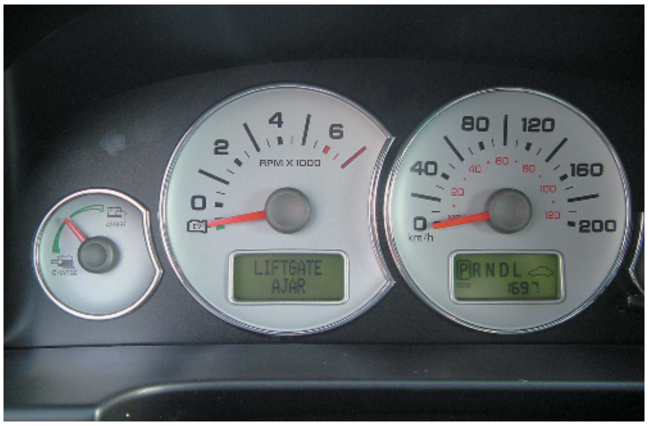

FIGURE 86–4 The Ford Escape Hybrid instrument panel showing the vehicle in park and the tachometer on "EV" instead of 0 RPM. This means the gasoline engine could start at any time depending on the state of charge of the HV battery and other factors.

PERSONAL PROTECTIVE EQUIPMENT (PPE)

EYE PROTECTION Eye protection should be worn when testing for high voltage, which is considered by many experts to be over 60 volts. Eye protection should include the following features:

1. Plastic frames (Avoid metal frames as these are conductive and could cause a shock hazard.)
2. Side shields
3. Meet the standard ANSI Z87.1

NOTE: Some vehicle manufacturers specify that full-face shields be worn instead of safety glasses when working with HV circuits or components. ● **SEE FIGURE 86–5.**

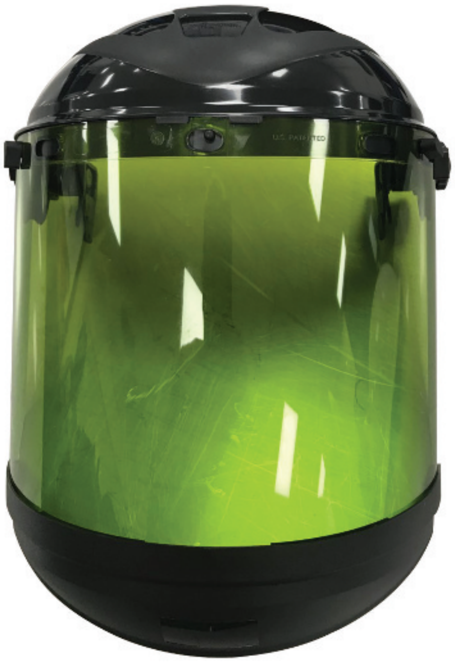

FIGURE 86–5 Safety glasses or a full-face shield similar to the items depicted must be worn when testing for the presence of high voltage.

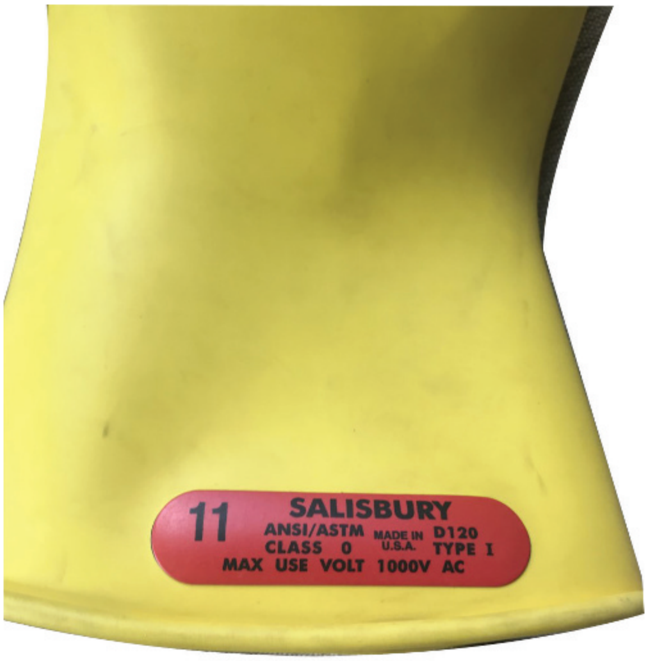

FIGURE 86–6 The gloves should be clearly marked indicating that they are class “0” and rated for 1,000 volts.

HIGH-VOLTAGE GLOVES Before working on the HV system of a hybrid electric vehicle, ensure that HV lineman’s gloves are available. Be sure that the gloves are rated at least 1,000 volts and class “0” by ANSI/ASTM. ● **SEE FIGURE 86–6**. The **American National Standards Institute (ANSI)** is a private, nonprofit organization that administers and coordinates the U.S. voluntary standardization and conformity assessment system. ANSI International, originally known as the **American Society for Testing and Materials (ASTM)**, was formed over a century ago to address the need for component testing in industry. The **Occupational Safety and Health Administration (OSHA)** requirements specify that the HV gloves get inspected every six months by a qualified glove inspection laboratory. Do not use gloves on which the expiration date has expired. Inspect the gloves carefully before each use. High voltage and current (amperes) in combination are fatal.

Before using the rubber gloves, they should be tested for leaks using the following procedure:

1. Roll the glove up from the open end until the lower portion of the glove begins to balloon from the resulting air pressure. Make sure to “lean” into the sealed glove to raise the internal air pressure. If the glove leaks any air, discard the gloves. ● **SEE FIGURE 86–7**.
2. An approved electric glove inflator can also be used to test the gloves before use. ● **SEE FIGURE 86–8**.
3. The gloves should not be used if they show any signs of wear and tear.

WARNING

Do not use shop air to test HV gloves. The high air pressure will damage the gloves and lead to a lack of personal protection against high voltage.

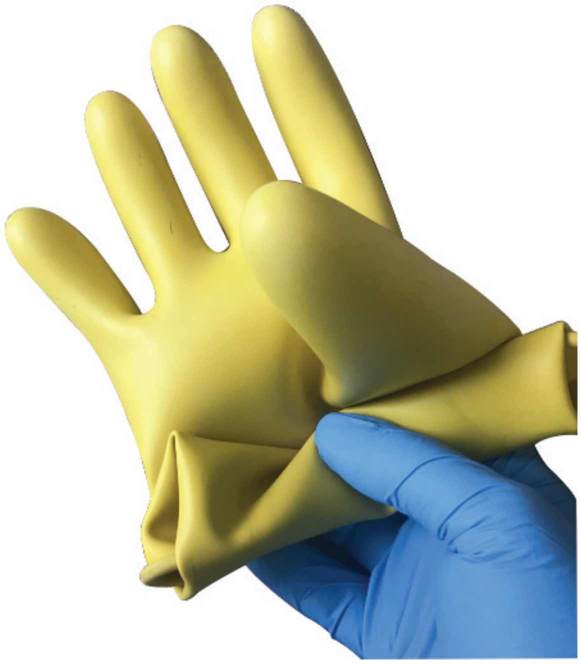

FIGURE 86–7 The glove is rolled up on the open end to check for air pressure and any air leakage.

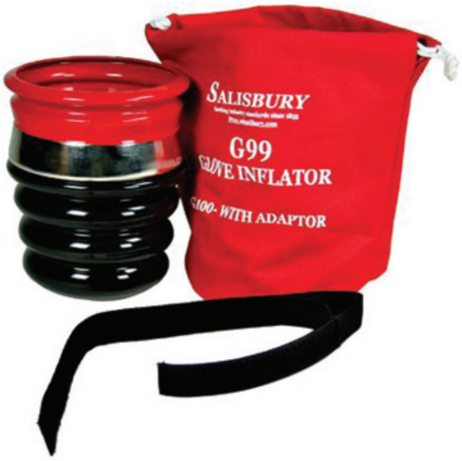

FIGURE 86–8 An electric glove inflator similar to this may be used for testing.

LEATHER PROTECTORS Use an outer leather glove to protect the HV rubber gloves. Be sure the rubber lineman’s glove extends at least 50 mm beyond the leather protector. The leather gloves should be clean and free of any material that might puncture the lineman’s glove or conduct electricity. ● **SEE FIGURE 86–9**.

SHOP UNIFORM Some manufacturers recommend arc flash clothing or long sleeve, 100% cotton clothing that is tucked into the gloves when working on HV components. Remove all jewelry, rings, watches, and bracelets before working on the vehicle.

INSULATED SHOES OR BOOTS Some manufacturers recommend the use of insulated boots or shoes to protect against exposure to high voltage. These are particularly useful in areas where water, oil, and other substances cannot be wiped off the floor. ● **SEE FIGURE 86–10**.

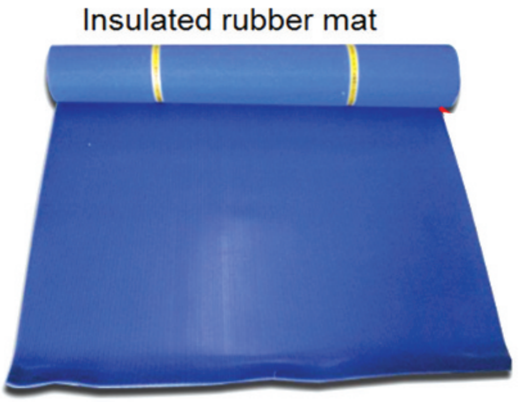
Insulated shoes
SAFETY SHOES

FIGURE 86–10 The sole of this shoe is designed to prevent the transfer of electrical current.

INSULATED RUBBER MATS AND BLANKETS Insulated rubber mats are placed on the floor when there is an exposure to high voltage. Insulated blankets are placed over the battery or other HV components after removal and during disassembly. ● **SEE FIGURE 86–11**.

FIRE EXTINGUISHERS Use ONLY a Class C fire extinguisher rated for electrical fires. An ABC-rated fire extinguisher may be used if a Class C is not available. ● **SEE FIGURE 86–12**.

OTHER PERSONAL PROTECTION EQUIPMENT Some manufacturers recommend that a 10-foot insulated fiberglass pole be available outside the safety zone to be used to pull a technician away from the vehicle in the unlikely event of an accident where the technician is shocked or electrocuted. Other manufacturers require a second set of safety equipment be available.



Insulated rubber mat

FIGURE 86–11 Some work locations require the use of insulated rubber mats in the work area.

FREQUENTLY ASKED QUESTION

Is the Radiation from a Hybrid Dangerous?

No. While there is a changing magnetic field surrounding any wire carrying an electrical current, the amount of electromagnetic radiation is very low. ● **SEE FIGURE 86–13**.

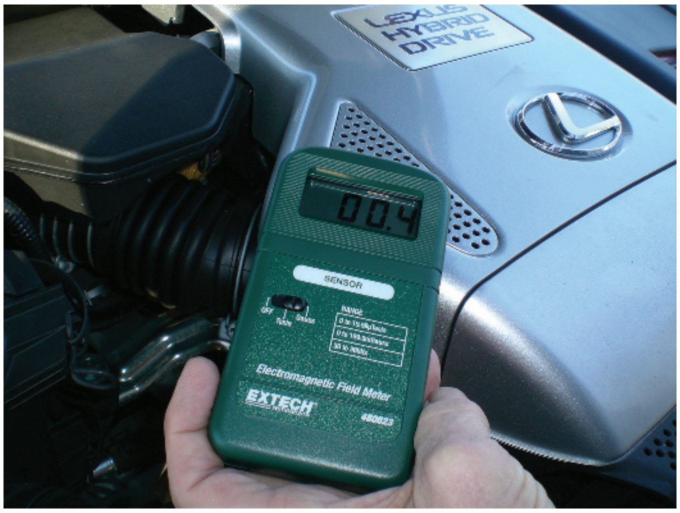

FIGURE 86–13 The radiation emitted from a hybrid electric vehicle is very low and is being measured in units of milligauss.

HIGH-VOLTAGE TOOLS AND EQUIPMENT

CAT-III RATED DIGITAL MULTIMETER Hybrid and electric vehicles are equipped with electrical systems whose voltages can exceed 600 volts DC. A **category three (CAT III)**-certified **digital multimeter (DMM)** is required for making measurements on these high-voltage systems.

The **International Electrotechnical Commission (IEC)** has several categories of voltage standards for meter and meter leads. These categories are ratings for over voltage protection and are rated CAT I, CAT II, CAT III, and CAT IV. The higher the category (CAT) rating of the meter, the greater the level of protection to the technician when measuring high-energy voltage. Under each category, there are various voltage ratings.

- **CAT I**—Typically a CAT I meter is used for low-voltage (LV) measurements, such as voltage measurements at wall outlets in the home. Meters with a CAT I rating are usually rated at 300–800 volts. CAT I is for relatively low-energy levels. While the voltage level is high enough for use when working on a hybrid electric vehicle, the protective energy level is lower than what is needed.
- **CAT II**—A CAT II meter is a higher-rated meter that would be typically used for checking voltages at the circuit-breaker panel in the home. Meters with a CAT II rating are usually rated at 300–600 volts. CAT II-rated meters have similar voltage ratings as the other CAT ratings, but the energy level of protection is higher with a CAT II compared to a CAT I.
- **CAT III**—CAT III is the minimum-rated meter that should be used for hybrid and electric vehicles. Meters with a CAT III rating are usually rated at 600–1,000 volts and the highest energy level that is needed to protect the service technician. ● **SEE FIGURES 86–14 AND 86–15.**
- **CAT IV**—CAT IV meters are for clamp-on meters only. A clamp-on meter is used to measure current (amperes) in a circuit by placing the clamp around the wire carrying the current. If a clamp-on meter also has meter leads for voltage measurements, that part of the meter will be rated as CAT III.

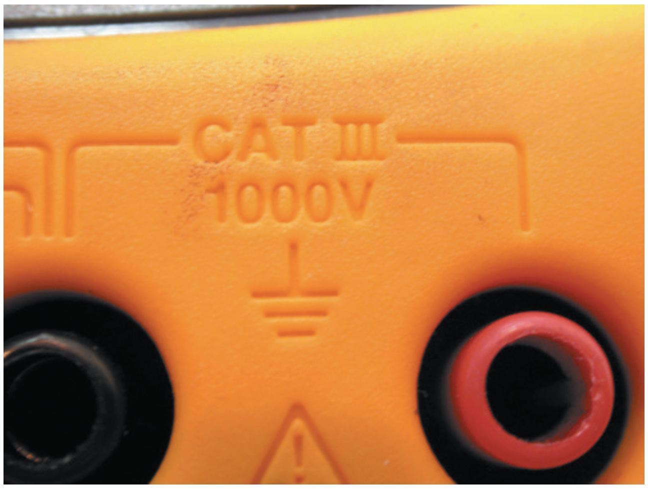

FIGURE 86–14 Use only a meter that is CAT III rated when making electrical measurements on an electric or hybrid electric vehicle.

FIGURE 86–15 The meter leads should also be CAT III rated when checking voltages on an electric or hybrid electric vehicle.

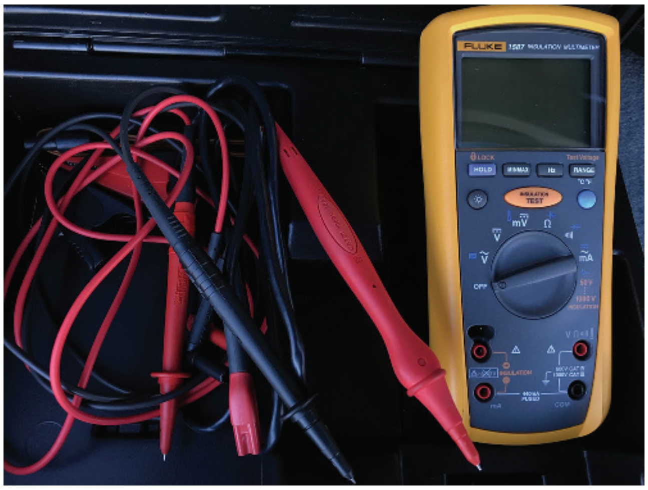

FIGURE 86–16 The Fluke 1587 is an example of an insulation tester that is able to test the HV circuit insulation to 1,000 volts. The resistance between the HV circuit and ground should be higher than one million ohms (1.0–22.2 MΩ).

MEGOHMMETER (INSULATION TESTER) A megohmmeteror insulation tester is used to check for continuity between the HV cables and the vehicle chassis. It contains an internal DC–DC converter that allows for the continuity test to occur at a much higher voltage than a conventional ohmmeter. ● **SEE FIGURE 86–16.**

INSULATED HAND TOOLS Although they are not required by all manufacturers, insulated tools such as a ratchets, extensions, sockets, pliers, and screwdrivers provide an additional margin of safety to the service technician when working around HV components and systems. ● **SEE FIGURE 86–17.**

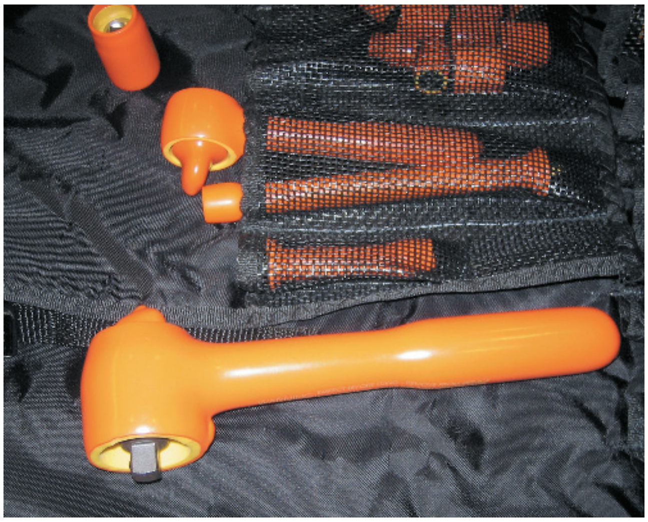

FIGURE 86–17 Insulated tools, such as this socket set, provide an additional margin of safety to the service technician when working around HV components and systems.

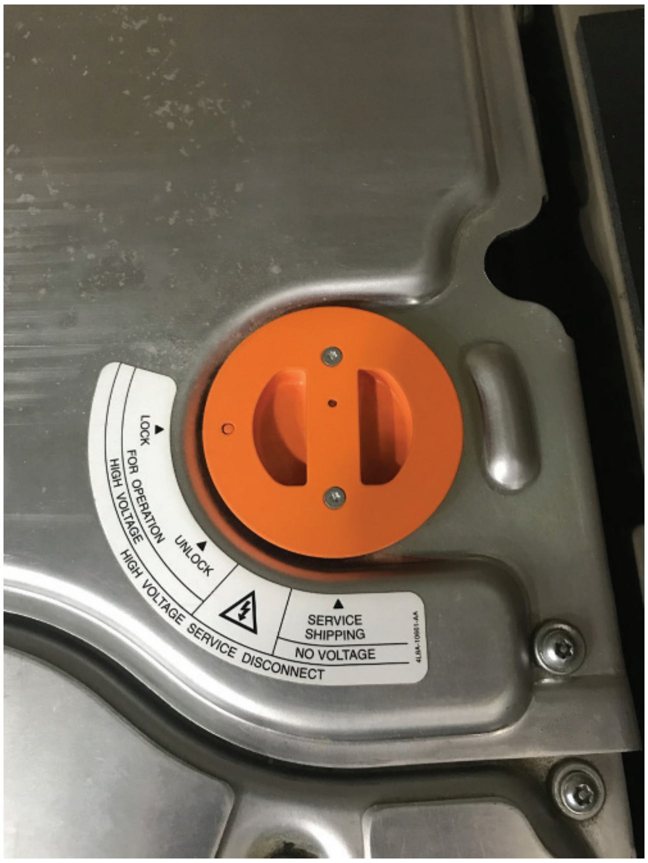

FIGURE 86–18 The manual disconnect on this Ford battery contains a fuse and safety interlock.

SAFETY INTERLOCK SYSTEM

PURPOSE AND FUNCTION The HV system uses contactors or heavy-duty relays to detect opens in the HV circuits.

This is a safety system that keeps the power circuits from closing with an open HV circuit. The manual safety disconnect switch protects the HV battery pack, and it includes a safety interlock switch that uses two small terminals. With an open detected, the HV controller does the following to keep the vehicle safe. ● **SEE FIGURE 86–18.**

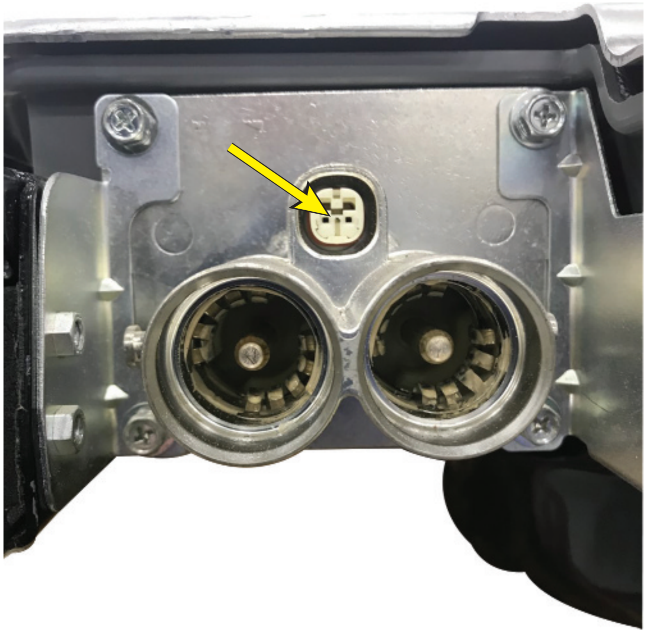

FIGURE 86–19 The small white connector is the local interlock on the HV connection to the battery.

- On a hybrid vehicle, if the engine is running, it will detect a fault and set a diagnostic trouble code (DTC). It also opens the power relays, turning off the “ready” light.
- If the hybrid vehicle is moving, it will allow it to continue until a stop, and will disable the internal combustion engine (ICE).
- If the hybrid vehicle is not moving, it will disable the ICE immediately.
- On an electric vehicle, the HV system will be depowered.

LOCAL INTERLOCK A local interlock is an LV circuit that uses separate switches and contacts to detect when there has been an open in LV circuits or components that are associated with the HV system. The local interlock can detect the removal of items such as covers, battery disconnects, air-conditioning compressors, or any other component that is associated with an HV circuit. ● **SEE FIGURE 86–19**. If an open has been detected, the controller (ECM) signals the hybrid controller to open the contactors or power relays and discharge the HV capacitors.

DEPOWERING THE HIGH-VOLTAGE SYSTEM

THE NEED TO DEPOWER THE HIGH-VOLTAGE SYSTEM During routine vehicle service work, there is no need to go through any procedures needed to depower or shut off the HV circuits. However, if work is going to be performed on any of the following components, service information procedures must be followed to prevent possible electrical shock and personal injury:

- The HV battery pack
- Any of the electronic controllers that use orange cables, such as the inverter and converters
- The air-conditioning compressor, if electrically driven, and has orange cables attached

ABUS
SAFETY REDBOX™
FOR LOCKOUT

FIGURE 86–20 A lock box is a safe location to keep the ignition keys of a hybrid or electric vehicle while it is being worked on.

To safely depower the vehicle, always follow the instructions found in service information for the exact vehicle being serviced. The steps usually include the following:

STEP 1 Turn the ignition off and remove the key (if equipped) from the ignition and store it in a lock box to prevent accidental starting. ● **SEE FIGURE 86–20**.

CAUTION: If a push-button start is used, remove the key fob at least 15 feet (5 meters) from the vehicle to prevent the vehicle from being powered on. With the key fob out of the vehicle, attempt to start the vehicle to confirm no other key fobs are present in the vehicle.

STEP 2 Remove the 12-volt power source to the HV controller and wait 10 minutes for all capacitors to discharge. This step could involve

- Removing a fuse or a relay
- Disconnecting the negative battery cable from the auxiliary 12-volt battery

STEP 3 Remove the HV fuse or service plug or switch.

STEP 4 Confirm there is no HV power present before beginning the repair.

HOISTING A HYBRID OR ELECTRIC VEHICLE

When hoisting or using a floor jack, refer to the manufacturer's service information for proper lift points. ● **SEE FIGURE 86–21**. Orange cables run under the vehicle just inside the frame rails on most hybrid and electric vehicles. The battery for many electric vehicles is underneath the vehicle and can be easily damaged by a hoist. In addition to the electrical circuits, many electric vehicles use coolant or refrigerant to maintain the temperature of the battery. Caution should be used to avoid damaging these lines. Some Honda hybrid vehicles use an aluminum pipe painted orange that includes three HV cables for the starter/generator and also three more cables for the HV air-conditioning compressor. If any damage occurs to any HV cables, the malfunction indicator Lamp (MIL) will light up and a no-start will result if the powertrain control module (PCM) senses a fault. The cables are not repairable and are expensive. The cables can be identified by an orange outer casing, but in some cases, the orange casing is not exposed until a black plastic underbelly shield is removed first.

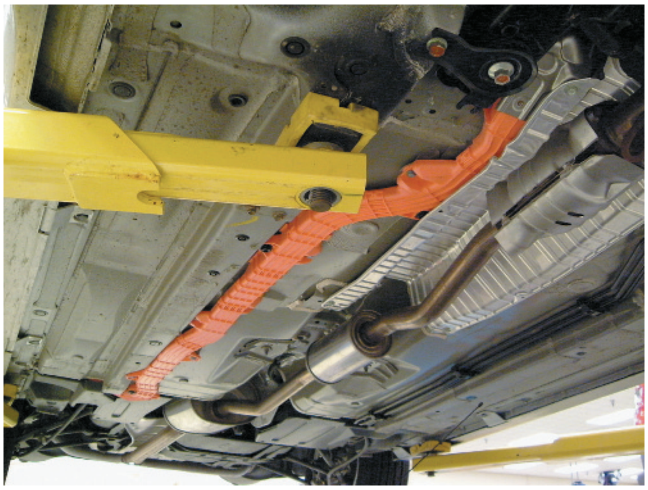

FIGURE 86–21 The HV wiring on this Honda hybrid is colored orange for easy identification.

MOVING A HYBRID OR ELECTRIC VEHICLE AROUND THE SHOP

After a hybrid or electric vehicle has been serviced, it may be necessary to push the vehicle to another part of the shop or outside as parts are ordered. Make sure to tape any orange HV cable ends that were disconnected during the repair procedure. Permanent magnets are used in all the drive motors and generators and it is possible that an HV arc could occur as the wheels turn and produce voltage. Another way to prevent this is to use wheel dollies. A sign that says "HIGH VOLTAGE–DO NOT TOUCH" could also be added to the roof of the vehicle or across the steering wheel. Remove the keys from the vehicle and keep in a safe location.

FREQUENTLY ASKED QUESTION

What Is That Sound?

Electric vehicles and most hybrid electric vehicles emit a sound through a speaker in the front at low speeds to warn pedestrians that a moving vehicle is nearby. This system is called **acoustic vehicle alerting system (AVAS)**. It creates the sound whenever the vehicle is traveling at low speed. The U.S. National Highway Traffic Safety Administration (NHTSA) requires the device to emit warning sounds when travelling at speeds less than 19 MPH (30 km/h) with compliance by September 2020. While easily heard from outside the vehicle, it is usually not heard inside the vehicle unless the windows are down. Some customers ask their service technician to disable this system, but it is a safety device and could help prevent personal injury if someone were to step in front or back of a moving vehicle that is almost silent.

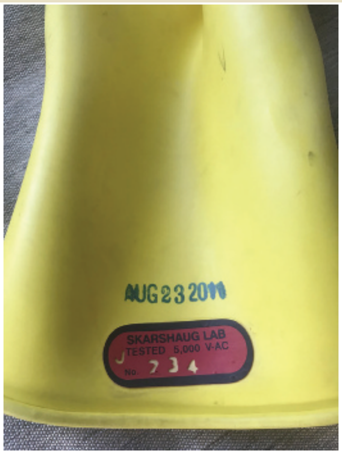
10" GAL.
CLASS 0
LEATHER PROTECTOR
WEAR OVER SIZE
11

The cuff of the rubber glove should extend at least 1/2 inch beyond the cuff of the leather protector.

2

To determine the correct glove size, use a soft tape measure around the palm of the hand. A measurement of 9 inches would correspond with a glove size of 9.

3



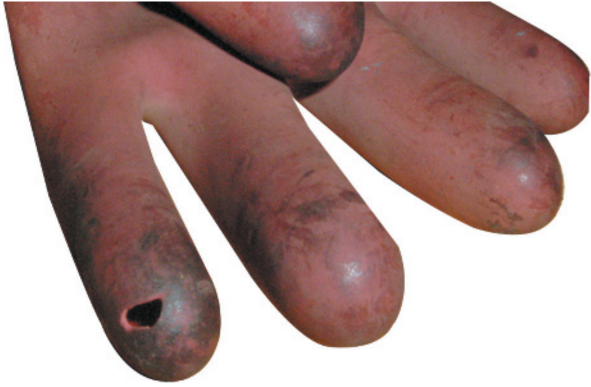
SKARSHAUG LAB
TESTED 5,000 V-AC
No. 2 3 4

The glove rating and the date of the last test should be stamped on the glove cuff.

4

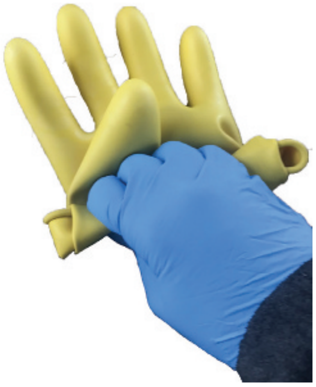
Start a visual inspection of the glove fingertips, making sure that no cuts or other damages are present.

5



The damage on this glove was easily detected with a simple visual inspection. Note that the rubber glove material can be damaged by petroleum products, detergents, certain hand soaps, and talcum powder.

6



Manually inflate the glove to inspect for pinhole leaks. Starting at the cuff, roll up the glove and trap air in the finger end. Listen and carefully watch for deflation of the glove. If a leak is detected, the glove must be discarded.

STEP BY STEP

7

Petroleum on the leather protector’s surface will damage the rubber glove underneath.

8

TEN-FOUR®
GLOVE
DUST
SALISBURY

Glove powder (glove dust) should be used to absorb moisture and reduce friction.

9

Put on the gloves and tighten the straps on the back of the leather protectors (if equipped).

10

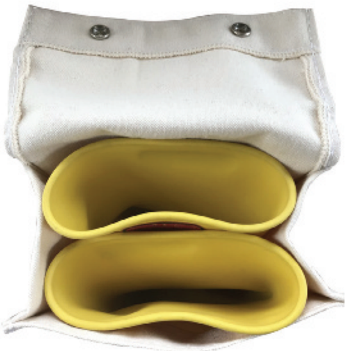
Technicians MUST wear HV gloves whenever working around the HV areas of a hybrid or electric vehicle.

11

ALWAYS
WEAR
YOUR

HV gloves should be placed in a canvas storage bag when not in use. Note the ventilation hole at the bottom of this bag.

12



Make sure the rubber gloves are not folded when placed in the canvas bag. Folding increases mechanical stress on the rubber and can lead to premature failure of the glove material.

REVIEW QUESTIONS

1. What actions are needed to disable the high-voltage (HV) circuit?
2. What are the personal safety precautions that service technicians should adhere to when servicing hybrid or electric vehicles?
3. What are the recommended tools and equipment that should be used when working on the HV circuits of a hybrid or electric vehicle?
4. What precautions should be taken when hoisting a hybrid or electric vehicle?
5. When should the HV system be depowered?

CHAPTER QUIZ

1. Rubber gloves should be worn whenever working on or near the HV circuits or components of a hybrid electric vehicle. Technician A says that the rubber gloves should be rated at 1,000 volts or higher. Technician B says that leather gloves should be worn over the HV rubber gloves. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
2. A CAT III-certified DMM should be used whenever measuring HV circuits or components. The CAT III rating relates to __________.
   - **a.** high voltage
   - **b.** high energy
   - **c.** high electrical resistance
   - **d.** both high energy and high voltage
3. All of the following will shut off the high voltage to components and circuits *except* __________.
   - **a.** opening the driver's door
   - **b.** turning off the ignition
   - **c.** disconnecting the auxiliary 12-volt battery
   - **d.** removing the main fuse, relay, or HV plug
4. What can occur if a hybrid electric vehicle is pushed in the shop?
   - **a.** The HV battery pack can be damaged.
   - **b.** The tires will be locked unless the ignition is on.
   - **c.** Damage to the electric control will occur.
   - **d.** High voltage will be generated by the motor/generator as the wheels turn.
5. When hoisting a hybrid or electric vehicle, what precautions must the technician follow to ensure personal safety and avoid damage to the vehicle?
   - **a.** Make sure the lift points do not contact HV cables.
   - **b.** Do not lift the vehicle by the battery case.
   - **c.** Ensure the lift points are clear of battery cooling and refrigeration lines.
   - **d.** All of the above are correct.
6. When does the HV system *not* need to be depowered?
   - **a.** When removing the HV battery pack
   - **b.** When performing routine service
   - **c.** When replacing the HV cables
   - **d.** When replacing the HV air-conditioning compressor
7. What will occur if the safety interlock system detects an open circuit on a hybrid vehicle?
   - **a.** If the engine is running, it will detect a fault and set a DTC. It also opens the power relays, turning off the "ready" light.
   - **b.** If the vehicle is moving, it will allow it to continue until a stop, and will disable the ICE.
   - **c.** If the vehicle is not moving, it will disable the ICE immediately.
   - **d.** All of the above are correct.
8. What precautions need to be taken to ensure the hybrid or electric vehicle work area is safe?
   - **a.** The area should be clean and dry.
   - **b.** The work area should be clearly marked.
   - **c.** No special precautions are needed.
   - **d.** The area should be clean and dry and clearly marked.
9. What is the purpose of a megohmmeter or insulation tester?
   - **a.** To check for continuity between the HV cables and the vehicle chassis
   - **b.** To measure the resistance of connections in the LV system
   - **c.** To measure the current flow through the HV cables
   - **d.** None of the above is correct.
10. What should be done if the HV rubber gloves inspection dates are found to be expired?
    - **a.** Use them anyway if they look ok.
    - **b.** Use them if they pass the air test.
    - **c.** Send them to a qualified inspection laboratory.
    - **d.** Throw the gloves away.

Chapter

87

INTRODUCTION TO ELECTRIC AND HYBRID ELECTRIC VEHICLES

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Define terms related to hybrid electric vehicles.
- Define terms related to electric vehicles.
- Explain the history of hybrid and electric vehicles.
- Compare the efficiency of electric motors to internal combustion engines.
- Describe the unique characteristics of owning or driving a hybrid or electric vehicle.
- Discuss the levels of hybrid vehicles.
- Describe the different powertrain configurations in a hybrid vehicle.
- Explain the differences between one-, two-, and three-motor systems.
- Compare the advantages and disadvantages of electric vehicles.

KEY TERMS:

Battery electric vehicles (BEV) 1008 • Electric vehicle (EV) 1007 • Hybrid electric vehicle (HEV) 1007 • Internal combustion engine (ICE) 1007 • Medium hybrid 1012 • Micro hybrid 1011 • Mild hybrid 1011 • One-pedal driving 1010 • Phone as a Key (PAAK) 1007 • Plug-in hybrid electric vehicle (PHEV) 1007 • Range anxiety 1010 • Strong hybrid 1012

HYBRID ELECTRIC VEHICLES

DEFINITION OF TERMS A hybrid vehicle is one that uses two different methods to propel the vehicle. A **hybrid electric vehicle (HEV)** uses both an internal combustion engine and an electric motor to propel the vehicle. Most hybrid vehicles use a high-voltage battery pack and a combination electric motor and generator to help or assist a gasoline engine. The **internal combustion engine (ICE)** used in a hybrid vehicle can be either gasoline or diesel, although only gasoline-powered engines are currently used in hybrid vehicles. An electric motor is used to help propel the vehicle, and in some designs, it is capable of propelling the vehicle alone without having to start the ICE.

FREQUENTLY ASKED QUESTION

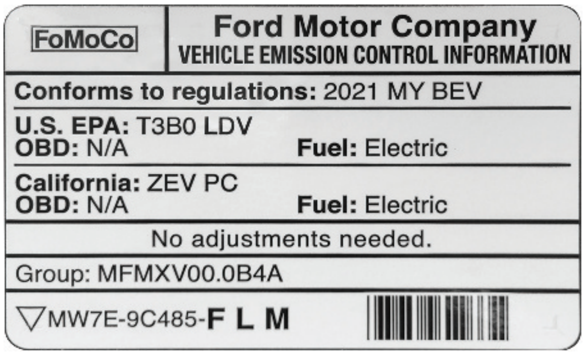
What Is Meant by "Phone as a Key (PAAK)"?

Many hybrid electric and electric vehicles, as well as some regular (ICE) vehicles, can be controlled using a smart phone application (app). This control of the vehicle, including remote start from the smart phone, is referred to as **Phone as a Key (PAAK)**. There are apps for using a smart watch as a key, which makes it very convenient to start and unlock a vehicle using just the smart watch.

A **plug-in hybrid electric vehicle (PHEV)** is an HEV with a larger capacity battery that can be recharged by the ICE or by plugging it into an AC power source or charging station. A PHEV can drive in electric-only mode for up to 40 miles on some vehicles.

ELECTRIC VEHICLES

DEFINITION OF TERMS An **electric vehicle (EV)**, also referred to as an electric drive vehicle, uses one or more electric motors to propel the vehicle. Electricity is used as the transportation fuel to power the EV. The electrical energy is typically stored in an energy storage device, such as a battery. The electrical energy is replenished by connecting to an electrical source, usually stationary. The Environmental Protection Agency (EPA) and the California Air Resources Board (CARB) define an EV as a zero-emission vehicle. ● **SEE FIGURE 87–1**.



FoMoCo
Ford Motor Company
VEHICLE EMISSION CONTROL INFORMATION
Conforms to regulations: 2021 MY BEV

FIGURE 87–1 The official emission sticker lists the vehicle as electric and producing zero emissions. The EPA rating is Tier 3, Bin 0 and a light-duty vehicle (T3B90, LDV). The California standards is listed as a zero emission vehicle and a passenger vehicle (ZEV PC).

HISTORY

EARLY ELECTRIC VEHICLES Early EVs, also called **battery electric vehicles (BEVs)**, were first used in the late 1800s, and it was not until the early 1900s that EVs were practically possible using rechargeable lead–acid batteries.

- One of the first was the 1903 Baker Electric Car, produced by the Baker Motor Vehicle Company in Cleveland, Ohio.
- The Detroit Electric Car Company (1907–1939) produced very practical fully EVs.

The old EV mechanical controller was able to switch all six batteries in various combinations of series and parallel configurations to achieve lower voltage for slow speeds and higher voltages for higher speeds. EVs did not have a long range and needed to have the batteries charged regularly, which meant that EVs could only be used for short distances. In fact, EVs were almost more popular than steam-powered vehicles in 1900—while steam-powered vehicles had 40% of the sales, EVs had 38% of the sales. The gasoline-powered cars represented only 22% of the vehicles sold.

EARLY HYBRID VEHICLES In 1901, Ferdinand Porsche developed the Lohner-Porsche Mixte Hybrid, the first gasoline-electric hybrid automobile in the world. It was originally an electric-powered vehicle and then a gasoline engine was added to recharge the battery. One of the first hybrid electric cars was produced by the Owen Magnetic Motor Car Corporation, manufactured in New York City and then in Wilkes-Barre, Pennsylvania, from 1915 until 1922. It failed because the fuel economy was about the same as a conventional gasoline-powered vehicle, yet cost more. Another vehicle that used both a gasoline engine and an electric motor to power the vehicle was built by Woods Motor Company of Chicago, Illinois, and was called the "Woods Dual Power" (1915–1918).

NOTE: Due to the oil embargo of 1973 and an increased demand for alternative energy sources, Congress enacted Public Law 94-413, the *Electric and Hybrid Vehicle Research, Development, and Demonstration Act of 1976*, which was designed to promote new technologies.

The hybrid electric vehicle did not become widely available until the release of the Toyota Prius in Japan in 1997, followed by the Honda Insight sold in the United States starting in 1999. In 2001, the first Toyota Prius was introduced in the United States.

EFFICIENCIES OF ELECTRIC MOTORS AND ICEs

Electric motors are more efficient compared to any ICE and have just one moving part compared to hundreds of moving parts in a typical gasoline-powered or diesel-powered ICE.

- An electric motor can have efficiency (including controller) of over 90%, while a gasoline engine has efficiency of only 35% or less.
- An ICE does not have the overload capability of an electric motor. That is why the rated power of an ICE is usually much higher than that required for highway cruising. Operating smoothly at idle speed produces a much lower efficiency than while operating at a higher speed.
- Maximum torque of an ICE is reached at intermediate speed and the torque declines as speed increases further.
- There is a maximum fuel efficiency point in the speed range for the ICE, and this speed is optimized by many hybrid vehicle manufacturers by using a transmission that keeps the engine speed within the most efficient range. ● **SEE FIGURE 87–2**.

Electric motors offer ideal characteristics for use in a vehicle because of the following factors:

- Constant power over all speed ranges
- Constant torque at low speeds needed for acceleration and hill-climbing capability
- Constant torque below base speed
- Constant power above base speed
- Only single gear or fixed gear is needed in the electric motor transmission

DRIVING A HYBRID OR ELECTRIC VEHICLE

DRIVING A HYBRID VEHICLE Driving a hybrid electric vehicle (HEV) is the same as driving any other conventional vehicle. In fact, many drivers and passengers are often not aware that they are driving or riding in a hybrid electric vehicle. Some unique characteristics that the driver may or may not notice include the following:

- After the ICE has achieved normal operating temperature and other conditions are met, the engine will stop when the vehicle slows down and stops. This condition may cause a concern to some drivers who may think that the engine has stalled and may try to restart it.
- The brake pedal may feel different, especially at slow speeds of about 5 MPH and 15 MPH when slowing to a stop. It is at about these speeds that the brake system switches from regenerative braking to actually applying brake force to the mechanical brakes. A slight surge or pulsation may be felt at this time. This may or may not be felt and is often not a concern to drivers.
- The power steering works even when the engine stops because all HEV and PHEV use an electric power steering system.

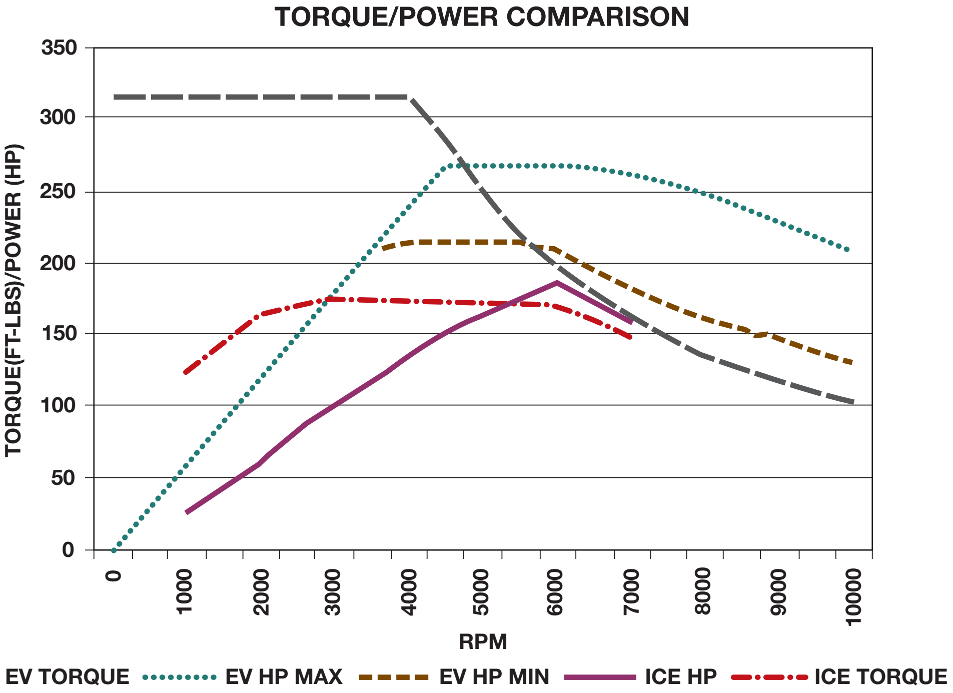

FIGURE 87–2 The graph shows a comparison of torque and power between an electric vehicle and a vehicle with an ICE.

- Some HEVs and all PHEVs are able to propel the vehicle using the electric motor alone, resulting in quiet, almost eerie operation.
- If an HEV is being driven aggressively and at a high rate of acceleration, there is often a feeling that the vehicle is not going to slow down when the accelerator pedal is first released. This is caused by two factors:
    1. The inertia of the rotor of the electric motor attached to the crankshaft of the ICE results in the engine continuing to rotate after the throttle has been closed.
    2. The slight delay that occurs when the system switches the electric motor from powering the vehicle to generating (regenerative braking). While this delay would rarely be experienced, it is not at all dangerous. For a fraction of a second, it gives a feeling that the accelerator pedal did not react to a closed throttle.

DRIVING AN ELECTRIC VEHICLE Driving an EV is a very different driving experience than a conventional vehicle. Some of the unique characteristics include the following:

- The startup and shutdown procedures are enough different than a conventional vehicle that many drivers need to be retrained on the processes.
- The lack of an ICE results in a much quieter ride. In many cases, the most predominate noise heard is the tires on the various road surfaces. Most electric vehicles come from the factory with tires that have acoustical foam inside of the tire to reduce the tire noise by up to 9 db. ● **SEE FIGURE 87–3**.

NOTE: The EV may be silent when in park or neutral. When put in drive or reverse, an artificial "running engine" sound is generated at the front of the vehicle through a speaker behind the front bodywork. Some vehicles have a second speaker mounted in the rear of the vehicle. Typically, the sound is present until the vehicle reaches approximately 20 MPH. ● **SEE FIGURE 87–4**.

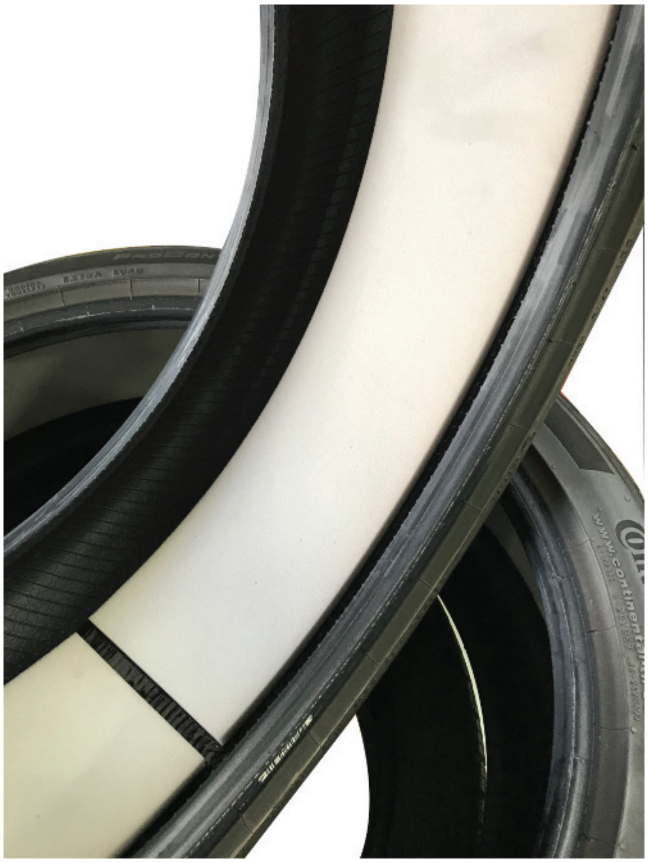

FIGURE 87–3 This Continental tire with acoustical foam on the inside is from a Tesla Model 3.

- The electric motors that propel the vehicle provide exceptional torque and responsiveness.
- The regenerative braking systems tend to slow the vehicle more aggressively than a conventional vehicle. Often the system can be set so that the brake pedal is not used during normal driving except to keep the vehicle

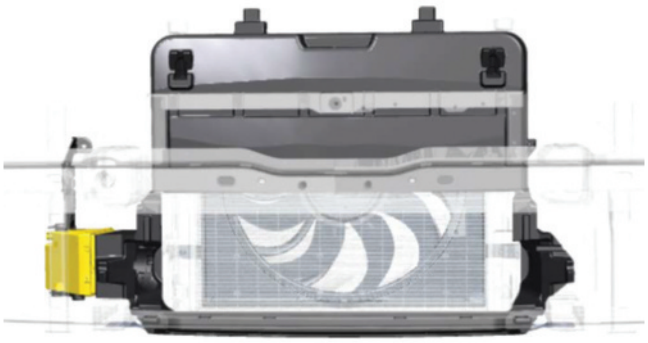

FIGURE 87–4 The sound generator on this 2021 VW ID.4 is located behind the front bumper assembly.

FREQUENTLY ASKED QUESTION

How Fast Does the Motor-Generator Turn the Engine When Starting?

The typical starter motor used on a conventional gasoline or diesel engine rotates the engine from 100 to 300 revolutions per minute (RPM). Because the typical engine idles at about 600 to 700 RPM, the starter motor is rotating the engine at a speed slower than it operates. This makes it very noticeable when starting because the sound is different when cranking compared to when the engine actually starts and runs.

However, when the motor-generator of an HEV rotates the engine to start it, the engine is rotated about 1000 RPM, which is about the same speed as when it is running. As a result, engine cranking is just barely heard or felt. The engine is either running or not running, which is a truly unique sensation to those not familiar with the operation of hybrid electric vehicles.

stationary when stopped. This feature is usually called **one-pedal driving**.

- Seasonal temperature changes, weather, and driving style will affect the battery range.
- Careful mapping of charging stations will be required when traveling a distance beyond the battery range capacity.
- **Range anxiety** is the fear that many potential owners of EV have that the vehicle will have insufficient range to reach their destination, and therefore could get stuck with a dead vehicle on the road. According to owners of EV, this fear tends to go away after about two weeks of ownership after seeing that the range and the charging can be easily controlled.

OWNING A HYBRID OR ELECTRIC VEHICLE

A hybrid or electric vehicle will cost and weigh more than a conventional vehicle. The increased initial purchase price is due to the batteries, electric motor(s), and controllers used plus the additional components needed to allow operation of the heating and air-conditioning systems during idle stop periods. The cost is offset, in part, by improved fuel economy as well as state and national government energy credits awarded at the time of purchase for some new technology vehicles.

Plug-in hybrid and electric vehicle owners will save money at the gasoline pump; however, they will experience a higher electric bill, depending on the amount of electricity these use. The increase in the cost of the electricity will vary based on the electrical providers' purchase plan. Some providers offer discounted rates when the electricity is consumed during off-peak hours.

ROUTINE MAINTENANCE

Most hybrid and electric vehicles have a different maintenance schedule than a conventional vehicle. In the case of an EV, most of these costs are eliminated. A typical EV requires just the following as part of routine maintenance:

- Windshield washer fluid
- Windshield wiper blades
- Cabin filter
- Tire rotation

● **SEE FIGURE 87–5**.

FREQUENTLY ASKED QUESTION

Can the Nissan Leaf Be Taken through a Car Wash?

Yes, the Nissan Leaf, and all hybrid and electric vehicles, can be taken through the car wash. All the high-voltage components, including the battery, that are outside of the passenger compartment are sealed from outside water entry. If there has been no damage to protective coverings, the components will not be damaged and there is no chance of electrical shock.

FIGURE 87–5 Adding windshield washer fluid to an EV is the item that requires most frequent maintenance depending on driving conditions.

CASE STUDY

The Case of the Vibrating Tesla

An owner of a Tesla Model Y visited a tire shop complaining of a vibration in the steering wheel at highway speeds. A local tire shop balanced both front tires. The right front only needed a quarter ounce whereas the left front required over four ounces to balance. After leaving the shop, the owner immediately noticed that the vibration was much worse. The owner returned to the shop and this time the tire was removed from the rim. It became apparent that the vibration issue was caused by the foam inside the tire. This foam that generally played the role of reducing noise had separated and was loose inside the tire. The shop removed the foam and did not try to reinstall it. The wheel was balanced, which solved the vibration concern. The driver did not notice any increase in noise. ● **SEE FIGURE 87–6**.

Summary:

Complaint—A Tesla owner complained of a vibration in the steering wheel at highway speeds.
Cause—The acoustical foam inside a tire that is supposed to reduce noise had separated from the inner liner of the left front tire.
Correction—The foam was removed from the tire and the tire/wheel assembly was balanced, which corrected the vibration concern.

FREQUENTLY ASKED QUESTION

Why Are EVs and PHEVs Taxed in Some States?

Recently some states have added fees to the cost of the license plate on hybrid and electric vehicles to recover loss fuel taxes. Typically, these fees have been in the $100 to $200 range. Depending on the number of miles driven per year, these fees may have a negative impact on the cost of ownership.

In the case of a hybrid vehicle, certain costs may actually increase because of materials used because a hybrid vehicle typically uses full-synthetic motor oil, which is more expensive than conventional motor oil. Additionally, the owner of a plug-in vehicle will need to make an investment in a recharging network for the home.

All of these factors must be considered when making an informed decision to purchase a hybrid or electric vehicle. It may take many years of operation before the extra cost is offset by cost savings from the improved fuel economy. However, many owners purchase a hybrid or electric vehicle for other reasons besides fuel savings, including a feeling that they are helping the environment and the love of the high technology involved.

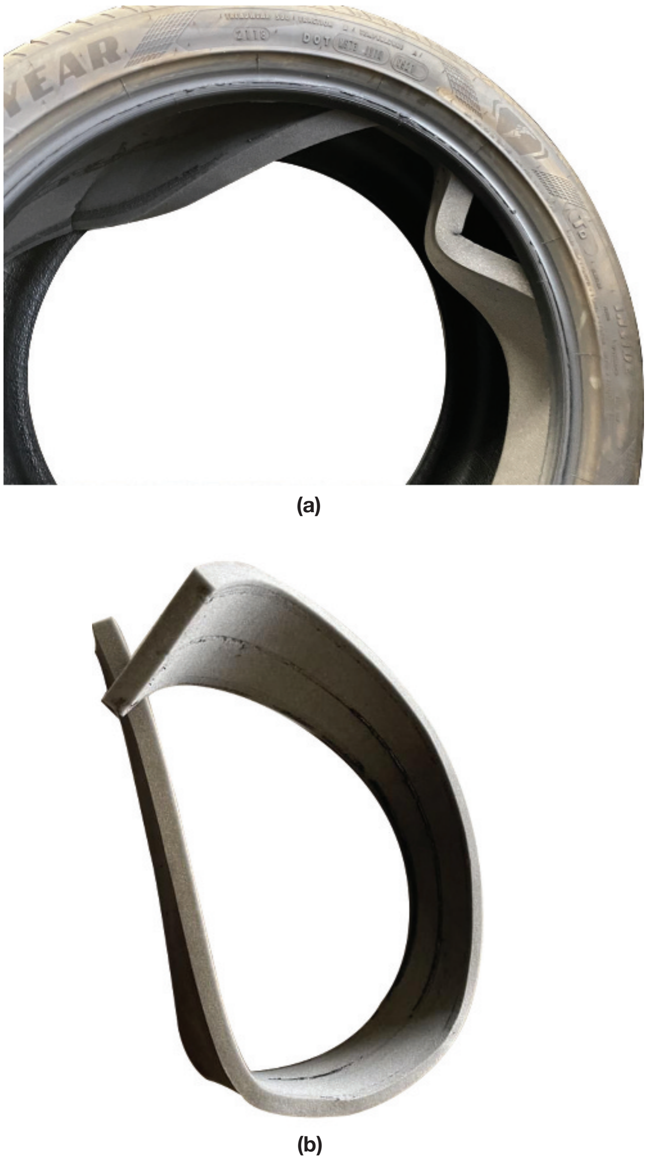

FIGURE 87–6 (a) The dismounted tire shows where the foam had become detached. (b) The foam removed in its entirety.

LEVELS OF HYBRID VEHICLES

MICRO HYBRID A **micro hybrid** will incorporate idle stop, but is not capable of propelling the vehicle without starting the ICE. A micro-hybrid system has the advantage of costing less, but saves less fuel compared to a full hybrid vehicle. The micro hybrid usually uses a second 12-volt battery and a heavy-duty starter motor and flywheel to restart the ICE when accelerating from a stop.

MILD HYBRID A **mild hybrid** will incorporate idle stop and regenerative braking, but is not capable of using the electric motor to propel the vehicle on its own without help from the ICE. A mild-hybrid system has the advantage of costing less, but saves less fuel compared to a full hybrid vehicle and usually uses a 42-volt electrical motor and battery package (36-volt batteries, 42-volt charging). An example of this type of hybrid is the 2004–2007 General Motors Silverado pickup truck and the 2007 Saturn VUE. The fuel savings for a mild type of hybrid design are about 8% to 15%.

FREQUENTLY ASKED QUESTION

Is a Diesel-Hybrid Electric Vehicle Possible?

Yes, using a diesel engine instead of a gasoline engine in an HEV is possible. While the increased efficiency of a diesel engine would increase fuel economy, the extra cost of the diesel engine is the major reason this combination is not currently in production.

FREQUENTLY ASKED QUESTION

What Is an Assist Hybrid?

An assist hybrid-electric vehicle is a term used to describe a vehicle where the electric motor is not able to start moving the vehicle on electric power alone. This type of hybrid would include micro hybrids (12 volt), all mild hybrids (36 to 42 volts), as well as the medium hybrids that use 144- to 158-volt systems.

MEDIUM HYBRID A **medium hybrid** uses 144- to 158-volt batteries that provide for engine stop/start, regenerative braking, and power assist. Like a mild hybrid, a typical medium hybrid is not capable of propelling the vehicle from a stop using battery power alone. Examples of a medium-hybrid vehicle include the Honda Insight, Civic, and Accord. The fuel economy savings are about 20% to 25% for medium-hybrid systems.

FULL HYBRID A **strong hybrid**, also called a *full hybrid*, uses idle stop, regenerative braking, and is able to propel the vehicle using the electric motor(s) alone. Each vehicle manufacturer has made its decision on which hybrid type to implement based on its assessment of the market niche for a particular model. Examples of a full or strong hybrid include the General Motors Silverado/Sierra (two-mode hybrid), Ford Escape SUV, Toyota Highlander, Lexus RX400h, Lexus GS450h, Toyota Prius, and Toyota Camry. The fuel economy savings are about 30% to 50% for full-hybrid systems.

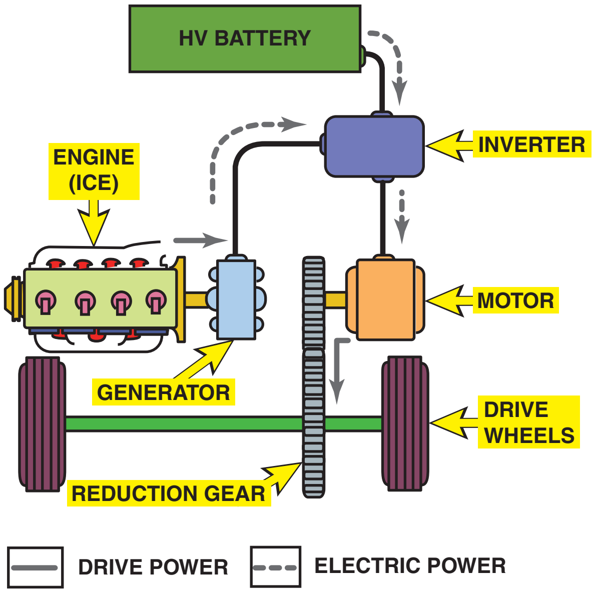

FIGURE 87–7 A drawing of the power flow in a typical series-hybrid vehicle.

CLASSIFICATIONS OF HYBRID VEHICLE POWERTRAIN

SERIES HYBRID POWERTRAIN In a series-hybrid design, sole propulsion is by a battery-powered electric motor, but the electric energy for the batteries comes from another onboard energy source, such as an ICE. In this design, the engine turns a generator and the generator can either charge the batteries or power an electric motor that drives the transmission. The ICE never powers the vehicle directly. ● **SEE FIGURES 87–7 AND 87–8.**

The engine is operated only to keep the batteries charged. Therefore, the vehicle could be moving with or without the ICE running. Series-hybrid vehicles also use regeneration braking to help keep the batteries charged. The Chevrolet Volt is an example of a series-hybrid design. The engine is designed to just keep the batteries charged, and, therefore, is designed to operate at its most efficient speed and load.

An advantage of a series-hybrid design is that no transmission, clutch, or torque converter is needed.

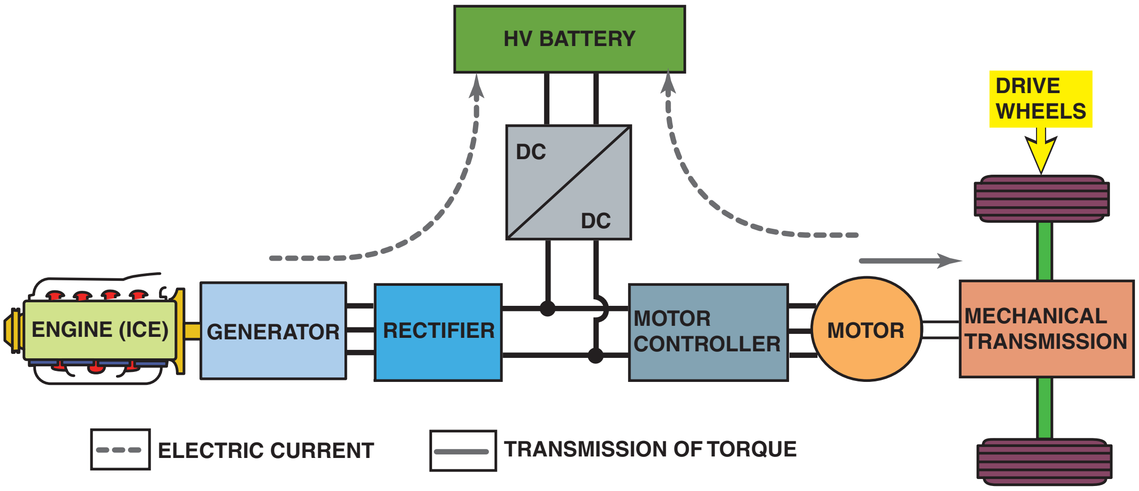

FIGURE 87–8 This diagram shows the components included in a typical series-hybrid design. The solid line arrow indicates the transmission of the torque to the drive wheels. The dotted line arrows indicate the flow of the electrical current.

A disadvantage of a series-hybrid design is the added weight of the ICE to what is basically an EV. The engine is actually a heavy on-board battery charger. Also, the electric motor and battery capacity have to be large enough to power the vehicle under all operating conditions, including climbing hills.

All power needed for heating and cooling must also come from the batteries, so using the air conditioning in hot weather and the heater in cold weather reduces the range that the vehicle can travel on battery power alone.

PARALLEL HYBRID POWERTRAIN In a parallel-hybrid design, multiple propulsion sources can be combined, or one of the energy sources alone can drive the vehicle. In this design, the battery and engine are both connected to the transmission.

The vehicle using a parallel-hybrid design can be powered by the ICE alone, by the electric motor alone (full hybrids only), or by a combination of engine and electric motor propulsion. In most cases, the electric motor is used to assist the ICE. ● **SEE FIGURES 87–9 AND 87–10**.

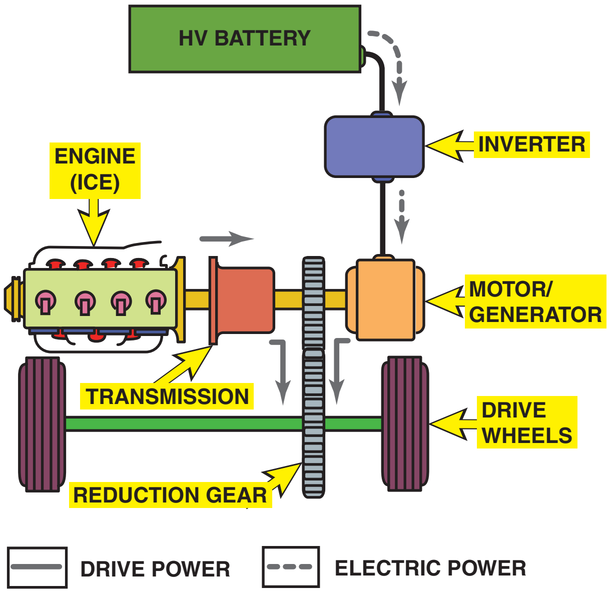

FIGURE 87–9 The power flow in a typical parallel-hybrid vehicle.

One of the advantages of using a parallel-hybrid design is that by using an electric motor or motors to assist the ICE, the engine itself can be smaller than would normally be needed.

NOTE: A parallel-hybrid design could include additional batteries to allow for plug-in capability, which could extend the distance the vehicle can travel using battery power alone.

One disadvantage of a parallel-hybrid design is that complex software is needed to seamlessly blend electric and ICE power. Another concern about the parallel-hybrid design is that it has to be engineered to provide proper heating and air-conditioning system operation when the ICE stops at idle.

SERIES-PARALLEL HYBRID POWERTRAIN The Toyota and Ford hybrids are classified as series-parallel hybrids because they can operate using electric motor power alone or with the assist of the ICE. Series-parallel hybrids combine the functions of both a series and a parallel design. The ICE may be operating even though the vehicle is stopped if the electronic controller has detected that the batteries need to be charged. ● **SEE FIGURE 87–11**.

NOTE: The ICE may or may not start when the driver starts the vehicle, depending on the temperature of the engine and other conditions. This can be confusing to some who are driving an HEV for the first time and sense that the engine did not start when they tried to start the engine.

ONE-, TWO-, AND THREE-MOTOR HYBRID SYSTEMS

ONE-MOTOR HYBRID SYSTEMS HEVs that use one electric motor include VW, Nissan, Honda, and General Motors. In these units, an electric motor is attached to the ICE (engine) crankshaft, which is used to perform two functions:

1. Start the ICE engine
2. Act as a generator to charge the high-voltage batteries

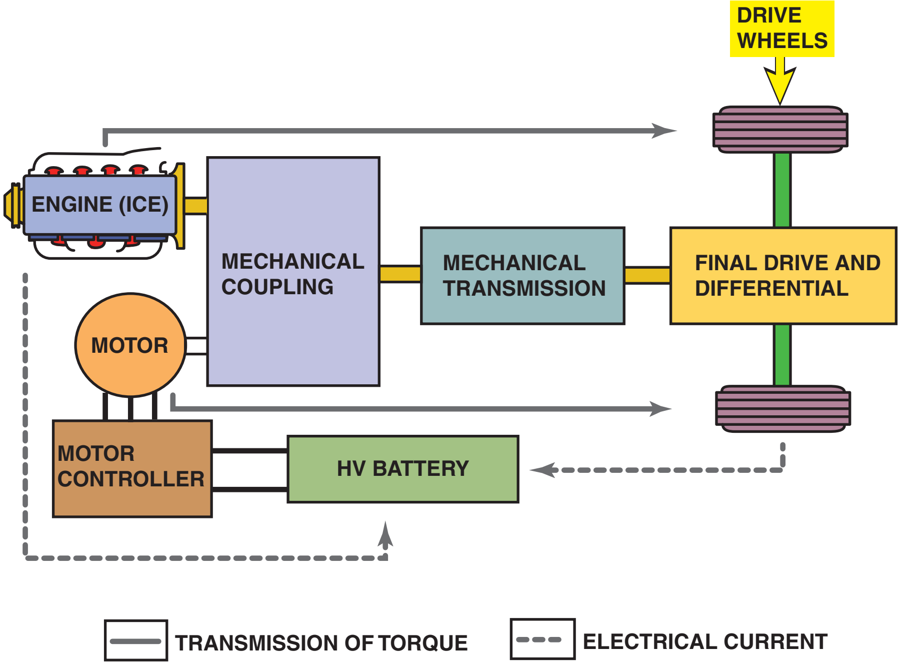

FIGURE 87–10 Diagram showing the components involved in a typical parallel-hybrid vehicle. The solid line arrows indicate the transmission of torque to the drive wheels, and the dotted line arrows indicate the flow of electrical current.

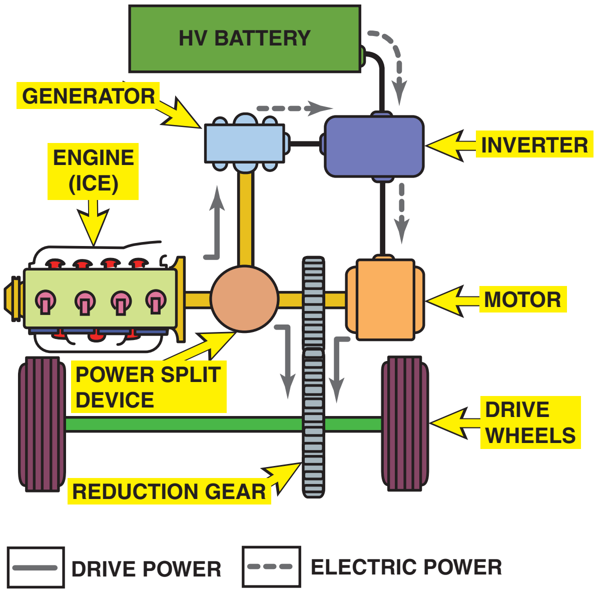

FIGURE 87–11 A series-parallel hybrid design allows the vehicle to operate in electric motor mode only or in combination with the ICE.

Hybrids that use one motor are often called mild hybrids, and usually are not able to power the vehicle using electric power alone. ● **SEE FIGURE 87–12**.

TWO-MOTOR HYBRID SYSTEMS HEVs that use two motors are the most commonly used hybrids by Toyota, Ford, and General Motors in their full-size two-mode trucks. Each electric motor serves two purposes:

- The motor/generator attached to the engine, usually labeled M/G1 or M/G A, is used to start the gasoline engine and to charge the high-voltage batteries.
- The motor/generator that is connected to the drive wheels, usually labeled M/G2 or M/G B, is used to propel the vehicle and to recharge the high-voltage battery during deceleration (regenerative braking).

Two-motor HEVs are full (strong) hybrids and are capable of propelling the vehicle using electric motor power alone for short distances. ● **SEE FIGURE 87–13**.

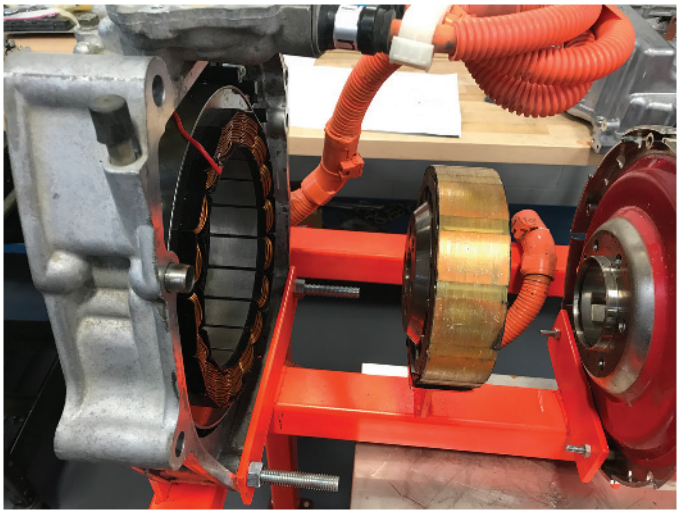

FIGURE 87–12 The exploded view of this Honda IMA motor assembly is an example of a one-motor hybrid system.

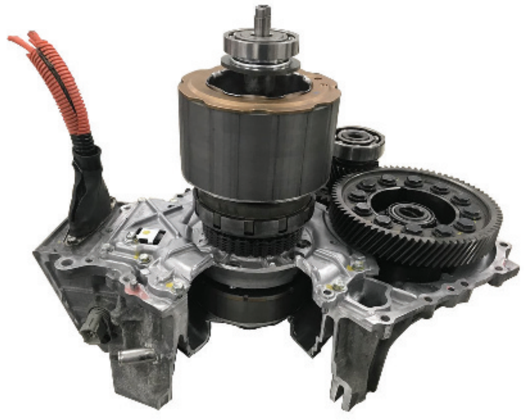

FIGURE 87–13 The cutaway of a second-generation Prius transmission (P112) shows two electric motors (MG1 and MG2). The vehicle can drive a short distance using just the electric motors.

THREE-MOTOR HYBRID SYSTEMS Three-motor HEVs are usually two-motor hybrids that use an additional electric motor to propel the rear wheels for all-wheel-drive capability. HEVs that use three electric motors include the Toyota Highlander and Lexus RX400h/450h SUVs.

ADVANTAGES AND DISADVANTAGES OF ELECTRIC VEHICLES

ADVANTAGES There are many advantages of an EV compared to a vehicle powered by an ICE, which include the following:

- **Initial torque**—Electric vehicles have high torque at the starting from a stop and can provide a rapid acceleration experience to the driver. ● **SEE FIGURE 87–14**.
- **Better handling and stability**—The high-voltage battery in an EV, being the heaviest electric component, is placed very low, on the body floor, resulting in a very low center of mass. This gives the vehicle more stability, resulting in better handling for the vehicle.

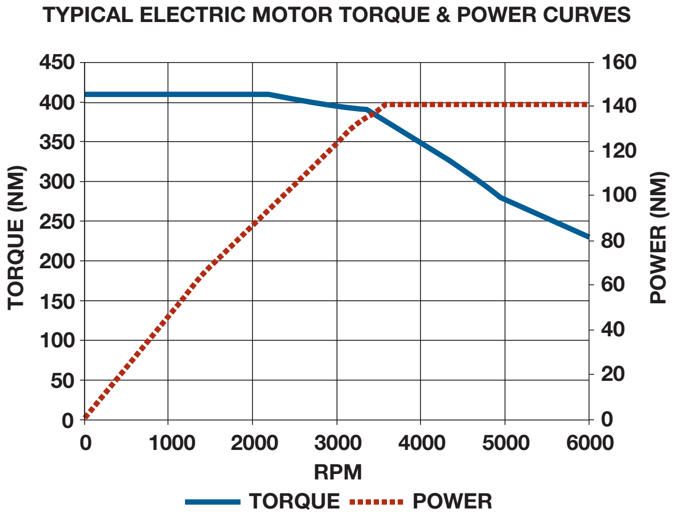

FIGURE 87–14 The graph shows how high the initial torque is in an electric motor and how quickly it generates power.

- **Maximum traction**—Electric motors are independently controlled, thereby providing precise control on each wheel for maximum traction in all-wheel-drive EVs.
- **More efficient than gasoline vehicles**—An EV is more efficient than a gasoline vehicle in converting stored energy into energy of motion. The efficiency of an electric motor is around 85% to 90%, whereas that of an ICE-powered vehicle is 35% to 40%.
- **Less cost of operation**—Cost of operation of an EV is less when compared to gasoline vehicle because the cost of electricity is less when compared to fossil fuels, as well as the high efficiency of the electric motor.
- **Less maintenance**—Fewer moving parts are included in EVs so the maintenance required is reduced. There is no need for oil changes and the brakes may last the life of the vehicle because of the regenerative braking technology. Only some items require periodical maintenance, which include tire rotation, changing the cabin filter, adding windshield washer fluid, and replacing the windshield wiper blades.
- **EVs are quiet and ecofriendly**—EVs are very quiet and do not make any sound while operating. So EVs will be more suitable for big cities where noise pollution is a concern. Also due to zero emission, it is considered ecofriendly.
- **Charge from your house**—Most of the EVs can be charged from the household itself.

DISADVANTAGES There are several disadvantages of an EV compared to an ICE vehicle including

- **Limited range**—While range is increasing due to improved battery designs, range is still a concern for many people. Early EVs had a range of up to 80 miles, but

FREQUENTLY ASKED QUESTION

Can an Electric Vehicle Be Towed?

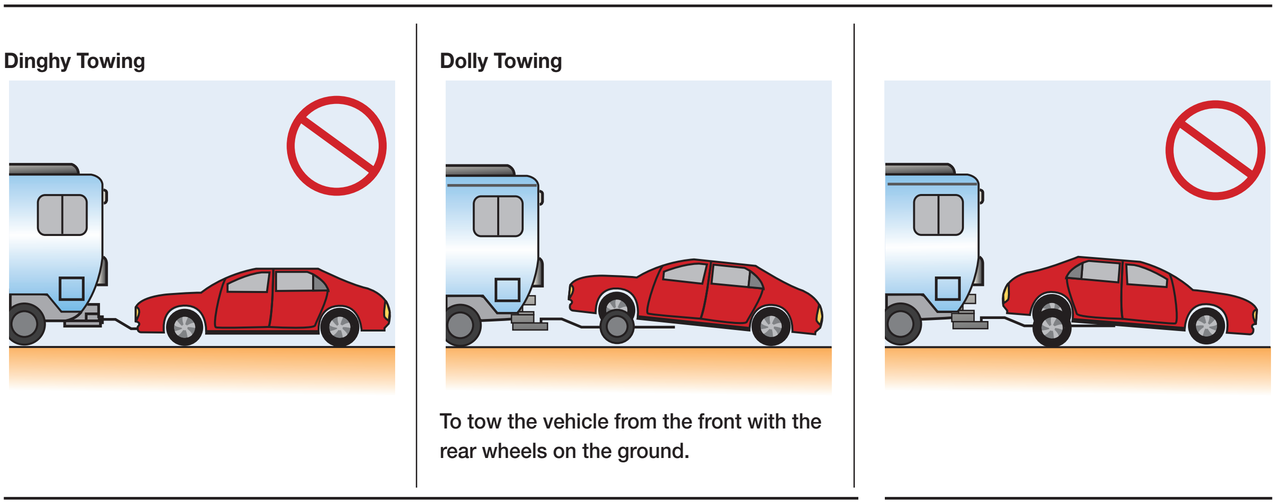
Yes, with some precautions to prevent damage to the vehicle. Most vehicle manufacturers recommended towing any vehicle with all four wheels off the ground. ● **SEE FIGURE 87–15**. The manual for a Chevrolet Bolt includes the following steps:

- Place the front wheels on a dolly.
- Place the shift lever in P (Park).
- Secure the vehicle to the dolly.

However, under "Electric Parking Brake" the owner's manual says that the electric parking brake (EPB) may automatically apply in some situations when the vehicle is not moving to check the correct operation of the EPB system. Some Bolt owners have reported that the EPB has engaged while being towed with the rear wheels on the ground, which ruined the rear tires. If any front-wheel-drive vehicle is being towed with the rear wheels on the ground, many experts recommend the following precautions:

- Disconnect the 12-volt battery to prevent the possibility of the electric parking brake being applied.
- Listen carefully to ensure that the car does not automatically apply the EPB between the time that the car is turned off and the time that the battery is disconnected.
- Make sure to keep the driver's door open until after the battery is disconnected, otherwise the car may automatically lock the doors requiring the use of the physical key to unlock the door.
- Always make sure to test that the wheels are rolling freely before departure.

Obviously, all the aforementioned precautions are not necessary if the vehicle is towed with all four wheels off the ground.



Dinghy Towing

Dolly Towing

To tow the vehicle from the front with the rear wheels on the ground.

FIGURE 87–15 How a front-wheel-drive EV should be towed as per the vehicle manufacture's instructions.

newer models are now reaching a range of 240 to 300 miles or more.

- **Electrical needs at home**—Most EVs are charged at home, and this usually means that the electric service needs to be installed or upgraded to provide a 220–240-volt outlet near the vehicle to allow overnight charging.
- **High initial cost**—Because the cost of the high-voltage batteries is high, the cost of an EV is higher than an ICE vehicle of the same type and size.

TIPS FOR RANGE INCREASE

- Accelerate slowly.
- Avoid high-speed driving because as the speed increases, the aerodynamic drag is increased by the square of the speed.
- Avoid using the air-conditioning unless absolutely needed.
- Check tire pressure. The door placard pressure offers the best compromise in terms of tire rolling resistance, braking distance, comfort, lateral dynamics, and wear.
- Pre condition the vehicle. As long as the vehicle is attached to the charging station, it makes sense to pre condition the interior and to specify the departure time in winter because the battery is only fully charged at the time of departure and is already at operating temperature.
- Reduce weight by removing unnecessary additional weight and roof structures, such as bike racks unless being used.

REVIEW QUESTIONS

1. What are the advantages and disadvantages of a series-hybrid design?
2. What are the advantages and disadvantages of micro, mild, medium, and full hybrids?
3. What are some of the advantages and disadvantages of owning an electric vehicle (EV)?
4. What is the purpose of the third motor in a three-motor hybrid system?
5. What are the items that will affect the range of an electric vehicle?

CHAPTER QUIZ

1. What is the difference between a mild hybrid and a full hybrid?
   a. A mild hybrid will propel the vehicle in electric mode.
   b. A full hybrid will propel the vehicle in electric mode.
   c. There are no differences between mild and full hybrid vehicles.
   d. None of the answers are correct.
2. What is the difference between a hybrid electric vehicle (HEV) and plug-in hybrid electric vehicle (PHEV)?
   a. Both an HEV and PHEV have to be plugged in.
   b. Only the PHEV needs to be plugged in to achieve maximum range.
   c. A PHEV does not use an ICE.
   d. An HEV uses a high-voltage battery that has a higher capacity than a PHEV.
3. One-pedal driving means ___________.
   a. the vehicle only has one pedal
   b. the vehicle has the ability to slow and often stop using just the accelerator pedal
   c. the vehicle does not use regenerative brakes but just friction brakes
   d. the vehicle uses the accelerator pedal to accelerate and the parking brake level to slow and stop
4. An electric vehicle (EV) is also called a ___________.
   a. self-driving vehicle
   b. battery electric vehicle (BEV)
   c. hybrid electric vehicle (HEV)
   d. plug-in hybrid electric vehicle (PHEV)
5. An electric motor is ___________ an internal combustion engine (ICE).
   a. less efficient than
   b. just as efficient as
   c. more efficient than
   d. None of the above
6. Range anxiety is ___________.
   a. the fear of running out of electrical battery charge and being left stranded
   b. the fear of having to recharge on the way to work if the distance is greater than 5 miles
   c. normal anxiety when first owning an EV
   d. Both a and c
7. In a series hybrid powertrain, the source of propulsion is the ___________.
   a. ICE
   b. electric motor
   c. three-speed transmission
   d. ICE or electric motor
8. In a three-motor hybrid vehicle, the third motor drives the ___________ wheels.
   a. rear
   b. front
   c. both front and rear
   d. None of the above
9. A full hybrid uses ___________.
   a. a 12-volt battery and a 144-volt battery
   b. two 12-volt batteries
   c. a 12-volt battery and a 42-volt battery
   d. a 12-volt battery and a 300-volt battery
10. What is NOT an advantage of an EV?
   a. Higher cost
   b. Lack of required oil changes and other services that an ICE requires
   c. More economical to operate on a cost per mile basis
   d. All of the above

Chapter

88

HYBRID AND ELECTRIC VEHICLE MAINTENANCE

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe routine service procedures for both hybrid and electric vehicles.
- Explain how to place a hybrid vehicle in maintenance mode.
- Describe an oil and filter change and engine maintenance on a hybrid vehicle.
- Explain how to service the base brake system on a hybrid or electric vehicle.
- Discuss related maintenance items including battery air filter, A/C service, tires, auxiliary battery, and steering systems.
- List diagnostic procedures for hybrid and electric vehicles.

KEY TERM:

Noise-reducing tire 1021

ROUTINE SERVICE PROCEDURES

CUSTOMER PERCEPTION Many customers love their hybrid and electric vehicle; however, routine maintenance is frequently overlooked because it is different from a vehicle with just an internal combustion engine (ICE). Over time, the customer begins to notice a decrease in the fuel economy. The perception is that the decrease is a result of a failing high-voltage battery. In many cases the decrease in fuel economy or performance is a result of a lack of routine maintenance. ● **SEE CHART 88–1**.

HEV/PHEV MAINTENANCE ITEMS	EV MAINTENANCE ITEMS
Oil changes (once or a year or when the OLM indicates)	NA
Engine air filter (every 2–3 years)	NA
Cabin filter (every 2–3 years)	Cabin filter (every 2–3 years)
Tire rotation (every 7,500 miles)	Tire rotation (every 7,500 miles)
Windshield washer fluid (as needed)	Windshield washer fluid (as needed)
Windshield wiper blades (as needed)	Windshield wiper blades (as needed)

CHART 88–1

Routine maintenance service.

INSTRUMENT CLUSTER WARNING MESSAGES As part of correctly diagnosing a hybrid or electric vehicle, the technician must understand what the indicators in the instrument cluster and message center mean. These indicators will help to confirm the customer's concern and provide a clue as to what may be wrong with the vehicle. The failure to understand these symbols may lead to unnecessary or incorrect initial diagnostic assumptions. ● **SEE FIGURE 88–1**.

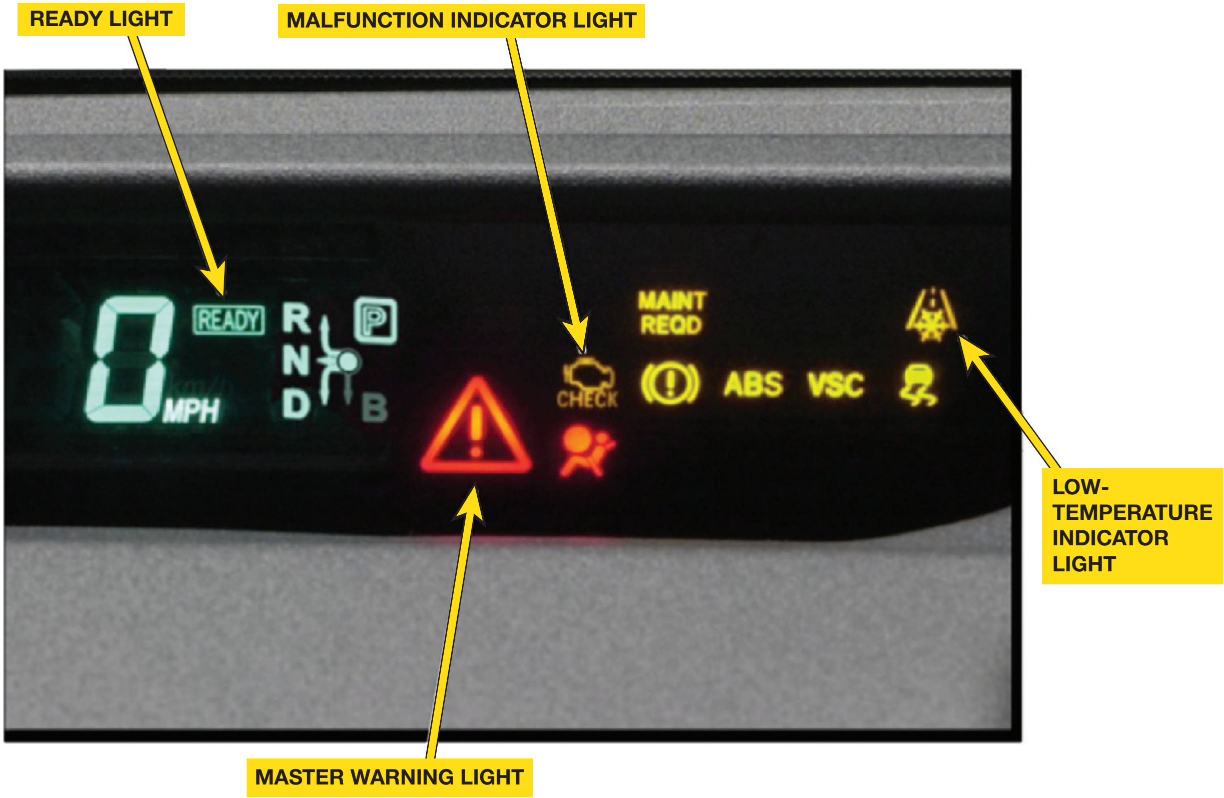


FIGURE 88–1 An example message screen from a Generation 2 Toyota Prius provides a wealth of information for the driver and the service technician.

NON-HIGH-VOLTAGE COMPONENTS THAT IMPACT FUEL ECONOMY When performing a vehicle inspection, it is important to notice the absence or change in any of the following components as it may affect the vehicles' fuel economy:

- Low rolling resistance tires
- Low-mass wheels
- Spoilers
- Underbody trays
- Aerodynamic assist steps

PLACING THE HYBRID VEHICLE IN MAINTENANCE MODE

There are times when the service technician needs to bypass the idle-stop feature and keep the engine running. These conditions can include the following:

- Checking air-conditioning pressures
- Bringing the engine to operating temperature
- Safety inspection of the exhaust system

Depending on the manufacturer, this mode is called any of the following:

- Service mode
- Maintenance mode
- Inspection mode

The vehicle can be placed in this mode either with a scan tool or through a specific sequence of steps inside the vehicle. Most vehicle manufacturers warn not to drive the vehicle while in this mode because torque limiting factors are disabled and damage to powertrain components could occur.

LIFTING AN ELECTRIC VEHICLE Most electric vehicle chassis are developed using a "skateboard design." In this configuration, the high-voltage battery and its covers fill a large portion of the underside of the vehicle. As a result, some vehicles require special adapters for lifting so that the battery and its covers are not damaged by the lift pads. Always follow the manufacturer's specific instructions to ensure the vehicle is safely lifted and damage does not occur. ● **SEE FIGURE 88–2**.

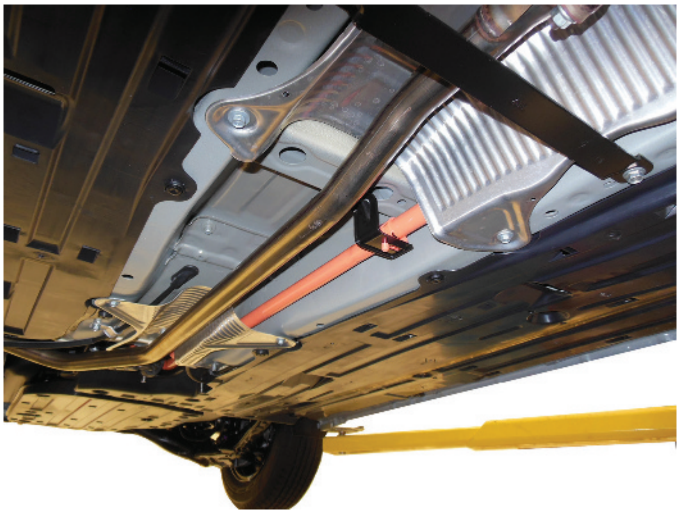

FIGURE 88–2 When positioning the lift, make sure the arms and contact points are clear of any high-voltage cables.

OIL AND FILTER CHANGE AND ENGINE MAINTENANCE

OIL AND FILTER SERVICE Performing an oil change in a hybrid vehicle is similar to changing oil in any vehicle equipped with an ICE. However, there are several items to know when changing oil in a hybrid electric vehicle (HEV).

Always use the specified oil viscosity. Most HEVs require either SAE 0W-20, SAE 0W-16, or SAE 5W-20.

Most hybrid vehicles use a full synthetic oil. Using the specified oil viscosity is important because the engine stops and starts many times and using the incorrect viscosity not only can cause a decrease in fuel economy, but also could cause engine damage. ● **SEE FIGURE 88–3**.

When replacing the oil filter, make sure it meets the manufacturer's original equipment specifications and it is correctly installed. A Honda Civic hybrid service procedure requires the oil filter to be prefilled upon installation to avoid a potential P1021 DTC.

Always follow the specified procedures. Be sure that the ICE is off and that the "READY" lamp is off. If there is a smart key or the vehicle has a push-button start, be sure that the key fob is at least 15 feet (5 meters) away from the vehicle to help prevent the engine from starting accidentally.

ENGINE MAINTENANCE Hybrid vehicles may have specific engine maintenance requirements. These may include the following:

- Honda Insight requires the indexing of spark plugs.
- Some Honda engines require mechanical valve lash adjustments.
- Atkinson cycle engines may require more frequent throttle body service.

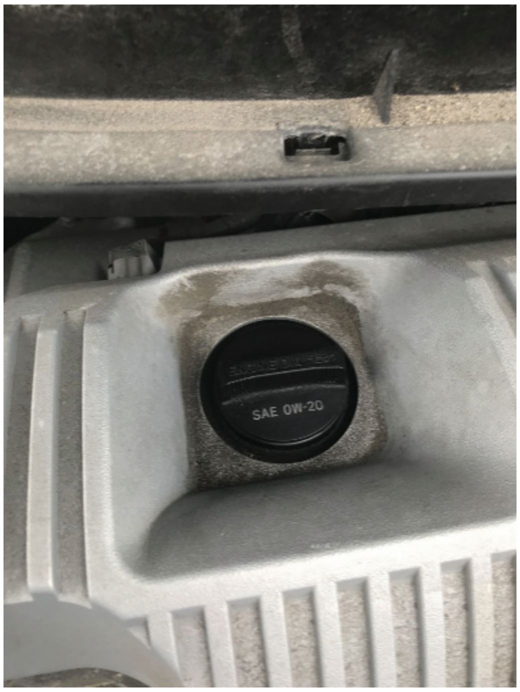

FIGURE 88–3 This Toyota Prius uses SAE 0W-20 as indicated by the oil filler cap.

FREQUENTLY ASKED QUESTION

When Do I Need to Depower the High-Voltage System?

During routine service work, there is no need for a technician to depower the high-voltage system. The only time when this process is needed is if service repairs or testing is being performed on any circuit that has an orange cable attached. These include

- AC compressor if electrically powered
- High-voltage battery pack or electronic controllers

The electric power steering system usually operates on 12 volts or 42 volts and neither is a shock hazard. However, an arc will be maintained if a 42-volt circuit is opened. Always refer to service information if servicing the electric power steering system, or any other system that may contain high voltage.

COOLING SYSTEM SERVICE Performing cooling system service is similar to performing this service in any vehicle equipped with an ICE. However, there are several items to know when servicing the cooling system on a hybrid and electric vehicle, including there may be two or three systems that require service. Always check service information for the exact procedure to follow. The procedure will include the following:

1. The specified coolant. Most vehicle manufacturers will recommend using premixed coolant because using tap water (half of the coolant) that has minerals could cause corrosion issues.

CASE STUDY

A No-Start Prius after a Routine Oil Change

A technician went to start a Toyota Prius after completing a routine oil and filter service. The technician discovered the engine would crank over briefly and then fail to start. A visual inspection was performed and no components were found to be damaged or disconnected as a result of the oil service. Further diagnosis revealed the engine crankcase was significantly overfilled. When motor generator 1 (MG1) turned over the crankshaft on startup, it was unable to achieve the desired engine RPM as a result of the extra resistance created by the excess oil in the crank case. The fail-safe or limp-in operation was a no-start condition. After the engine oil level was lowered to the correct level, the vehicle started and operated normally.

Summary:

The vehicle failed to start due to a crankcase overfill condition that caused MG1 to go into a fail-safe or limp-in condition.

Concern—The vehicle would not start.
Cause—An over-full engine crank case was observed.
Correction—Lowered the engine oil to the correct level.

2. The specified coolant replacement interval. While this may be similar to the coolant replacement interval for a conventional vehicle, always check to be sure that this service is being performed at the specified time or mileage interval.
3. The specified precautions. Some Toyota Prius HEVs use a coolant storage bottle that keeps the coolant hot for up to three days. Opening a coolant hose could cause the release of this hot coolant and can cause serious burns to the technician.
4. Always read, understand, and follow all of the service information instructions when servicing the cooling system on a hybrid or electric vehicle. In many cases a vacuum lift or evacuation system will be needed in order to get all the air out of the system and the system completely full of the coolant mixture. A failure to get the system completely full may result in an overheat condition and possible component failure.
5. When replacing the coolant bottle caps, make sure the cap goes back onto the correct bottle. Some hybrid vehicles use a different pressure cap on the engine as compared to the electronics cooling systems. ● **SEE FIGURES 88–4 AND 88–5**.

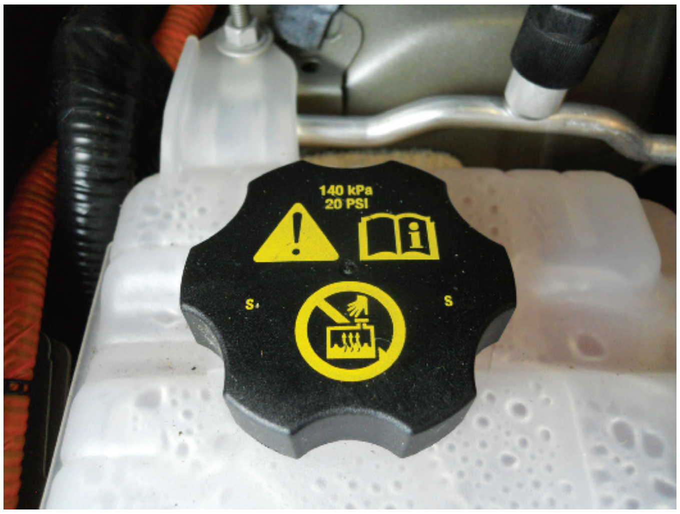

FIGURE 88–4 Chevrolet Volt engine cooling system with a 20 PSI-rated reservoir cap.

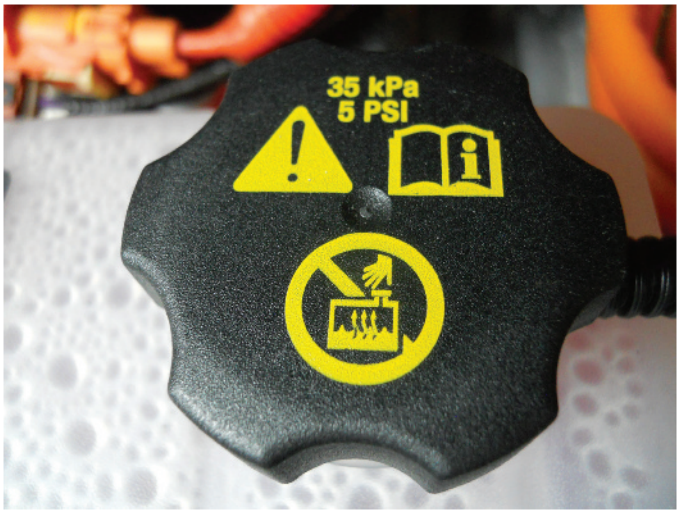

FIGURE 88–5 Chevrolet Volt electronic cooling system with a 5 PSI-rated reservoir cap.

BRAKING SYSTEM SERVICE

Performing braking system service is similar to performing this service in any vehicle equipped with an ICE. However, there are several items to know when servicing the braking system on a hybrid or electric vehicle. They are as follows:

1. Check service information for any precautions that are specified to be followed when servicing the braking system on a hybrid or electric vehicle.
2. Before beginning any base brake service on a hybrid or electric vehicle, make sure to have the needed scan tools, pressure bleeders, and other required tools to properly disable, bleed, and re-enable system.
3. All hybrid and electric vehicles use a regenerative braking system, which captures the kinetic energy of the moving vehicle and converts it to electrical energy and is sent to the high-voltage battery pack. The amount of current produced during hard braking can exceed 100 amperes. This current is stored in the high-voltage battery pack and is used as needed to help power the vehicle.
4. The base brakes used on HEVs are the same as any other conventional vehicle except for the master cylinder and related control systems. There are no high-voltage circuits associated with the braking system as the regeneration occurs inside the electric drive (traction) motors and is controlled by the motor controller.
5. The base brakes on many hybrid and electric vehicles are often found to be stuck or not functioning correctly because the brakes are not doing much work and can rust. The use of regenerative braking decreases the amount of heat generated at the brake assembly and reduces the amount of evaporation of moisture. This is a very common occurrence in the part of the country that the auto manufacturers refer to as the “salt belt.” ● **SEE FIGURE 88–6**.

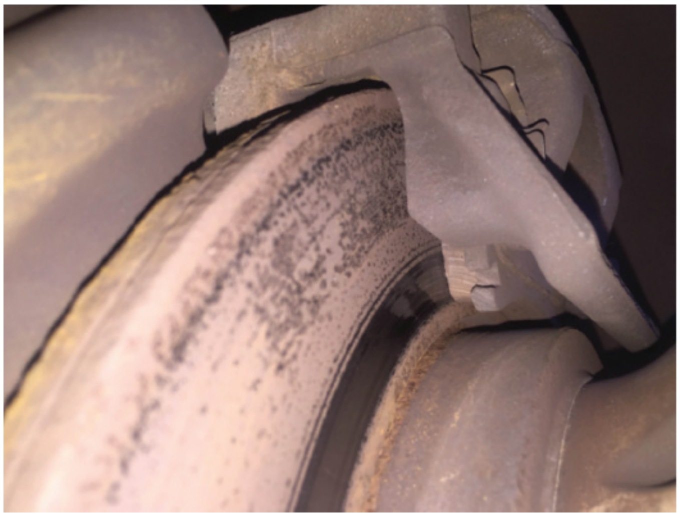

FIGURE 88–6 The brake rotor on this Audi Q5 hybrid is rusted and has very little pad contact due to a seized brake caliper pin.

RELATED MAINTENANCE ITEMS

HIGH-VOLTAGE BATTERY AIR FILTER Many hybrid vehicles rely on the air that is heated and cooled for the passenger compartment to regulate the temperature of the high-voltage battery. To prevent the intrusion of passenger compartment debris from the entering the high-voltage battery cooling system, a filter is placed in the air-intake system. These filters must be replaced at specific service intervals to ensure proper cooling. ● **SEE FIGURE 88–7**.

AIR-CONDITIONING SERVICE Performing air-conditioning system service is similar to performing this service in any vehicle equipped with an ICE. However, there are several items to know when servicing the air-conditioning system on a hybrid or electric vehicle. They are as follows:

- Many hybrid and electric vehicles use an air-conditioning compressor that uses high voltage from the high-voltage battery pack to operate the compressor.
- Make sure the high-voltage system has been properly depowered before removing the compressor for service.
- If the system is electrically driven, special refrigerant oil, POE oil, is used that is nonconductive and will not degrade the insulation on the electric motor windings. This means that a separate recovery machine should be used to avoid the possibility of mixing regular refrigerant oils with the oil used in hybrid and electric systems. ● **SEE FIGURE 88–8**.

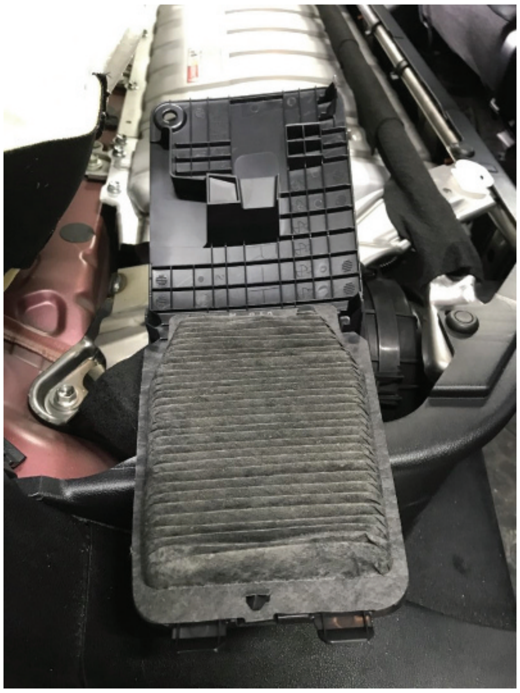

FIGURE 88–7 This Toyota Prius has a high-voltage battery air filter that must be replaced at the documented time or mileage to prevent the battery from overheating.

FIGURE 88–8 This POE refrigerant oil is specific to FCA brand products.

TIRE SERVICE Performing tire-related service is similar to performing this service in any vehicle equipped with an ICE. However, there are several items to know when servicing tires on a hybrid or electric vehicle. They are as follows:

1. Tire pressure is very important not only to the fuel economy but also to the life of the tire. Lower inflation pressure increases rolling resistance and reduces load-carrying capacity and tire life. Always inflate the tires to the pressure indicated on the door jamb sticker or found in service information or the owner's manual.
2. All tires create less rolling resistance as they wear. Even if the same identical tire is used as a replacement, the owner may experience a drop in fuel economy.
3. Tires can have a big effect on fuel economy. It is best to warn the owner that replacement of the tires can and often will cause a drop in fuel economy, even if low rolling resistance tires are selected.
4. Try to avoid using tires that are larger than used from the factory. The larger the tire, the heavier it is, and it takes more energy to rotate, resulting in a decrease in fuel economy.
5. Follow normal tire inspections and tire rotation intervals as specified by the vehicle manufacturer.

NOISE-REDUCING TIRES The purpose of a **noise-reducing tire** is to eliminate noise in the 130–240 Hz range that would be normally covered up by normal engine noise in a vehicle with an ICE. The noise reduction is accomplished by adding acoustical foam to the inside of a tire. The sound is created within the structure of the tire itself and is not transmitted through the air, but rather through the chassis of the vehicle. The sound is similar to the sound heard when blowing across a partially filled glass Coke bottle. As result, this sound is often referred to a "Coke bottle resonance." This sound is most noticeable with electric vehicles (EVs) because there is no drivetrain noise to drown out the resonance. ● **SEE FIGURE 88–9**.

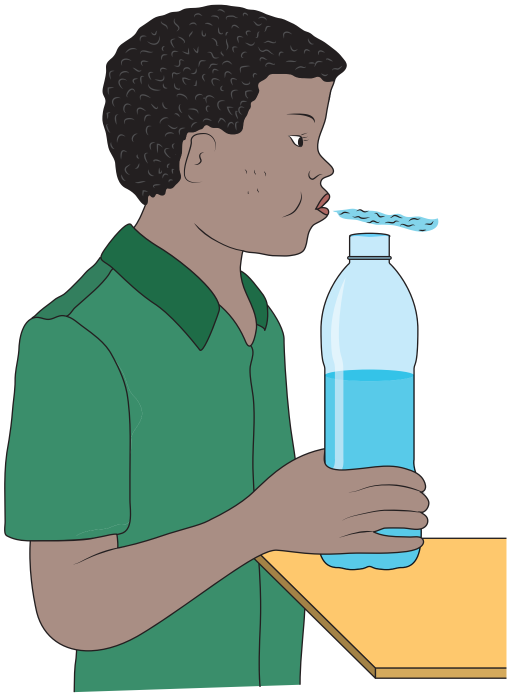

FIGURE 88–9 Blowing across the top of an empty “Coke” bottle creates a noise similar to a vehicle without noise-reducing tires.

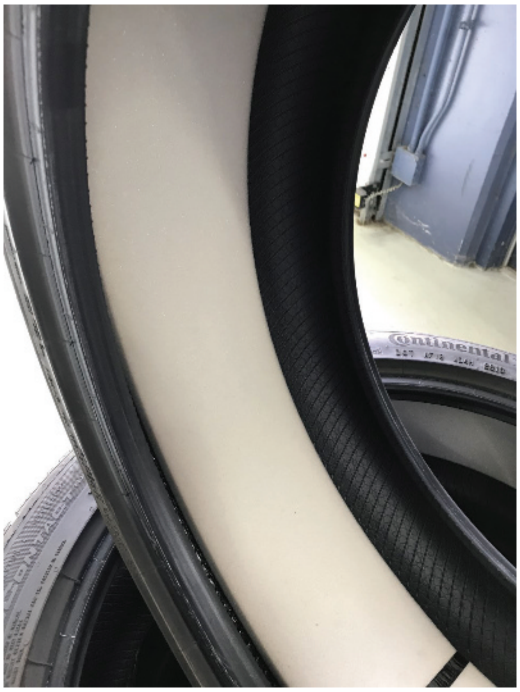

FIGURE 88–10 A tire off a Tesla Model 3 with acoustical foam.

The tire repair process is different on many noise-reducing tires because of the use of acoustical foam. In most instances, the acoustical foam must be carefully cut from the area of the wound and after the repair is complete it must be reattached. ● **SEE FIGURE 88–10**.

AUXILIARY BATTERY TESTING AND SERVICE

Performing auxiliary battery service is similar to performing this service in any vehicle equipped with an ICE. However, there are several items to know when servicing the auxiliary battery on a HEV. They are as follows:

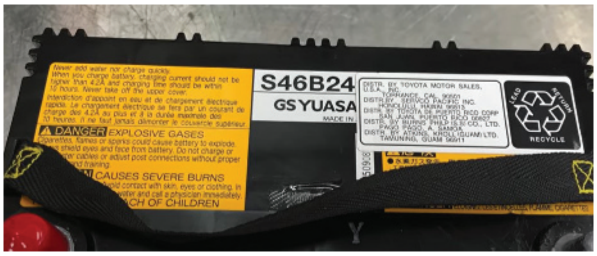

FIGURE 88–11 This Toyota battery is rated using the Japanese Industrial Standard (JIS) rather than cold-cranking amperes.

1. Auxiliary 12-volt batteries used in hybrid or electric vehicles are located in one of two general locations.
    - Under the hood—If the 12-volt auxiliary battery is under the hood, it is generally a flooded-type lead–acid battery and should be serviced the same as any conventional battery.
    - In the passenger or trunk area—If the battery is located in the passenger or trunk area of the vehicle, it is usually of the absorbed glass mat (AGM) design. This type of battery requires that a special battery charger that limits the charging voltage be used.
2. The auxiliary 12-volt battery is usually smaller than a battery used in a conventional vehicle because it is not used to start the engine.
3. The 12-volt auxiliary battery can be tested and serviced the same as any battery used in a conventional vehicle.
4. Some micro hybrids with the stop-start feature will have two 12-volt batteries. The batteries must be isolated during testing to obtain accurate results.
5. Always read, understand, and follow all of the service information instructions when servicing the auxiliary battery on a hybrid or electric vehicle. ● **SEE FIGURE 88–11**.

STEERING SYSTEM SERVICE

Performing steering system service is similar to performing this service in any vehicle equipped with an ICE. However, there are several items to know when servicing the steering system on a hybrid or electric vehicle, which include the following:

1. Check service information for any precautions that are specified to be followed when servicing the steering system on a hybrid or electric vehicle.
2. Most hybrid or electric vehicles use an electric power steering system. These can be powered by one of two voltages:
    - 12 volts—These systems can be identified by the red or black wiring conduit and often use an inverter that increases the voltage to operate the actuator motor (usually to 42 volts). While this higher voltage is contained in the controller and should not create a shock hazard, always follow the specified safety precautions and wear protective high-voltage gloves as needed.
    - 42 volts—These systems use a yellow or blue plastic conduit over the wires to help identify the possible hazards from this voltage level. This voltage level is not a

shock hazard, but can maintain an arc if a circuit carrying 42 volts is opened.

- Many electric power steering systems contain capacitors that provide additional voltage to the system under heavy operating loads. When depowering the power steering system to make repairs, it is important to follow the specific wait times to ensure the capacitors are completely discharged. ● **SEE FIGURE 88–12**.

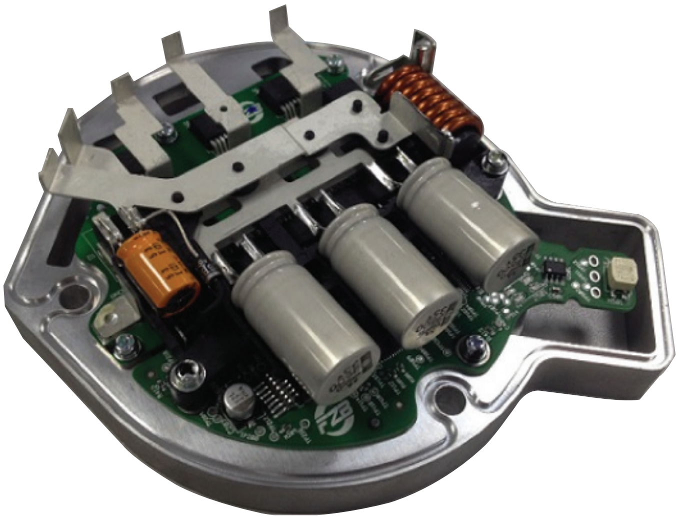

FIGURE 88–12 The capacitors in the power steering assist unit provide additional power when needed but must be allowed to discharge before service work begins.

DIAGNOSIS PROCEDURES

Hybrid and electric vehicles should be diagnosed the same as any other type of vehicle. This means following a diagnostic routine, which usually includes the following steps:

STEP 1 Verify the customer concern.

STEP 2 Check for diagnostic trouble codes (DTCs). An enhanced or factory level scan tool may be needed to get access to codes and sub codes.

STEP 3 Perform a thorough visual inspection. If a DTC is stored, carefully inspect those areas that might be the cause of the trouble code.

STEP 4 Check for technical service bulletins (TSBs) that may relate to the customer concern.

STEP 5 Follow service information specified steps and procedures. This could include checking scan tool data for sensors or values that are not within normal range.

STEP 6 Determine and repair the root cause of the problem.

STEP 7 Verify the repair and clear any stored DTCs unless in an emission testing area. If in an emission test area, drive the vehicle until the powertrain control module (PCM) passes the fault and turns off the malfunction indicator lamp, thereby allowing the vehicle to pass the inspection.

STEP 8 Complete the work order and record the “three Cs” (complaint, cause, and correction).

REVIEW QUESTIONS

1. What is the purpose of the hybrid vehicle maintenance mode?
2. Why do most manufacturers of hybrid vehicles use full synthetic engine oil.
3. Why do most manufacturers recommend premixed coolant when servicing the hybrid or electric vehicle cooling systems?
4. Why does the base brake system require more frequent maintenance in the “salt belt” portion of the country?
5. What is the purpose of the acoustical foam in the noise-reducing tire?

CHAPTER QUIZ

1. The purpose of the hybrid vehicle maintenance mode is to ___________.
   a. bypass the idle stop feature
   b. service the base brake system
   c. change the oil and filter
   d. service the cooling system
2. Why do most hybrid vehicles use a full synthetic engine oil?
   a. The engine stops and starts more frequently.
   b. It helps to reduce engine damage.
   c. It helps to improve fuel economy.
   d. All of the above are correct.
3. Why do most manufacturers recommend using a premixed replacement coolant when servicing a hybrid or electric vehicle cooling system?
   a. The minerals in tap water can cause corrosion issues.
   b. It is difficult to get the mixture ratio correct.
   c. Both a and b are correct.
   d. Neither a nor b is correct.
4. Why do base brake systems require more frequent maintenance in the “salt belt” portion of the country?
   a. Salt causes the brake pads to separate from their backing.
   b. The use of regenerative brakes causes less heat at the brake rotor and leads to a decrease in the evaporation rate of moisture on the brake system.
   c. Corrosion causes the brake pins and sliders to stick.
   d. All of the above are correct.
5. What special procedures may be needed when repairing a puncture on a noise-reducing tire?
   a. The tire cannot be repaired, it must be replaced.
   b. The acoustical foam in the area of the leak will need to be removed prior to repairing the wound.
   c. The acoustical foam will need to be reattached after the repair is complete.
   d. Both b and c are correct.

6. Lack of proper maintenance could cause ____________, leading the customer to think the HV battery is failing.
    - **a.** noises
    - **b.** dim headlights
    - **c.** decreased fuel economy
    - **d.** None of the above

7. Electric power steering systems operate at what voltage level?
    - **a.** 12 volts
    - **b.** 42 volts
    - **c.** 60 volts
    - **d.** Both a and b are correct

8. What cautions should be observed when servicing an electric air-conditioning compressor?
    - **a.** Make sure the high-voltage system has been properly depowered.
    - **b.** Make sure the proper refrigerant oil is used in the repair.
    - **c.** Use the appropriate refrigerant recovery machine.
    - **d.** All of the above are correct.

9. What is the purpose of the high-voltage battery cabin filter?
    - **a.** To prevent the intrusion of passenger compartment debris
    - **b.** To help regulate the temperature of the battery
    - **c.** Both a and b are correct.
    - **d.** Neither a nor b is correct.

10. Why is the eight-step diagnostic procedure used when diagnosing a hybrid or electric vehicle?
    - **a.** To ensure a problem is not overlooked
    - **b.** To ensure the vehicle is repaired as efficiently as possible
    - **c.** To make sure the repair is properly documented
    - **d.** All of the above are correct.

Chapter 89

EV AND HEV HIGH-VOLTAGE BATTERIES

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss hybrid and electric vehicle high-voltage batteries.
- Describe nickel-metal hydride batteries and designs used in hybrid electric vehicles.
- Explain the operation of lithium-ion high-voltage batteries.
- Describe the designs of lithium-ion cells.
- Describe the types of lithium-ion batteries.
- Explain HEV/EV electronics cooling.
- Explain high-voltage battery cooling and heating.
- Discuss battery capacity versus vehicle range.
- Discuss the high-voltage battery control components.
- Discuss the factory authorized lithium-ion battery repair procedure.
- Describe battery degradation and balancing.

KEY TERMS:

Active balancing 1038 • Battery density 1030 • Battery control module (BCM) 1034 • Battery management system (BMS) 1035 • Electrical Distribution System (EDS) 1035 • Guess-O-Meter (GOM) 1033 • Lithium iron phosphate ($LiFePO_4$) 1030 • Nickel, cobalt, and aluminum (NCA) 1030 • Nickel, manganese, and cobalt (NMC) 1030 • Nickel-metal hydride (NiMH) 1026 • MPGe 1033 • Passive balancing 1038 • Pouch cell 1029 • System Main Relays (SMRs) 1034 • Worldwide harmonized Light vehicles Test Procedure (WLTP) 1033

HYBRID AND ELECTRIC VEHICLE HIGH-VOLTAGE BATTERIES

PURPOSE AND FUNCTION Hybrid electric vehicles (HEVs) use a dual-voltage electrical system:

- The high-voltage (HV) system is used to power the electric drive (traction) motor.
- A conventional 12-volt system is used to power all other aspects of vehicle operation.

One advantage to using this system is that the vehicle can use any conventional electrical accessories in its design.

NOTE: It is possible for an HEV to have three separate voltage systems. The Toyota Highlander HEV, for example, has a 12-volt auxiliary system, a 42-volt system for the electric power assist steering, and a 288-volt system for the hybrid drive.

ELECTRIC MOTOR REQUIREMENTS EVs and HEVs use high-output electric motors to drive and assist vehicle movement. These motors are rated anywhere from 10 to 50 kW for HEVs and as much as 450 kW for some EVs, so they consume large amounts of electrical power during operation. If a conventional 12-volt electrical system was used to power these motors, the amount of current flow required would be extremely large and the cables used to transmit this energy would also be so large as to be impractical. Also, the motors used in these systems would have large gauge windings and would be big and heavy relative to their power output. Automotive engineers overcome this problem by increasing the voltage provided to the motors, thus decreasing the amount of current that must flow to meet the motor's wattage requirements (see Frequently Asked Question, "Why Do Higher Voltage Motors Draw Less Current?"). Smaller amounts of current flowing in the cables mean that the cables can be sized smaller, making it much more practical to place a battery in the rear of the vehicle and run cables from there to the drive motor in the engine compartment. ● **SEE FIGURE 89–1**.

The motors can also be made much smaller and more powerful when they are designed to operate on higher voltages.

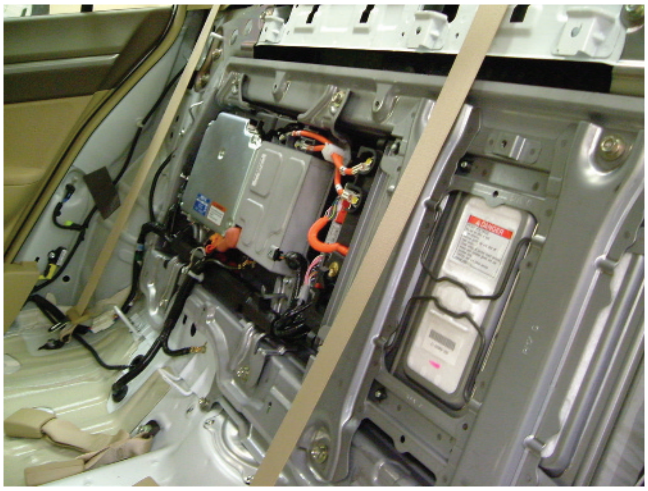

FIGURE 89–1 The high-voltage battery and motor controls are located behind the rear passenger's seat in a Honda.

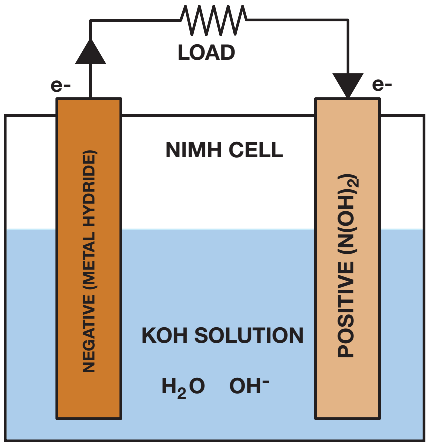

FIGURE 89–2 An NiMH cell. The unique element in a nickel-metal hydride cell is the negative electrode, which is a hydrogen-absorbing alloy. The positive electrode is nickel hydroxide. The electrolyte does not enter into the chemical reaction and is able to maintain a constant conductivity regardless of the state-of-charge of the cell.

NICKEL-METAL HYDRIDE BATTERIES

USES Many HEVs use **nickel-metal hydride (NiMH)** battery technology for the high-voltage battery. NiMH batteries are being used for these applications because of their performance characteristics, such as specific energy, cycle life, and safety. From a manufacturing perspective, the NiMH battery is attractive because the materials used in its construction are plentiful and recyclable.

DESCRIPTION AND OPERATION NiMH batteries have a positive electrode made of nickel hydroxide. The negative electrode is unique, in that it is a hydrogen-absorbing alloy, also known as a metal hydride. The electrolyte is an alkaline, usually potassium hydroxide. The nominal voltage of an NiMH battery cell is 1.2 volts.

ELECTROLYTE NiMH batteries are known as alkaline batteries due to the alkaline (pH greater than 7) nature of the electrolyte. The electrolyte is aqueous potassium hydroxide. Potassium hydroxide works well for this application because it does not corrode the other parts of the battery and can be housed in a sealed steel container. Also, potassium hydroxide does not take part in the chemical reaction of the battery, so the electrolyte concentration stays constant at any given state-of-charge. These factors help the NiMH battery achieve high-power performance and excellent cycle life. ● **SEE FIGURE 89–2**.

OPERATION DURING CHARGING During battery charging, hydrogen ions (protons) travel from the positive electrode to the negative electrode, where they are absorbed into the metal hydride material. The electrolyte does not participate in the reaction and acts only as a medium for the hydrogen ions to travel through.

OPERATION DURING DISCHARGING When the battery is discharged, this process reverses, with the hydrogen ions (protons) traveling from the negative electrode back to the positive electrode. The density of the electrodes changes somewhat during the charge/discharge process, but this is kept to a minimum as only protons are exchanged during battery cycling. Electrode stability due to minimal density changes is one of the reasons why the NiMH battery has a very good cycle life. ● **SEE FIGURE 89–3**.

FREQUENTLY ASKED QUESTION

Why Do Higher Voltage Motors Draw Less Current?

Keep in mind that an electric motor is powered by wattage. Every electric motor is rated according to the amount of power (in watts) it consumes. Power is calculated using the following formula:

$$P = I \times E$$

or

$$\text{Power in watts} = \text{Current (in amperes)} \times \text{Voltage (in volts)}$$

An electric motor rated at 144 watts will consume 12 amperes at 12 volts of applied voltage (12 volts × 12 amperes = 144 watts). If this same motor was powered with 6 volts, it would draw 24 amperes to achieve the same power output. This increase in current draw would require a much bigger cable to efficiently transmit the electric current and minimize voltage drop. The motor windings would also have to be much heavier to handle this increased current. Imagine that we power this same motor with a 144-volt battery. Now we require only 1 ampere of electrical current to operate the motor (144 volts × 1 ampere = 144 watts). The cable required to transmit this current could be sized much smaller and it will now be much easier to run the cables over the length of the car without significant power loss. Also, the electric motor can be made much smaller and more efficient when less current is needed to power it. Some hybrid systems have motors that operate at up to 650 volts in an effort to increase system efficiency.

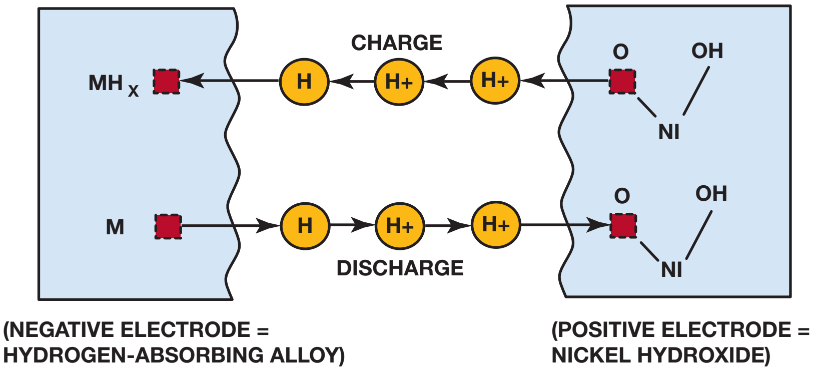

FIGURE 89–3 Chemical reactions inside an NiMH cell. Charging and discharging both involve an exchange of hydrogen ions (protons) between the two electrodes.

ADVANTAGES Nickel-based alkaline batteries have a number of advantages over other battery designs. These include the following:

- High specific energy.
- The nickel electrode can be manufactured with large surface areas, which increase the overall battery capacity.
- The electrolyte does not react with steel, so NiMH batteries can be housed in sealed steel containers that transfer heat reasonably well.
- The materials used in NiMH batteries are environmentally friendly and can be recycled.
- Excellent cycle life.
- Durable and safe.

DISADVANTAGES Disadvantages of the NiMH battery include the following:

- High rate of self-discharge, especially at elevated temperatures.
- Moderate levels of memory effect, although this seems to be less prominent in newer designs.
- Moderate to high cost.

FREQUENTLY ASKED QUESTION

How Is an Alkaline Battery Different from a Lead–Acid Battery?

Lead–acid batteries use sulfuric acid as the electrolyte, which acts as the medium between the battery's positive and negative electrodes. Acids have a pH that is below 7, and pure water has a pH of exactly 7. If electrolyte from a lead–acid battery is spilled, it can be neutralized using a solution of baking soda and water (an alkaline solution). Alkaline batteries use an electrolyte such as potassium hydroxide, which has a pH greater than 7. This means that the electrolyte solution is basic, which is the opposite of acidic. If an alkaline battery electrolyte is spilled, it can be neutralized using a solution of vinegar and water (vinegar is acidic). Both nickel-cadmium (Ni-Cd) and nickel-metal hydride (NiMH) batteries are alkaline battery designs.

NiMH BATTERY DESIGNS There are two primary designs for an NiMH battery cell. These are:

1. **Cylindrical type.** The cylindrical type has the active materials made in long ribbons and arranged in a spiral fashion inside a steel cylinder (case). The negative electrode is wound alongside the positive electrode, and the separator material holding the electrolyte is placed between them. The negative electrode is attached to the steel battery case, while the positive electrode attached to the (–) terminal at the top of the battery. There is a self-resealing safety vent located at the top of the battery case, which will relieve internal pressure in case of overcharge, short circuiting, reverse charge, or other abuse. Cylindrical cells are often constructed very similar to a conventional "D" cell. Cylindrical cells are most often incorporated into modules with a group of six cells connected in series. This creates a single battery module with a 7.2-volt output. Groups of these modules can then be connected in series to create higher voltage battery packs. ● **SEE FIGURE 89–4**.
2. **Prismatic type.** The prismatic type is a rectangular or box-like design with the active materials formed into flat plates, much like a conventional lead–acid battery. The positive and negative plates are placed alternately in the battery case, with tabs used to connect the plate groups. Separator material is placed between the plates to prevent them from touching, but still allow electrolyte to circulate freely. ● **SEE FIGURE 89–5**.

FIGURE 89–5 A prismatic NiMH cell. Prismatic cells are built with flat plates and separators similar to conventional lead–acid batteries.

BATTERY CELLS ARE CONNECTED IN SERIES Battery designers are limited by the nominal cell voltage of the battery technology. In the case of NiMH batteries, each cell is capable of producing only 1.2 volts. A high-voltage battery based on NiMH technology must be built using multiples of 1.2 volts. In order to build a 144-volt battery, 114 individual NiMH cells must be connected together in series (144 × 1.2 volts). Obviously, the higher the voltage output of the battery, the greater the number of individual battery cells that must be used to achieve the necessary voltage. ● **SEE FIGURES 89–6, 89–7, AND 89–8.**

LITHIUM-ION HIGH-VOLTAGE BATTERIES

USES A battery design that shows a great deal of promise for electric vehicles (EV) and hybrid electric vehicles (HEV) applications is lithium-ion (Li-ion) technology. Lithium-ion batteries have been used extensively in consumer electronics since the early 1990s and are currently used in most electric and plug-in hybrid electric vehicles (PHEVs).

DESCRIPTION A lithium-ion cell is named because during battery cycling, lithium ions move back and forth between the positive and negative electrodes. Lithium-ion has approximately twice the specific energy of nickel-metal hydride.

CONSTRUCTION The positive electrode in a conventional lithium-ion battery has lithium cobalt oxide as its main ingredient, with the negative electrode being made from a specialty carbon. The electrolyte is an organic solvent, and this is held in a separator layer between the two electrode plates. To prevent battery rupture and ensure safety, a pressure release valve is built into the battery housing that will release gas if the internal pressure rises above a preset point. ● **SEE FIGURE 89–9.**

OPERATION The lithium-ion cell is designed so that lithium ions can pass back and forth between the electrodes when the battery is in operation.

1. During battery discharge, lithium ions leave the anode (negative electrode) and enter the cathode (positive electrode) through the electrolyte and across the separator.

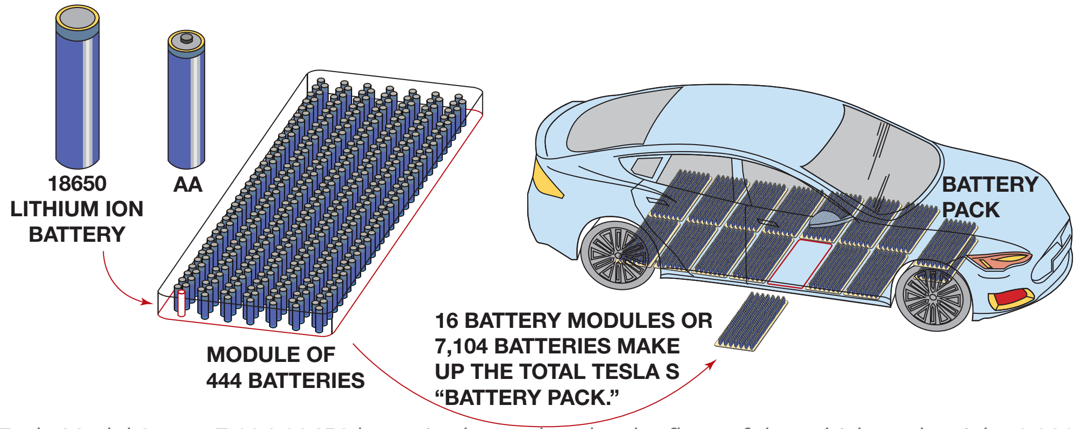

FIGURE 89–10 A Tesla Model S uses 7,104 18650 batteries located under the floor of the vehicle and weighs 1,200 pounds (544 kg).

FREQUENTLY ASKED QUESTION

How Much Lithium Is There in a Typical Li-Ion High-Voltage EV Battery?

In a typical electric vehicle, such as the Tesla Model S, it is estimated that there is a total of about 15 pounds (7 kg) of lithium used in all of the cells. This is about the weight of a bowling ball.

2. Lithium ions leave the cathode and move through the electrolyte into the anode.

ADVANTAGES Lithium-ion batteries have the following advantages:

- High specific energy
- Good high-temperature performance
- Low self-discharge
- Minimal memory effect
- High nominal cell voltage. The nominal voltage of a lithium-ion cell is 3.6 volts, which is three times that of nickel-based alkaline batteries. This allows for fewer battery cells being required to produce high voltage from an HV battery.

DISADVANTAGES Disadvantages of the lithium-ion battery include

- High cost
- Issues related to battery overheating

NOTE: Early lithium-ion battery designs have experienced problems with thermal runaway, which has led to fire and even explosions. Lithium-ion battery packs in automotive applications are designed with cooling and safety systems that prevent overheating and isolate cell failures.

DESIGNS OF LITHIUM-ION CELLS

CYLINDRICAL A cylindrical cell has high specific energy, good mechanical stability, and lends itself to automated manufacturing. Cylindrical cell design cycles well, offers a long life and is low cost, but it has less than ideal packaging density. The cylindrical cell design is used by many electric vehicle manufacturers such as Tesla.

Tesla, for example, uses several sizes of cylindrical cells including

- 18650 cells manufactured by Panasonic in the Models S and X cars since 2012. These are small battery cells, slightly larger than the standard AA cells. The Tesla cylindrical cells are 18 mm in diameter and 65 mm tall. ● **SEE FIGURE 89–10**.
- Tesla Model 3 and Y use 2170 batteries, which are 21 mm in diameter and 70 mm tall.
- Tesla Cyber Truck uses 4680 cells, which are 46 mm in diameter and 80 mm tall.

PRISMATIC—HARD CASE The prismatic type is a rectangular or boxlike design with the active materials formed into flat plates, much like a conventional lead–acid battery. The positive and negative plates are placed alternately in the battery case, with tabs used to connect the plate groups. Separator material is placed between the plates to prevent them from touching, but still allow electrolyte to circulate freely. ● **SEE FIGURE 89–11**.

PRISMATIC—POUCH TYPE Pouch design HV battery uses laminated architecture in a bag referred to as **pouch cell**. It is light and cost-effective, but exposure to humidity and high temperature can shorten its life. The pouch cell offers a simple, flexible, and lightweight battery design. The pouch cell makes most efficient use of space and achieves 90–95% packaging efficiency, the highest among battery packs.

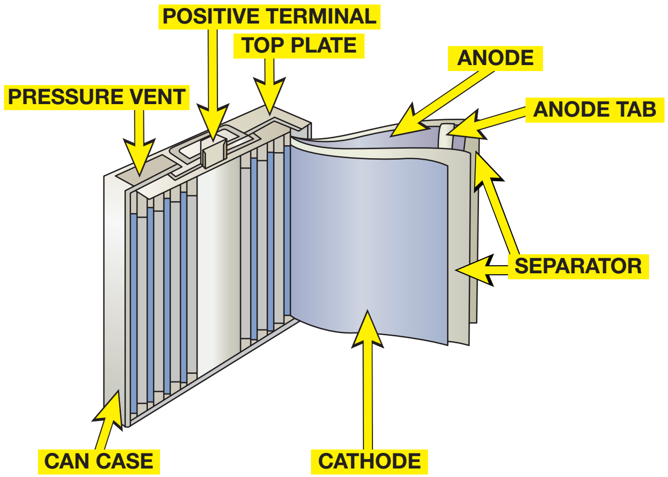

FIGURE 89–11 The prismatic type is a rectangular or boxlike design that allows them to be stacked close together to create a HV battery pack.

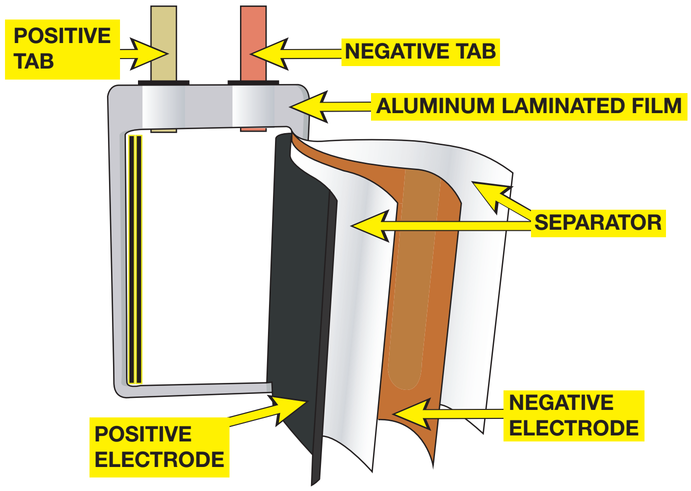

FIGURE 89–12 The pouch design uses a flexible outer container that is able to expand when being charged without damaging the battery.

Eliminating the metal enclosure reduces weight, but the cell needs support and allowance to expand in the battery compartment. The pouch packs are used in consumer, military and automotive applications, and are used in the Jaguar I-Pace, Mustang Mach E, and the GMC Hummer EV electric vehicles. The General Motor's Ultium batteries are unique because of their large-format, pouch-style cells, which can be stacked vertically or horizontally inside the battery pack. No standardized pouch cells exist as each manufacturer designs its own. ● **SEE FIGURE 89–12**.

TYPES OF LITHIUM-ION BATTERIES

NUMEROUS MATERIALS There are numerous types of lithium-ion batteries, and the list is growing. While every component of the battery is under development, the primary difference between the various designs is the materials used for the positive electrode or cathode. The original Li-ion cell design used lithium cobalt oxide for its cathode, which has good energy storage characteristics, but suffers chemical breakdown at relatively low temperatures. This failure results in the release of heat and oxygen, which often leads to a fire or explosion as the electrolyte ignites. In order to make lithium-ion batteries safer and more durable, a number of alternative cathode materials have been formulated.

CATHODE MATERIAL Vehicle manufacturers use several different cathode materials:

- A combination of **nickel, manganese, and cobalt (NMC)** for the cathode material. This cathode material results in slightly lower energy, but is less volatile and can withstand variation in temperature.

  NOTE: This design of battery is used in the 48-volt mild-hybrid Ram truck.

- Tesla uses **nickel, cobalt, and aluminum (NCA)** cathode material, which results in a long battery life and faster charging capability.
- Another cathode design for automotive applications includes **lithium iron phosphate ($LiFePO_4$)**, which is stable at higher temperatures and does not contain cobalt, which is in limited supply worldwide.

The lithium iron phosphate battery is the most promising future battery and is constructed using lithium iron phosphate as the cathode, and a graphitic carbon electrode with a metallic backing as the anode. The lithium iron phosphate battery offers a longer life cycle, low cost, low toxicity, well-defined performance, and long-term stability making it a likely battery for use in future electric vehicles. ● **SEE CHART 89–1**.

CHEMICAL NAME	MATERIAL	ABBREVIATION
Lithium Cobalt Oxide	$LiCoO_2$	LCO
Lithium Nickel Cobalt Oxide	$LiNi_xCOyAl_zO_2$	LNCO
Lithium Nickel Manganese Cobalt Oxide	$LiNiMnCoO_2$	NMC
Lithium Manganese Oxide	$LiMn_2O_4$	LMO
Lithium Iron Phosphate	$LiFePO_4$	LFP
Lithium Nickel Cobalt Aluminum Oxide	$LiNiCoAlO_2$	NCA

CHART 89–1

Chart of the most commonly used Li-ion batteries.

FREQUENTLY ASKED QUESTION

What Is "Battery Density"?

Battery density refers to the amount of energy in kilowatt-hours (kWh) that a battery can store per kilogram of mass (kWh per kilograms) or volume (kWh per liter) of volume. The higher the number, the higher the energy density of the battery. ● **SEE CHART 89–2**.

BATTERY TYPE	ENERGY DENSITY (kWh/kg)	ENERGY DENSITY (kWh/L)
Lead–Acid	0.11–0.14	0.22–0.27
Nickel-Metal Hydride	0.36	1.44
Lithium Cobalt Oxide	0.70	2.0

CHART 89–2

The higher the number, the higher the energy density of the battery. Notice that the lithium-ion battery has the highest energy density compared to lead–acid and nickel-metal hydride batteries.

FREQUENTLY ASKED QUESTION

What Is a "Solid State" Battery?

Many manufacturers including Toyota are working on a solid-state battery that does not use a liquid or gel electrolyte. A prototype solid-state battery is said to use a lithium-nickel-manganese-cobalt cathode and a flexible ceramic separator. The lithium ions from the cathode create a metal film on the collector when charging. The advantages of a solid-state battery include a faster charging rate, lower weight, and higher capacity.

HEV/EV ELECTRONICS COOLING

NEED FOR COOLING Hybrid electric vehicles are unique in that they have electric motors and electronic controls that are not found in vehicles with conventional drivetrains. These components are designed to operate under heavy load with high current and voltage demands, so they tend to generate excessive heat during vehicle operation. Special auxiliary cooling systems are incorporated into hybrid electric vehicles to prevent overheating of these critical components and keep those components at efficient operating temperatures.

EFFECTS OF HEAT ON THE ELECTRICAL/ELECTRONIC SYSTEM Electronic components operate more efficiently as their temperature decreases, but can suffer permanent damage if they overheat. All hybrid electric vehicles have cooling systems for their motors and motor controls, and some use air-cooling to remove excess heat from these components. ● **SEE FIGURE 89–13**.

For example, a Chevrolet Bolt electric vehicle has two expansion valves in the A/C system. One is used to cool the passenger compartment and the other is used to cool the electronics and the high-voltage battery.

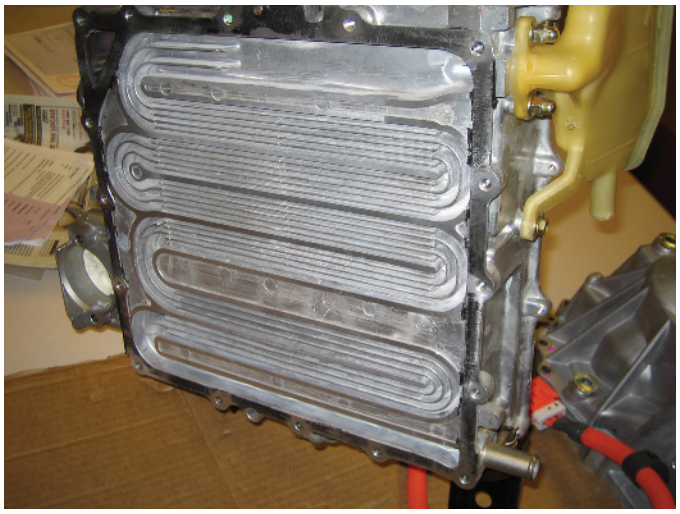

FIGURE 89–13 The underside of the Toyota Prius controller showing the coolant passages used to cool the electronic control unit.

Many hybrid electric vehicles use a liquid cooling system for their motors and motor controls. These systems are often separate from the ICE's cooling system and typically operate at lower temperatures.

SYSTEM CONSTRUCTION The liquid cooling systems used for the motors and motor controls on hybrid electric vehicles have much in common with conventional ICE cooling systems. There is a separate expansion tank that acts as a coolant reservoir for the system, and the coolant is often the same type that is used for the ICE cooling system. A radiator is used to dissipate excess heat and is located at the front of the vehicle. Some designs may have the radiator incorporated into the ICE radiator, or it may be separate. ● **SEE FIGURE 89–14**.

A low-voltage electric water pump is used to circulate the coolant, and it is often configured to run whenever the vehicle is in operation. The coolant is circulated through the various components in the system, which could include the following:

- Electric motor-generator(s)
- DC–DC converter
- Inverter
- Transmission oil cooler
- Other high-load control modules

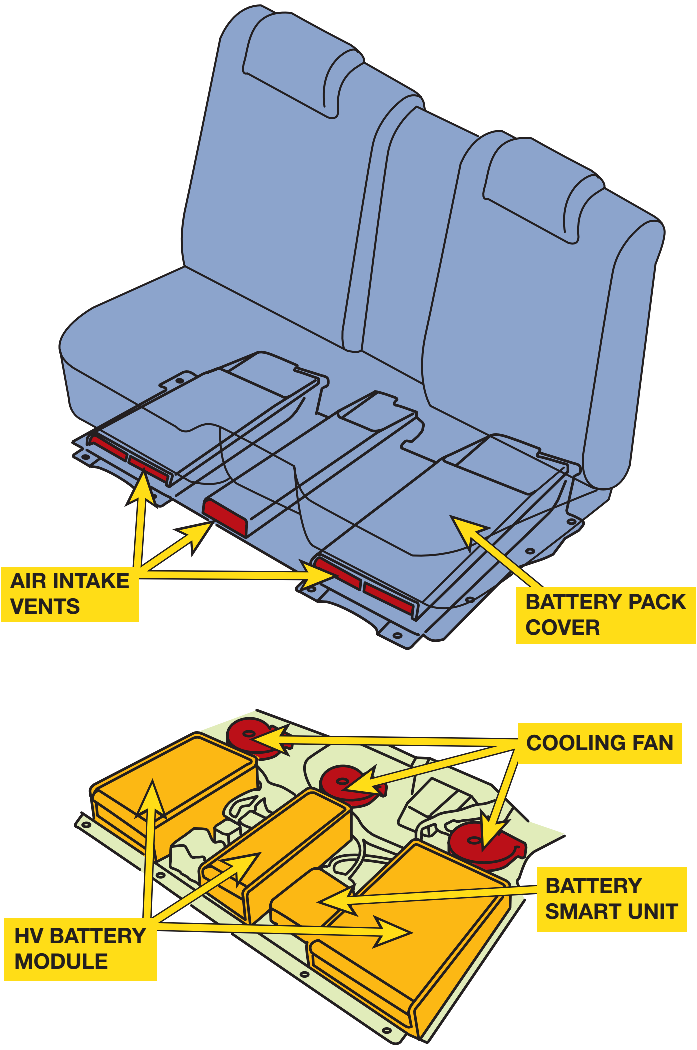

FIGURE 89–14 The motor and HV battery electronics on Toyota hybrid SUV.

FREQUENTLY ASKED QUESTION

Why Isn't the ICE Cooling System Used to Cool HEV Motors and Motor Controls?

Most ICE cooling systems operate at over 200 degrees F (93 degrees C). For maximum efficiency, it is important that the ICE operate at close to this temperature at all times. Electric motors and the motor controls, however, tend to operate more efficiently at lower temperatures. The ICE cooling system runs too hot to allow these components to operate at peak efficiency, so a separate low-temperature system is often used.

NOTE: The first- and second-generation Ford Escape Hybrid also uses a cabin filter in the auxiliary climate control (battery zone) system to prevent particulate matter from collecting on the traction battery cooling passages. ● SEE FIGURE 89–15.

HIGH-VOLTAGE BATTERY COOLING AND HEATING

THE NEED TO HEAT/COOL HV BATTERIES High operating temperatures can lower performance and cause damage to an NiMH or lithium battery pack. The cooling systems can be categorized as either air or liquid cooling systems. Most current production HEVs use air cooling to control HV battery pack temperature. Cabin air is circulated over the battery cells using an electric fan and ducting inside the vehicle. ● **SEE FIGURE 89–16**.

In some cases, the air-conditioning system has an extra zone that cools the air being circulated over the HV battery pack. The first- and second-generation Ford Escape Hybrid is an example of this type of system. ● **SEE FIGURE 89–17**.

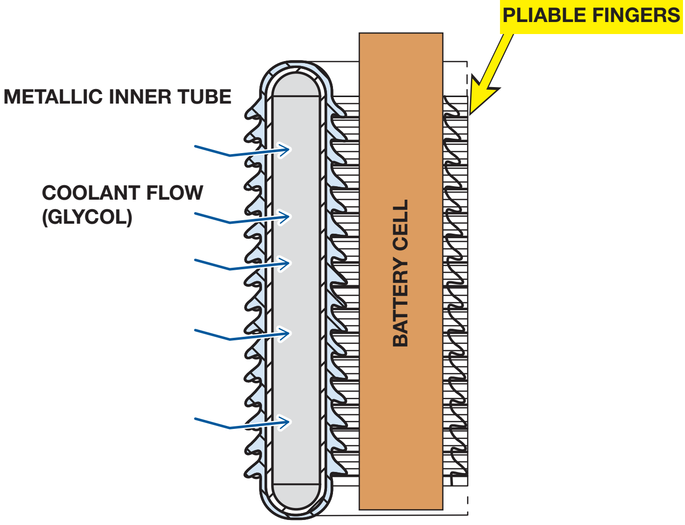

FIGURE 89–15 The electric motors and the motor controls are cooled using a separate cooling system. This Toyota Hybrid Synergy Drive (HSD) system uses a radiator that is integral with the ICE cooling system radiator.

Most current electric vehicles use a liquid cooling system. Coolant is circulated through a dedicated system that transfers battery heat to the outside air through a dedicated radiator. In a battery using prismatic cells, there is an aluminum cooling plate inserted between each pair of cells. A battery using cylindrical cells uses a ribbon-type tube between the cells.

Temperature sensors (thermistors) are mounted in various locations in the battery pack housing to send data to the module responsible for controlling battery temperature. These inputs are used to help determine battery charge rate and cooling system operation.

HIGH-VOLTAGE BATTERY COOLING SYSTEM SERVICE The service of high-voltage battery cooling systems falls into two main categories:

1. Service of the air distribution system
2. Service of the liquid system

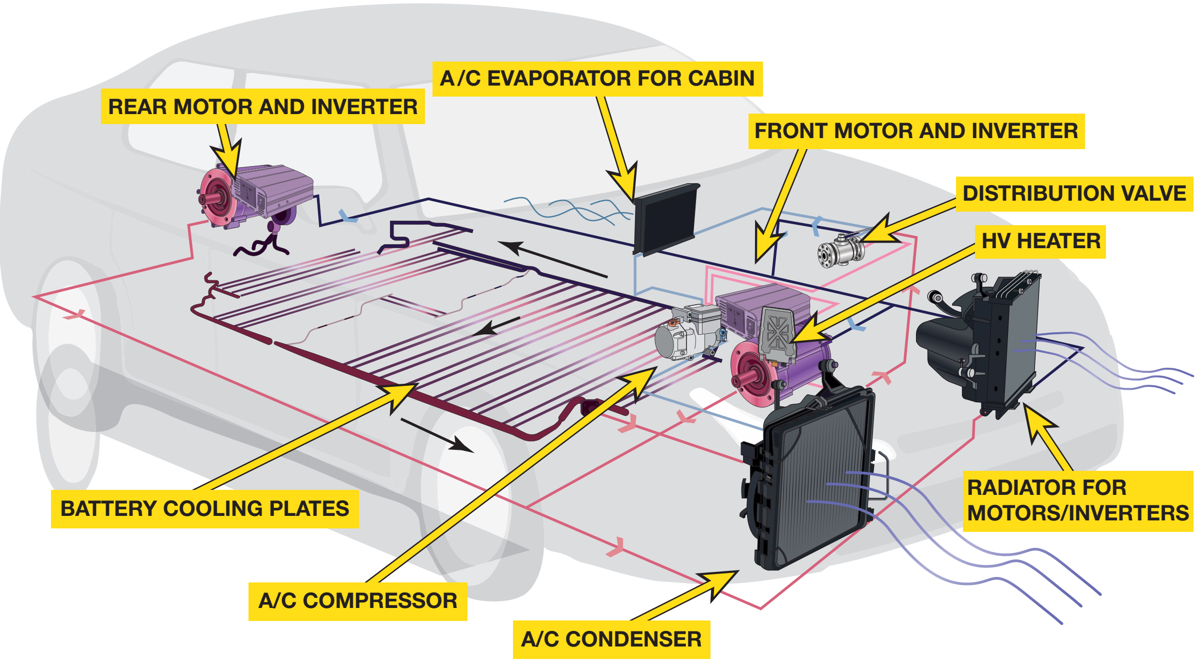

FIGURE 89–16 The battery and electronics are included as part of the temperature control system.

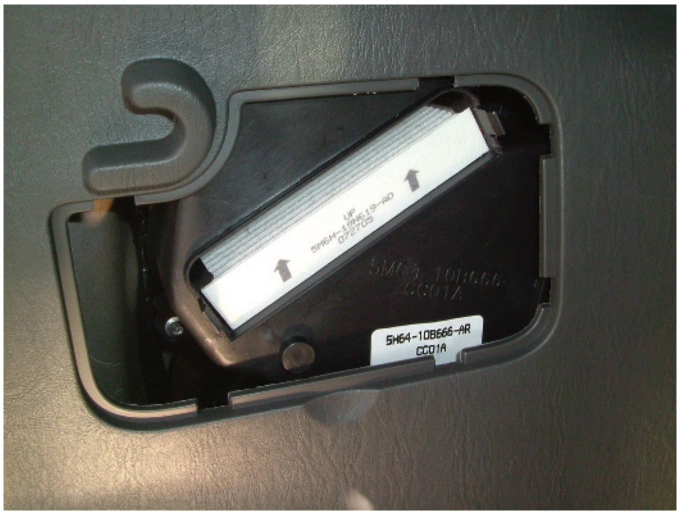

FIGURE 89–17 The HV battery cooling system from a Ford Escape Hybrid. Ford uses outside air to cool the battery pack, then increases cooling with a separate zone in the A/C system when necessary. The battery zone filter was only used on a first generation Ford Escape Hybrid.

The service of the air distribution system is similar to HVAC systems. The blower motor must be operational and the fan must be free of debris. The air intake inlets must be inspected and found to be free of anything that would restrict airflow. If the system has a dedicated cabin filter, it must be replaced at the specified interval.

The service of the liquid cooling system is similar to a conventional cooling system. On a regular basis the cooling system level must be checked to ensure there are no leaks and the freeze protection and pH level should be checked with a refractometer or test strip. The coolant should be replaced at the specified service interval using the recommended replacement coolant. The electric water pump must be inspected for proper operation. This is verified by actuating the pump with a factory-level scan tool. The dedicated radiator needs to be checked for airflow obstructions and for proper cooling fan operation.

EV BATTERY HEATER The electric vehicle battery heating methods include heater pads that are typically 0.011 inch (0.28 mm) thick and can be applied between cells, wrapped around cells, or modules bonded to the surface of a cold plate directly under a module. The pads ensure quicker time to temperature while achieving better uniformity from cell to cell, and function as a dielectric barrier between cells/modules/plates with minimal impact on cooling performance.

NOTE: A water-cooling system for Hyundai and Kia's EV battery packs, rather than air cooling, have yielded further increases in range because water-cooling channels take up less space than air-cooling channels, increasing battery density by up to 35%.

BATTERY CAPACITY VS VEHICLE RANGE

ICE VEHICLE MILEAGE In the United States, fuel economy for an internal combustion engine (ICE) vehicle is expressed in miles per gallon (MPG). Outside of the United States, fuel economy is measured in the number of liters of fuel needed to travel 100 kilometers (62 miles), abbreviated L/100 km. This means that as the number increases, the fuel economy decreases. In the metric system, the fuel is measured; in the United States, the miles are measured.

EPA VS WLTP In the United States, the Environmental Protection Agency (EPA) estimates electric vehicle range, while in Europe electric vehicle range uses the **Worldwide harmonized Light vehicles Test Procedure (WLTP)**. When the range is expressed using the WLTP standard, drivers can convert it to approximate EPA range estimates by dividing the WLTP value by 1.12. However, the EPA range is in fact just an estimate and real-world range can be different.

EV EQUIVALENT ECONOMY A kilowatt (kW) is a rate of energy flow similar to the gallons per minute that a water hose or pump can deliver. A kilowatt-hour (kWh) is a quantity of electricity, similar to what a gallon is with water. A bigger battery pack with a higher number of kWh will hold more electricity, just as a bigger bucket will hold more gallons of water.

With an electric vehicle, how far it can travel is measured in *miles per kilowatt-hours.* A typical electric vehicle can travel about 3 to 4 miles per kilowatt-hour of battery capacity. The larger the battery in kWh, the greater the range, like an ICE vehicle that has a larger fuel tank capacity.

To help consumers compare the energy consumption of electric vehicles with those that run on fossil fuel, the EPA created a miles-per-gallon measurement, called **MPGe**. This is calculated based on a conversion factor of 33.705 kilowatt-hours of electricity equaling one gallon of gasoline. Therefore, a battery that has a capacity of 100 kWh is equal to the energy of about three gallons of gasoline.

FREQUENTLY ASKED QUESTION

What Is a "Guess-O-Meter"?

The dash display that shows the miles per kWh is often called a **Guess-O-Meter (GOM)** because it is often not accurate. Good numbers for miles per kWh are 4.3 to 4.9 miles of travel for each kWh consumed. It can be used to help plan a trip. For example, if the GOM indicates the battery capacity is 60 kWh in the battery, this usually means the vehicle can travel about 235 miles, so plan on charging at about 200 miles. ● **SEE FIGURE 89–18**.

TECH TIP

The Rule of Thumb Is 3

To help estimate the range of an electric vehicle (EV), multiply the battery capacity in kilowatt-hours (kWh) by three to get a good idea as to the range of the vehicle. For example, a Tesla Model 3 has a battery capacity of 75 kWh and when multiplied by 3 equals 225 miles ($75 \times 3 = 225$).

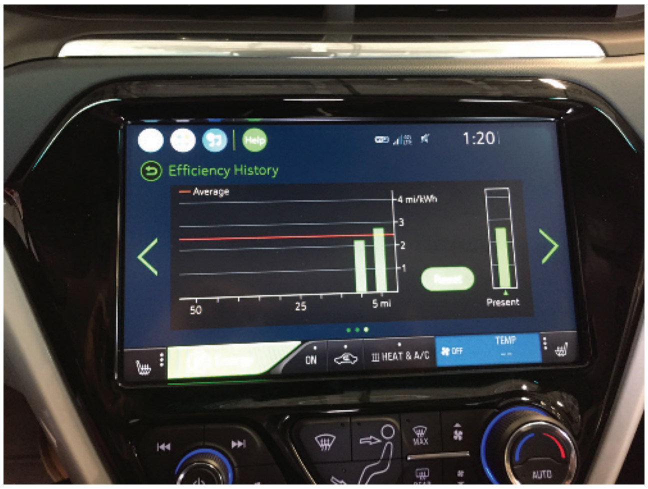

FIGURE 89–18 The dash display on a Chevrolet Bolt indicates the miles per kWh, which may or may not be accurate. Because the displayed estimated range varies, it is often referred to as "Guess-O-Meter."

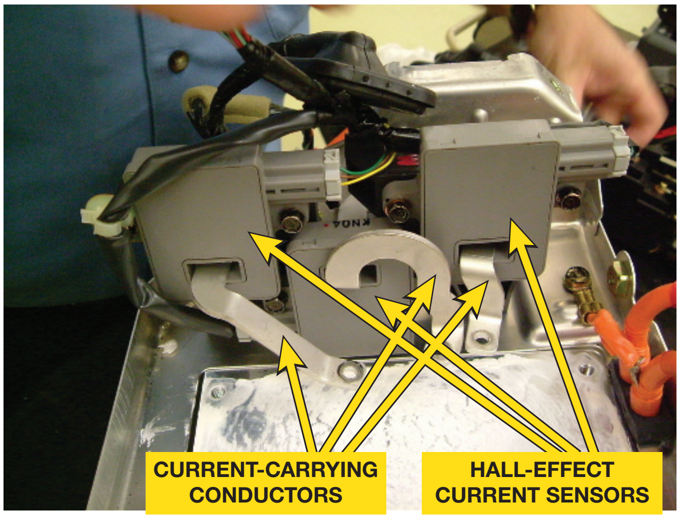

FIGURE 89–19 The three legs of the brushless motor run through three Hall-effect-type current sensors. The conductors used in the Honda unit are flat aluminum and attach to the motor controller terminals.

HIGH-VOLTAGE BATTERY CONTROL COMPONENTS

BATTERY CONTROL MODULE

The **battery control module (BCM)** is responsible for controlling the operation of the high-voltage battery based on the requests from the hybrid control module. The BCM monitors the voltage blocks, the current sensor, and temperature sensors to determine the need for charging. The BCM communicates with the other vehicle modules on the CAN BUS network and its data is accessible with a scan tool.

SYSTEM MAIN RELAYS (SMRs)

System Main Relays (SMRs) are heavy duty relays that control the high-voltage circuit between the battery and the other components of the high-voltage system. SMRs are often referred to as contactors. Depending on the design of the battery control system, the battery will contain one to three SMRs. The battery control module controls the low-voltage side of the SMR. When the load side of the SMR closes, high-voltage current is allowed to flow from the battery. In a three SMR system design, one SMR controls the positive circuit and two SMRs control the negative circuit. On the negative side, one SMR is in-series with a high-wattage resistor that pre-charges the system capacitors. To allow current to flow:

- The BCM will first close the SMR for the positive cable.
- The BCM will close the SMR with the resistor on the negative cable. This will reduce the initial current flow to the system capacitors and also reduce the possibility of arcing across the high-current SMR contacts.
- The BCM will then close the second SMR on the ground cable and open the SMR in-series with the resistor. This will allow for full current flow.

CURRENT SENSORS

The current sensor is used to measure the current flowing into the battery during charging and is used to measure current flowing out of the battery when it is discharging. The sensor may be mounted on the positive or the negative cable based on design. This data is combined with individual cell temperature and voltage to provide an overall state-of-charge (SOC) of the battery. The sensor will be either a Hall-effect design or a shunt, depending on the manufacturer and the design of the system. The BCM will set a fault code if the senor becomes open, shorted, or if the current running through the sensor becomes abnormally high or low. ● **SEE FIGURE 89–19**.

VOLTAGE BLOCK MONITORING CIRCUITS

Each cell block, which consists of multiple battery cells, is monitored by the BCM for voltage level. These are low-voltage circuits that allow the BCM to flag a group of cells that are out of range when compared to the cell groups in the battery. A variance of 0.3 volts between cell groups is allowed. Any variance of measured voltage that is greater than 0.3 volts will set a fault code. This condition could be as a result of a bad cell or an imbalance condition.

TEMPERATURE SENSORS

Temperature sensors are used to measure the temperature of the battery cells and temperature of the air entering the pack if a forced air system is used to cool the battery. The primary use of this data is to control the fan speed of the blower used to cool the battery. The data is also used in the calculation of the battery state-of-charge (SOC). The sensors are PTC thermistors so the higher the battery temperature, the lower the resistance of the sensor. ● **SEE FIGURE 89–20**.

NOTE: The General Motors electric vehicles using the Ultium batteries incorporate a wireless transmitter connected to the battery cells. Instead of running wires from each battery cell to the battery control module, the wireless system reduces the number of wires and connections.

HV DISCONNECT

The purpose of the HV battery disconnect switch is to remove power from the high-voltage system prior to repairs. When removing the HV disconnect switch, personal protective equipment (PPE) must be worn to protect against electrocution. Many HV disconnect switches contain a high-voltage fuse. Most HV disconnect switches also contain a low-voltage monitoring circuit. Failure to properly install and latch the HV disconnect switch will result in a no-start or failure to power-up condition. ● **SEE FIGURE 89–21**.

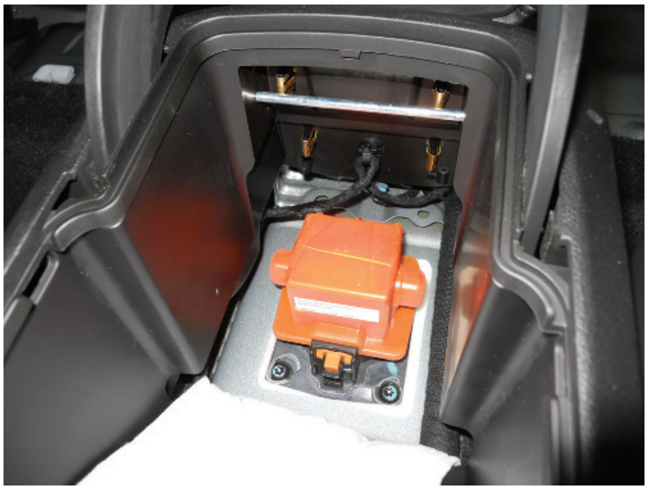

FIGURE 89–21 The battery disconnect on a Chevrolet Volt is located under the center console.

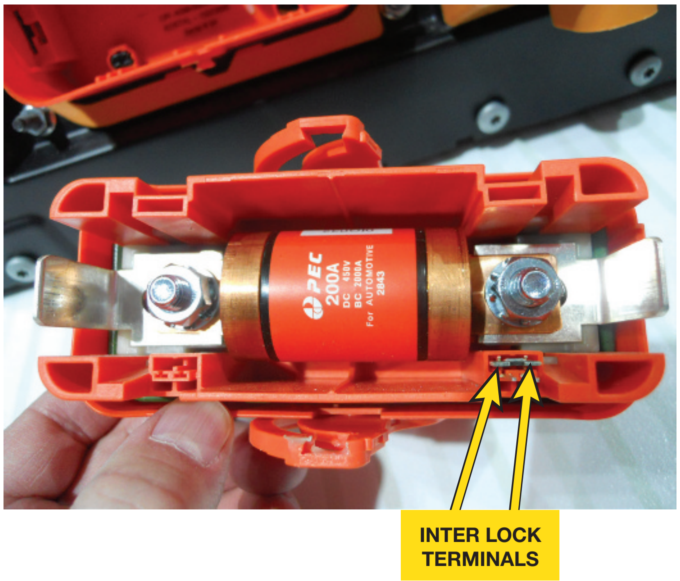

FIGURE 89–22 The HV disconnect plug has two small terminals used to signal the HV controller that the safety/service plug has been removed.

BATTERY MANAGEMENT SYSTEM (BMS) The battery cells or modules need to be monitored and controlled for temperature and voltage. The **battery management system (BMS)** is an electronic system that manages cells in a battery pack. The BMS monitors and controls

- State-of-charge (SOC)
- State of health (SOH)
- State of function (SOF)
- Safety and critical safeguards
- Temperature
- Load balancing/individual cell efficiency

The BMS receives inputs from voltage and temperature sensors in the modules. In some packs, the BMS may also provide outputs to drive other components, such as fans, pumps, or valves for the battery cooling system. External connectors enable robust and safe connection between the battery pack and other vehicle systems.

ELECTRICAL DISTRIBUTION SYSTEM (EDS) The primary function of the **Electrical Distribution System (EDS)** is to provide the electrical conduction path through the battery pack and includes the following features:

- Isolates the conduction path
- Measures current and voltage in the high-voltage (HV) line
- Provides pre-charge function when energizing the HV line
- Fuses the HV line in case of over-current
- Provides manual disconnect of the HV line for vehicle servicing
- Monitors effectiveness of the electrical insulation

The low-voltage (LV) wiring provides power for the battery control functions and allows communication between the battery and vehicle (CAN protocol). The LV wiring is also used to confirm all external connectors are correctly in place, and to ensure that HV conductors cannot be contacted externally. ● **SEE FIGURE 89–22**.

ISOLATION TESTING The high-voltage system is completely isolated from the vehicle. A loss of isolation in the high-voltage system will result in a vehicle that will not power-up to the ready mode and set a series of diagnostic trouble codes. Some vehicles will set additional information codes that will help to identify the area where the loss of isolation has occurred.

To verify the loss of isolation has occurred, a meg ohm meter is used to perform the isolation test. The use of class 0 high-voltage safety gloves is required when performing this

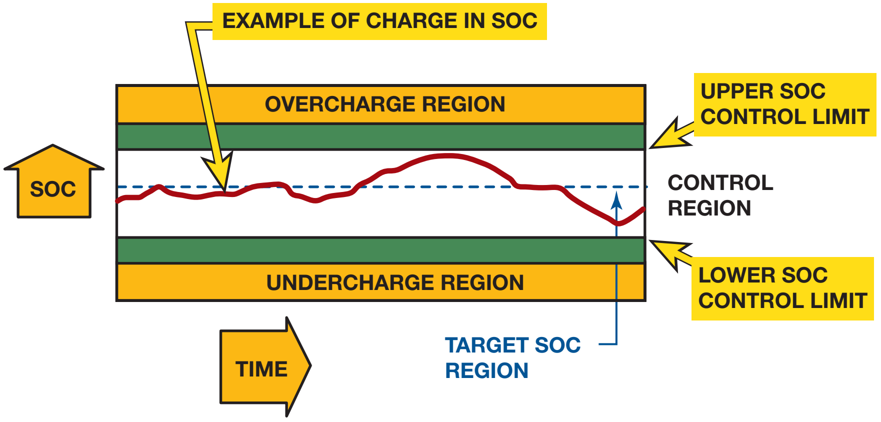

FIGURE 89–23 The HV battery pack SOC is maintained in a relatively narrow range to prevent overheating and maximize service life.

test. With the high-voltage battery disconnected, the meg ohm meter is connected between the high-voltage system and chassis ground. During the test, the meter will charge its internal capacitor to up to 1,000 volts and measure the resistance between the high-voltage system and chassis ground. If continuity is detected, the loss of isolation needs to be identified and repaired. The system should be tested again after the repair is complete to verify the repair was successful.

STATE-OF-CHARGE MANAGEMENT The HV battery in a hybrid electric vehicle (HEV) is subjected to constant charging and discharging during normal operation. The battery can overheat under the following conditions:

- The battery state-of-charge rises above 80%.
- The battery is placed under a load when its SOC is below 20%. In order to prevent overheating and maximize service life, the battery SOC must be carefully managed. In most hybrid-electric vehicle applications, a target SOC of 60% is used, and the battery is then cycled so its SOC varies no more than 20% higher or lower than the target. ● **SEE FIGURE 89–23**.

NOTE: The Chevrolet Volt is designed to allow the state-of-charge to drop to 25–35% before the gasoline engine is started to maintain that level of state-of-charge. The cooling system and software are designed to allow this reduced SOC so that the vehicle can be driven for an extended distance without having to start the engine.

HEV HIGH-VOLTAGE BATTERY MONITOR The HV battery pack controller monitors the state-of-charge.

- During acceleration, the battery pack state-of-charge (SOC) may drop slightly, and rise when the vehicle decelerates as a result of regenerative braking, which charges the HV battery.
- Scan data displays charge and discharge levels. Normal operating HV battery SOC range for most hybrid electric vehicles is within 52–68%.
- When the SOC drops to 50%, the ICE starts to recharge the HV batteries. This means that the idle stop (start-stop) function is disabled if the SOC is at or below 50%, and will resume after it reaches 52% or higher in most cases. ● **SEE FIGURE 89–24**.
- If the SOC reaches 80% or higher, the regenerative braking stops. This means that during vehicle braking when the SOC is high, a harder than normal brake pedal effort is often noticed.
- Reduction of electric traction motor power occurs when the state-of-charge falls to 40%. If the ICE does start, there will be little or no electric assist from the electric traction motor. This will likely only occur if the vehicle runs out of fuel for the ICE and the vehicle operates on electric power alone. However, the main warning light will be on and the system will set and store multiple diagnostic trouble codes (DTCs) if this happens.

2013 Lexus GS 450h 3.5L V6 MFI Hybrid (2GR-FXE) 02:36PM

Battery Data - Internal Resistance R01(ohm) 743 / 2000

Battery Block Vol -V14(V)	20.56
Internal Resistance R01(ohm)	0.029
Internal Resistance R02(ohm)	0.028
Internal Resistance R03(ohm)	0.028
Internal Resistance R04(ohm)	0.029
Internal Resistance R05(ohm)	0.029
Internal Resistance R06(ohm)	0.029

FIGURE 89–25 The internal resistances of the battery blocks are available on the data stream as shown using an aftermarket scan tool. The internal resistance should be between 15 and 40 milliohms (0.015 to 0.040 ohms).

TECH TIP

Check State-of-Charge First

If a hybrid vehicle owner complains of a lack of power on acceleration, check the state-of-charge (SOC) first. There may be nothing wrong with the traction motor or its controller. It may be simply that the HV battery pack is not within a normal state-of-charge, usually due to a fault with the battery pack or related electrical connections.

SCAN DATA TEST PROCEDURE Connect the scan tool and select the vehicle, and then select the following parameter identification (PID) items:

- State-of-charge
- Battery temperature
- Battery voltage
- Battery current draw
- Check the battery block internal resistance as displayed on a scan tool for Toyota/Lexus HEVs. Normal internal resistance is 15 to 40 milliohms (0.015 to 0.040 ohms).

  ● **SEE FIGURE 89–25**.

LITHIUM-ION BATTERY REPAIR

PURPOSE Some original equipment manufacturers (OEMs) are replacing defective high-voltage battery components rather than replacing the entire battery. This reduces the amount of time the vehicle is in a non-drivable condition and it reduces the cost of the repair. Included in the list of replaceable components is the high-voltage battery module.

PROCEDURE A typical example of a factory-authorized procedure that addresses failed high-voltage battery modules used by Nissan/Infinity on specific hybrid and electric vehicles includes a battery cell replacement as determined by a diagnostic trouble code. A P3374 DTC indicates that a cell is more than 100 mV lower than other cells. The scan tool data indicates that cell #27 was more than 100 mV lower than the rest of the cells. ● **SEE FIGURE 89–26**.

Before the battery is removed, it is essential that all the required tools are available. The specified tools include the required PPE, insulated tools, and the module balance adjuster tool. The procedure includes the following steps:

STEP 1 Following the service procedures and observing all high-voltage cautions, the battery should be removed from the vehicle and made ready for repair.

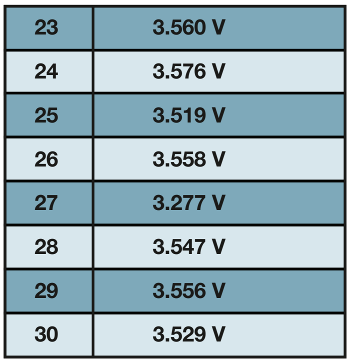
STEP 2 Using the service information, identify the location of the defective module within the pack.

STEP 3 Remove the battery covers, the controller, and other components needed to access the battery modules as described in the service procedures. ● **SEE FIGURE 89–27**.

STEP 4 Prior to completing the final disassembly of the battery, all module voltages must be measured using a digital multimeter to determine the module charge balance of the battery. This data will be used to determine the adjustment voltage for the replacement module.

STEP 5 The new replacement battery module must be installed in the module charge balancer, and the adjustment voltage must be entered into the charger. This will allow the charge to be adjusted to match the rest of the battery.

STEP 6 The defective module can now be removed and the new module installed.



23	3.560 V
24	3.576 V
25	3.519 V
26	3.558 V
27	3.277 V
28	3.547 V
29	3.556 V
30	3.529 V

FIGURE 89–26 The scan tool data indicates that cell #27 was a lot lower than the rest of the cells, which indicates a problem and the reason for the diagnostic trouble code to be set.

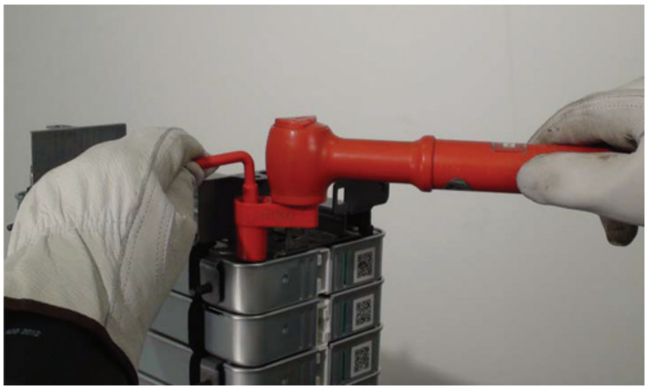


FIGURE 89–27 Whenever working on any potential high-voltage components, always follow the recommended safety procedures including using insulated tools and rubber gloves.

STEP 7 Reinstall all parts that have been removed during the disassembly process and make the battery ready for reinstallation.

BATTERY DEGRADATION AND BALANCING

RATE OF DEGRADATION Most HV batteries will outlast the usable life of the vehicle. However, some factors that affect battery life and the rate of degradation include the following:

- The average decline in energy storage is 2.3% per year.
- EV batteries decline in a non linear fashion, which means that at the beginning of the battery life, there is an early drop, but the rate of decline slows down in subsequent years.
- Liquid-cooled batteries decline slower than air-cooled packs. For example, a liquid-cooled EV has an average annual degradation rate of 2.3%, compared to an air-cooled EV rate of 4.2%.
- Higher vehicle use does not necessarily equal higher battery degradation.
- Vehicles driven in hot temperatures show a faster decline in battery health.
- The use of DC fast-chargers speeds up the process of degradation, but there is not much difference in battery health based on frequent use of Level 1 versus Level 2 charging. Losses that happen with frequent DC charging are made worse in hot climate conditions.

PASSIVE AND ACTIVE CELL BALANCING Long battery life requires that the electronics in the vehicle perform passive and active battery cell balancing.

- **Passive balancing** is achieved by having energy drawn from the most charged cell and dissipated as heat, usually through resistors. Passive balancing allows the stack to act as if every cell has the same capacity as the weakest cell. Using a relatively low current, it drains a small amount of energy from high SOC cells during the charging cycle so that all cells charge to their maximum state-of-charge (SOC).
- **Active balancing** is achieved when energy is drawn from the most charged cell and transferred to the least charged cells, usually through DC–DC converters.

NORMAL OPERATION During normal vehicle operation, the charge and discharge cycles of the high-voltage battery in an HEV are monitored and controlled by the battery management system (BMS). This module monitors battery temperature, current, and voltage to calculate SOC and determine at what rate the battery should be charged. While dealerships sometimes have a special high-voltage battery charger for recharging HEV battery packs, the best charger is the vehicle itself. If the HV battery in an HEV becomes discharged, the first step should be getting the vehicle started to recharge the battery pack. The procedure will vary depending on the model in question. Always follow the manufacturer's specified procedures when starting a disabled hybrid vehicle.

CASE STUDY

The Case of the Broken Prius

The owner of a Prius complained that "the engine never shuts off" and fuel economy has dropped to as low as 25 MPG instead of the normal 40+ MPG. By "never shuts off," the customer means that the idle stop (auto start/stop function) is suspended. The master warning light was also on, indicating a serious problem has been detected. The technician used a scan tool and retrieved the following diagnostic trouble codes (DTCs):

- P0A80—The difference in voltage between two of the blocks in the battery pack is too high.
- P3006—Uneven state-of-charge.

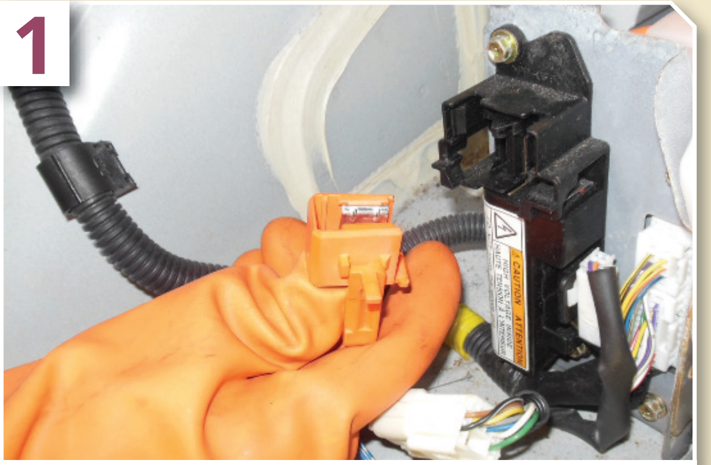
Scan tool data showed battery block voltages reading ranging from 4.65 to 15.01 volts. Generally, if a battery block is under 7.5 volts, it cannot be restored to useful service. Even if it can be charged, the module will have a short service life. The shop recommended, and the customer approved, a replacement reconditioned battery pack supplied by a nationally known company. The battery pack was replaced and the vehicle was restored to normal operation and fuel economy.

Summary:

Complaint—The owner of a Prius complained of reduced fuel economy.
Cause—The difference in voltage between two of the blocks in the battery pack is too high.
Correction—The battery pack was replaced and the vehicle was restored to normal operation and fuel economy.

PHOTO SEQUENCE HEV-HV BATTERY INSPECTION AND TESTING STEP BY STEP

1

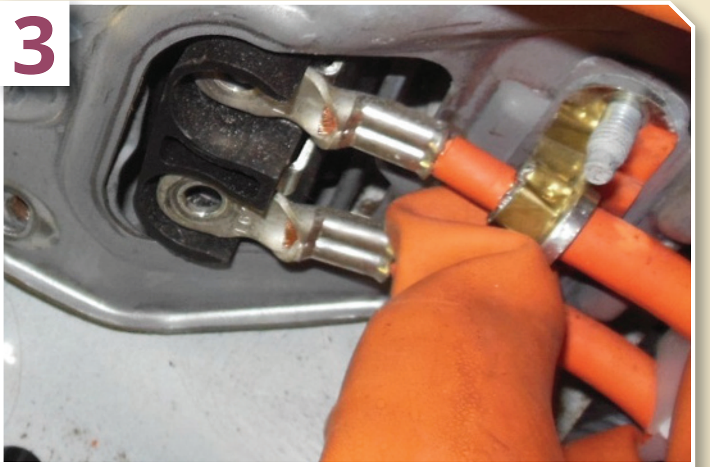


To depower the high-voltage system, the ignition was off and the negative battery cable was disconnected from the 12-volt auxiliary battery, then the HV battery safety plug was removed.

2

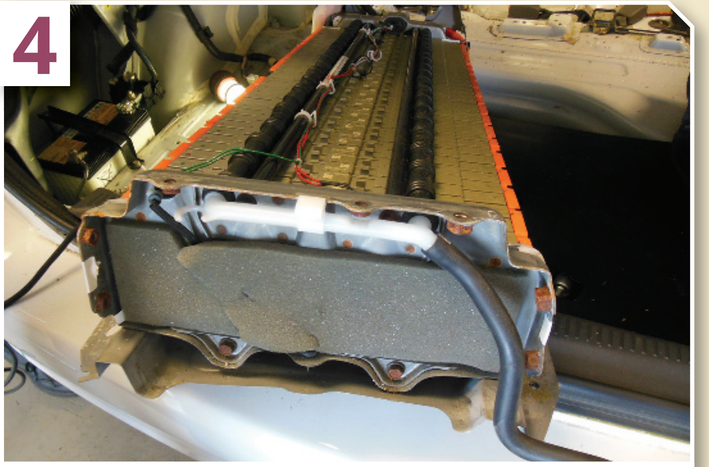
After checking that the voltage level is safe, the rear seat and HV battery cover were removed. Always follow the safety procedures specified by the manufacturer for the vehicle being serviced and adhere to all safety warning and precautions.

3



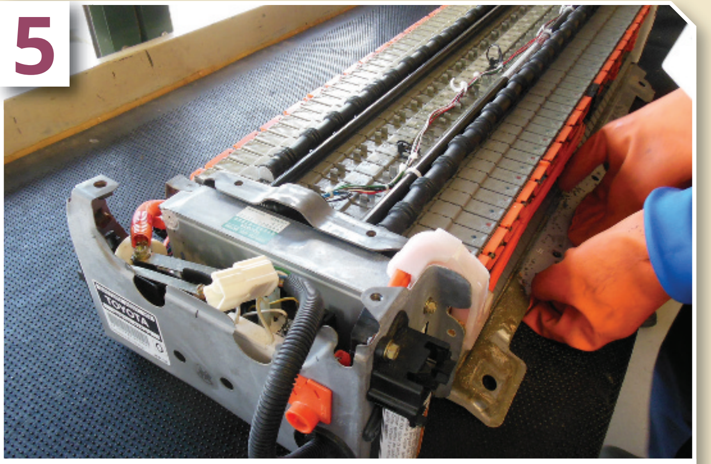
The high-voltage wires were removed from the battery pack while wearing HV gloves.

4



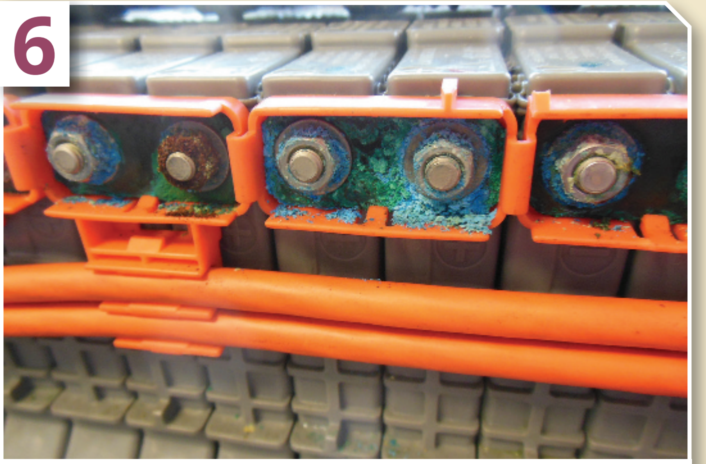
The HV battery pack is being removed through the rear of the vehicle.

5



The HV battery pack is placed on a workbench that is covered with a thick rubber (insulating) mat. A wood top bench can also be used.

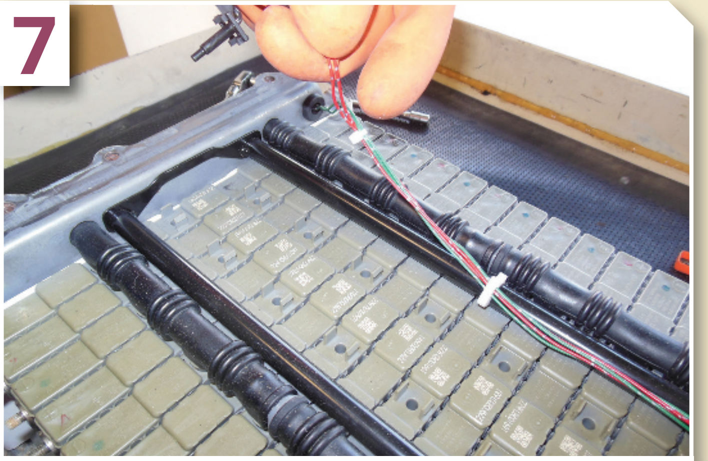
6



A visual inspection shows that many electrical connections between battery modules are corroded.

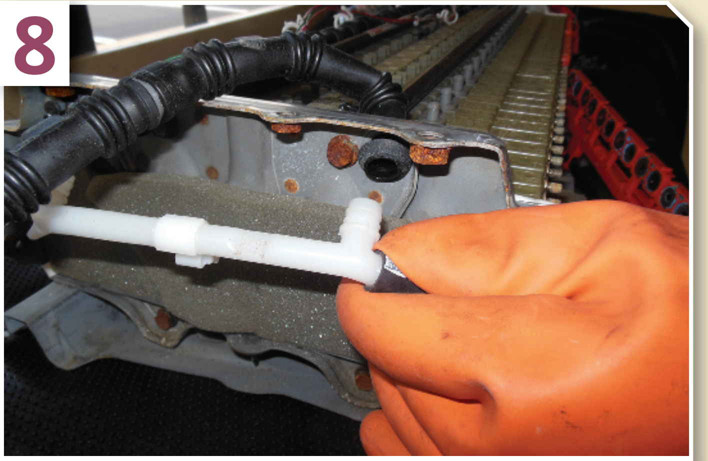
PHOTO SEQUENCE HEV-HV BATTERY INSPECTION AND TESTING

7



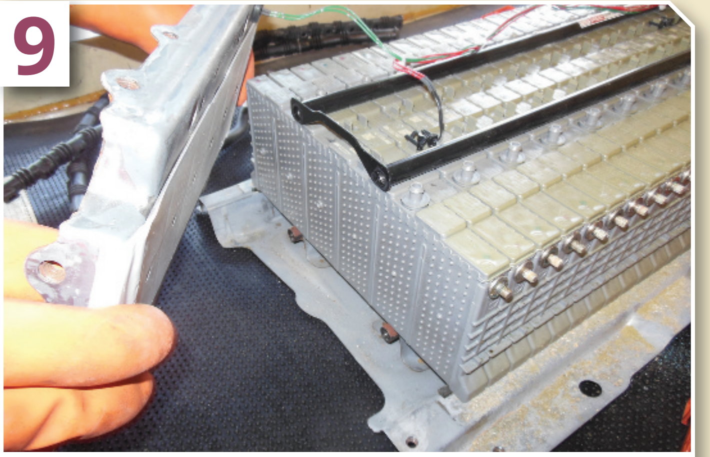
The HV battery pack temperature sensors are removed.

8



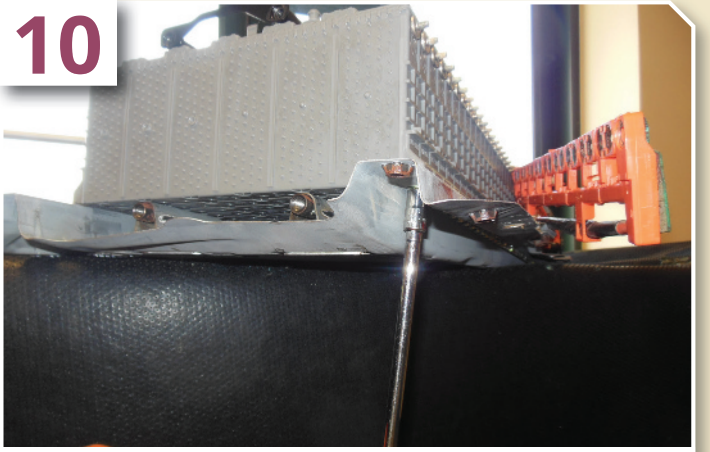
The HV battery vent tubes are removed from the battery pack.

9



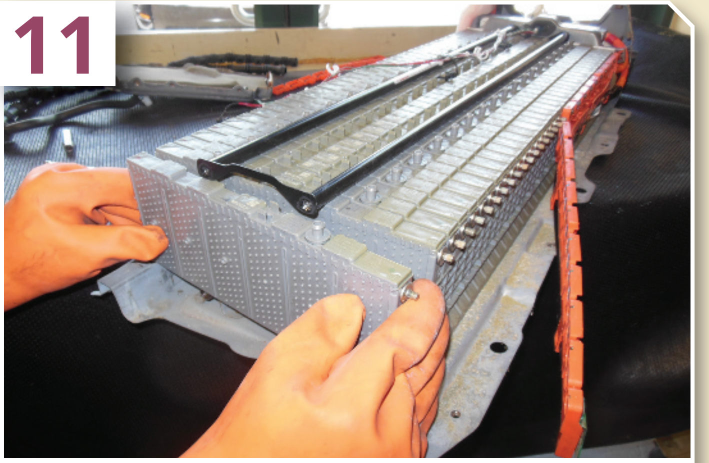
The end caps are removed from the battery pack.

10



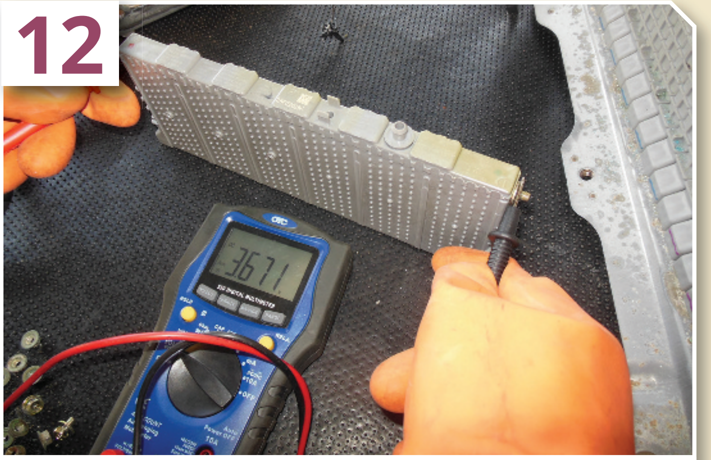
The fasteners that hold the battery modules to the base of the battery pack are removed.

11



The end module is being removed from the battery pack.

12



The individual modules were measured using a voltmeter and most modules were found to be about 3.6 volts, which is far below the minimum of 5.4 volts that most experts think can be restored by charging.

REVIEW QUESTIONS

1. Why do high-voltage batteries need to be heated if cold or cooled if hot?
2. What advantages do lithium-ion batteries have comparted to NiMH batteries?
3. What is the primary function of the Electrical Distribution System (EDS)?
4. What are the steps involved to address failed high-voltage battery modules?
5. What occurs if the state-of-charge exceeds 80%?

CHAPTER QUIZ

1. High-voltage batteries are used in ___________
   - **a.** hybrid electric vehicles
   - **b.** battery electric vehicles
   - **c.** ICE vehicles
   - **d.** Both a and b
2. The nominal voltage of an NiMH battery cell is ___________.
   - **a.** 1.2 volts
   - **b.** 3.2 volts
   - **c.** 3.6 volts
   - **d.** 4.8 volts
3. A lithium-ion cell produces ___________ per cell.
   - **a.** 1.2 volts
   - **b.** 3.2 volts
   - **c.** 3.6 volts
   - **d.** 4.8 volts
4. Electronic components operate more efficiently as their temperature ___________.
   - **a.** increases
   - **b.** decreases
   - **c.** remains constant
   - **d.** changes from hot to cold rapidly
5. Lithium-ion cells can be ___________.
   - **a.** cylindrical cell
   - **b.** prismatic—hard case
   - **c.** prismatic—pouch type
   - **d.** Any of the above
6. An electric vehicle can travel ___________ miles per killowatt-hour.
   - **a.** about 10 to 12
   - **b.** about 3 to 4
   - **c.** about 100 or more
   - **d.** less than 2
7. In most hybrid electric vehicle applications, a target SOC of ___________ is used, and the battery is then cycled so its SOC varies no more than ___________ higher or lower than the target.
   - **a.** 100%; 50%
   - **b.** 80%; 20%
   - **c.** 70%; 50%
   - **d.** 80%; 40%
8. In a three SMR system design, one SMR controls the positive circuit and two SMRs control the negative circuit. On the negative side an SMR is in-series with a(n) ___________.
   - **a.** capacitor
   - **b.** resistor
   - **c.** diode

Chapter 90

EV AND PHEV CHARGING

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe plug-in hybrid electric vehicles (PHEVs).
- Explain how the high-voltage batteries are recharged in an electric vehicle (EV), including battery capacity, and range correlation.
- Discuss Level 1 charging.
- Discuss Level 2 charging.
- Discuss Level 3 charging.
- Discuss owning and charging an electric vehicle (EV).

KEY TERMS:

Always Be Charging (ABC) 1047 • Battery electric vehicle (BEV) 1044 • Combo Charging System (CCS) 1048 • DCFC (DC Fast Charge) 1047 • Destination charging 1050 • Electric vehicle (EV) 1044 • EV range 1042 • kilowatt-hour (kWh) 1042 • kWh/100 mi 1045 • Miles per hour (MPH) 1046 • Public Charging Stations (PCS) 1049 • Plug-in hybrid electric vehicle (PHEV) 1042 • Range per hour (RPH) 1046 • Range anxiety 1045 • State-of-charge (SOC) 1043 • Time-of-use (TOU) 1049 • Work place charging (WPC) 1049 • Zero-emission vehicles (ZEVs) 1044

PLUG-IN HYBRID ELECTRIC VEHICLES

TERMINOLOGY A **plug-in hybrid electric vehicle (PHEV)** is a vehicle that is designed to be plugged into an electrical outlet at home, at work, or when traveling to charge the batteries. By charging the batteries in the vehicle, it can operate using electric power alone (stealth mode) for a longer time, thereby reducing the use of the internal combustion engine (ICE). The less the ICE is operating, the less fuel is consumed, which lowers the emissions of the vehicle. Some PHEVs offer the driver an option to use the ICE first and switch to EV mode (electric only) later in the trip. This option is commonly used where the driver is first traveling on the highway and uses the ICE to propel the vehicle, saving the energy in the battery to be used when arriving in the city.

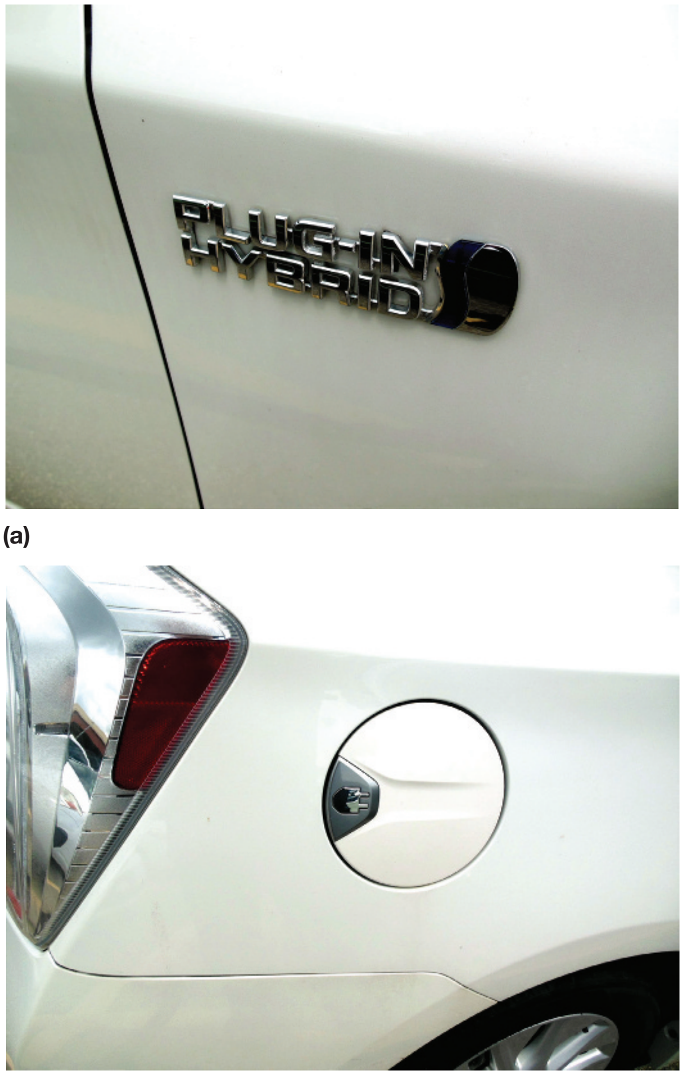
IDENTIFYING A PHEV Many PHEV are built using a conventional or a hybrid-electric vehicle (HEV) configuration with just added battery capacity. As a result, some PHEVs may be difficult to pick out, such as the plug-in version of the Toyota Prius. Features that identify a plug-in version of an HEV include the following:

- Different badges (usually stating that it is a PHEV, sometimes including PHEV on the badge).
- An access door for the charging cable in addition to the normal ICE fueling door.
- A different instrument panel cluster.

● **SEE FIGURE 90–1**.

The operation of the plug-in version is the same as the HEV version of the same vehicle, so from a service or maintenance point of view, it does not really matter whether it is a PHEV or an HEV.

PHEV BATTERY CAPACITY The size or capacity of the battery pack used determines how far that the vehicle can travel without using the ICE, commonly called the **EV range**. Battery capacity is measured in **kilowatt-hour (kWh)**. A kilowatt is 1,000 watts and a watt is a volt times an ampere, which is a measurement of electrical power. The higher the kWh rating of the battery, the more electrical energy it can store.



(a)

(b)

FIGURE 90–1 (a) About the only way to tell a plug-in Prius from a regular Prius is from the badge on the sides or (b) by the charge port door on the passenger side at the rear.

- A lower kilowatt-hour (kWh)-rated battery weighs less and is less expensive, but the range that the vehicle can travel on battery power alone is limited.
- A higher kWh rating battery means that the battery is capable of propelling the vehicle for a greater distance before the ICE is used. This reduces the fuel used, but the larger battery weighs and costs more.
- The high-voltage battery is continuously checked for state-of-charge. The **state-of-charge (SOC)** is the percentage of the available capacity that can be stored in a battery. A battery that has a state-of-charge of 100% is fully charged.

Therefore, a plug-in vehicle is a compromise between cost and weight of the battery.

PHEV EXAMPLES A standard Toyota Prius has a 1.3 kWh battery pack, whereas the plug-in version has a larger 4.4 kWh battery, allowing electric-only travel of about 10 miles before the ICE is used. When the battery pack state-of-charge has been depleted, the vehicle operates as a standard HEV with the ICE and electric motor both used to propel the vehicle.

RESERVED FOR
CHARGING
ONLY

FIGURE 90–2 Chevrolet Volt extended range electric vehicle (EREV), also called a plug-in hybrid electric vehicle (PHEV), being charged at a row of charging stations at the Corvette assembly plant in Blowing Green, KY.

VEHICLE MAKE AND MODEL	BATTERY CAPACITY
BMW i8	11 kWh
Chevrolet Volt	16 kWh
Ford C-Max Energi	7.6 kWh
Ford Fusion Energi	7.6 kWh
Honda Accord PHEV	6.7 kWh
Porsche Cayenne PHEV	9.4 kWh
Porsche Panamera S PHEV	9.4 kWh
Toyota Prius PHEV	4.4 kWh
Toyota RAV4	8.1 kWh
Volvo XC60/XC90	11.6 kWh
VW Golf PHEV	8.8 kWh

CHART 90–1

The higher the capacity of the HV battery, the further the vehicle can travel using electric power only; it takes longer to be fully charged when plugged into a charger.

A Chevrolet Volt has a larger 16 kWh battery pack and, as a result, can travel about 40 miles on electric power alone, without using the ICE until the battery has been discharged to about 25% to 35%. At this stage, the ICE is operated to keep the battery pack at a level high enough to keep propelling the vehicle. ● **SEE FIGURE 90–2**.

● **SEE CHART 90–1** for a comparison of many of the current PHEVs.

CHARGING A PHEV After the battery pack has been discharged propelling the vehicle, the ICE is used to keep the battery charged enough to propel the vehicle, but it does not fully recharge the battery pack. To fully charge the high-voltage battery pack in a plug-in hybrid electric vehicle, it should be plugged into either a 110/120-volt or a 220/240-volt outlet. ● **SEE FIGURE 90–3**.

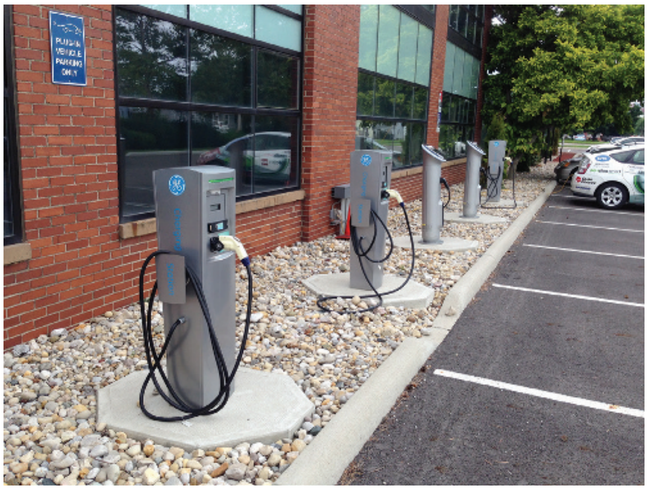


FIGURE 90–3 Charging stations that are equipped with SAE standard J1772 chargers are often found at large companies, colleges, universities, and shopping malls in many parts of the country.

TECH TIP

Turn on Heat or A/C While Still Connected

If charging a plug-in hybrid or an electric vehicle, use a smartphone app to access the vehicle to turn on the air conditioning (A/C) or heat 15 minutes before leaving from work. For example, an owner of a Nissan Leaf, who works in Phoenix, AZ, uses the phone app to start the A/C while it is still connected to the charging station at work. The interior is nice and cool when the owner is ready to leave work, even though the vehicle has been sitting in the hot sun on a 100-degree day. Because the operation of the A/C is occurring while still plugged into the charging station, the range of the Leaf is not affected, and the ride home is done in comfort. The same can be done to heat the interior in cold weather, too.

ELECTRIC VEHICLES

EV BATTERY CAPACITY An **electric vehicle (EV)**, also called a **battery electric vehicle (BEV)**, uses a high-voltage battery pack to supply electrical energy to an electric motor(s) to propel the vehicle under all driving conditions. Electric vehicles that use battery power alone to propel the vehicle are called **zero-emission vehicles (ZEVs)**. The capacity of the battery pack, in kilowatt-hours, determines the range of the vehicle. It has to be plugged in to recharge the battery before it can be driven further. The time it takes to charge an electric vehicle can be as little as 30 minutes or more than 12 hours, depending on the size of the battery and the speed of the charging station.

TECH TIP

Batteries Like the Same Temperature Range as Humans

Batteries work best when they are kept within a temperature range that is also the most comfortable for humans. Most people are comfortable when the temperature is between 68°F and 78°F (20°C and 26°C).

- Below 68°F (20°C), most people want heat.
- Above 78°F (26°C), most people want cooling.

Batteries perform best when they are exposed to the same temperature range. Therefore, a proper heating and cooling system must be used to keep the batteries within this fairly narrow temperature range for best performance.

COLD-WEATHER CONCERNS Past models of electric vehicles, such as the General Motors electric vehicle (EV1), were restricted to locations such as Arizona and southern California that had a warm climate. Cold weather is a major disadvantage to the use of electric vehicles for the following reasons:

- Cold temperatures reduce battery efficiency.
- Additional electrical power from the batteries is needed to heat the batteries themselves to be able to achieve reasonable performance.
- Passenger compartment heating is a concern for an electric vehicle because it requires the use of resistance units or other technology that reduces the range of the vehicle.

HOT-WEATHER CONCERNS Batteries do not function well at high temperatures, and therefore, some type of battery cooling must be added to the vehicle to allow for maximum battery performance. This results in a reduction of vehicle range due to the use of battery power needed just to keep the batteries working properly. Besides battery concerns, the batteries also have to supply the power needed to keep the interior cool, as well as all of the other accessories. These combined electrical loads represent additional battery drain and reduce the range of the vehicle.

RANGE How far an electric vehicle can travel on a full battery charge is called **range**. The range of an electric vehicle depends on many factors, including

- Battery energy storage capacity
- Vehicle weight
- Outside temperature
- Terrain (driving in hilly or mountainous areas requires more energy from the battery)
- Use of heating or air-conditioning systems and other electrical devices
- Driving style or habits

EVs have a shorter driving range than most conventional vehicles although EV driving ranges are improving. Many early EVs could travel less than 100 miles on a charge, but now typical range for an electric vehicle is in excess of 200 miles, depending on the make and model. A typical electric vehicle will consume about 30 kW per 100 miles (62 km). ● **SEE FIGURE 90–4**.

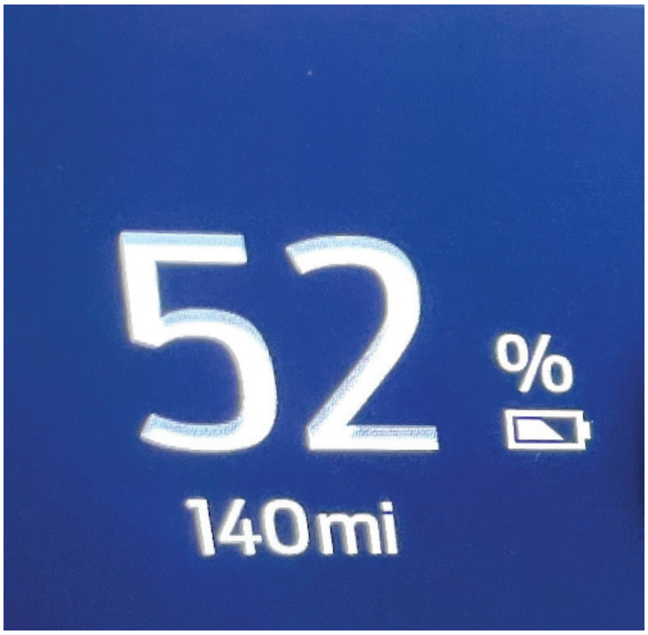

FIGURE 90–4 The "gas gauge" on an electric vehicle is the miles remaining and the state-of-charge. According to those who have owned an electric vehicle, range anxiety lasts only about 10 days after they see that their travel distance can be easily achieved after being charged.

TECH TIP

Use Phone App to Turn on Seat and Steering Wheel Heaters

If not plugged into a charging station on a cold day, most experts recommend that just the steering wheel and seat warmers be turned on to help conserve electrical power. Heating the seats and steering wheel will give the driver a sense of warmth without draining the HV batteries in an effort to heat the air in the entire passenger compartment.

COST OF CHARGING The national average for electricity is about $0.11 per kilowatt-hour. Charging an all-electric vehicle with a 250-mile range (assuming a fully depleted 96 kWh battery) will cost about $10.56 to reach a full charge. This cost is about the same as operating an average central air conditioner for about 6 hours. General Motors estimates the annual energy use of the Chevy Volt is about 2,520 kilowatt-hours, which is less energy than is required to power a typical water heater or central air conditioning.

FREQUENTLY ASKED QUESTION

What Is Range Anxiety?

Range anxiety is a feeling that many drivers experience when driving an electric vehicle because they fear running out of electric battery energy before they reach their destination. This condition is very common, but according to studies, this feeling lasts about two weeks after first getting an electric vehicle. Within those first two weeks, the driver develops experience regarding how far the vehicle can travel on a full charge and knows that their regular trip can be completed without any issues.

KILOWATTS PER 100 MILES The EPA also expresses an EV's energy consumption in terms of the number of kilowatts per hour needed to run the vehicle for 100 miles shortened to **kWh/100 mi**. For example, a Tesla Model 3 uses about 28 KW per 100 miles.

LEVEL 1 CHARGING

20-AMPERE CIRCUIT Level 1 charging uses 110/120-volt standard electric outlet (20-ampere circuit). The maximum power with a Level 1 charging is 1.9 kW. This low rate of charging means that it is best to charge the vehicle overnight, so it is ready to go the next morning. The advantage is that there is little, if any, installation cost because many houses are equipped with 110/120-volt outlets and can supply up to 16 amperes protected by a 20-ampere circuit breaker. ● **SEE FIGURE 90–5**.

Level 1 charging results in 2 to 5 miles of range for each hour of charging. Before plugging an EV into any outlet, be sure that the circuit does not supply other appliances, such as refrigerators or lights. For the connector, nearly all EVs come with a portable Level 1 cord set, which has a standard three-prong household plug on one end for the outlet and a standard J1772 connector for the vehicle. For Level 1 charging when plugged into regular 120-VAC outlet, a lot of vehicles will limit the rate 12 A which is 1.4 kW, while the peak allowed by the standard (and typical household wiring) is 16 A (1.9 kW). ● **SEE FIGURE 90–6**.

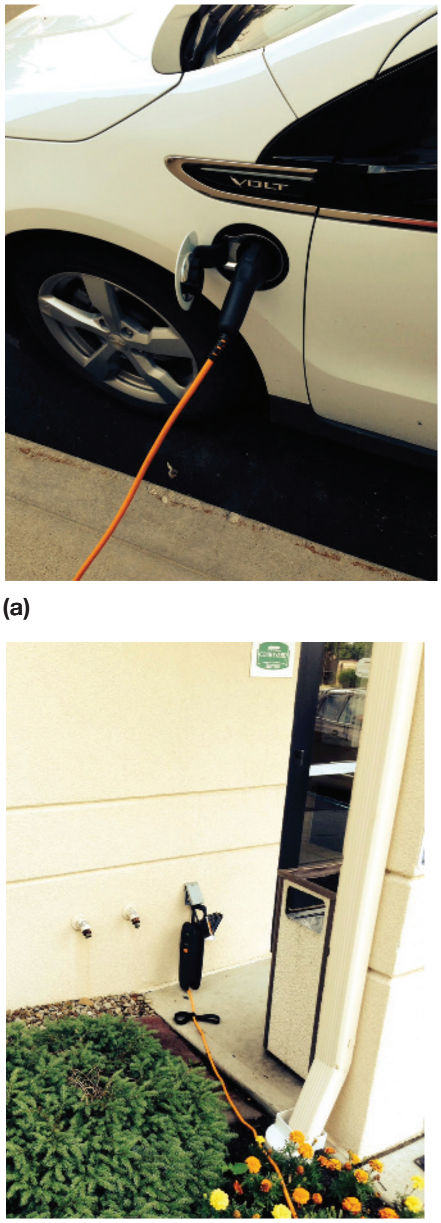
PRECAUTIONS USING A LEVEL 1 CHARGING When using the 110/120-volt plug of the charging cord that comes with the

TECH TIP

Tip on Using Some Generators

If trying to use a gasoline-powered generator to charge an electric vehicle, the neutral and ground have to be tied together or the charger errors out. For example, an owner of a Honda EU 2000i generator got a plug with the two lead (neutral and ground) tied together that it can be plugged into the other socket if needed to charge the vehicle. The electric vehicle needs to see 120 volts on the hot lead and 0 volt on neutral when referenced to ground. Some generators will show 60 volts and 60 volts, and then the vehicle may display a ground fault error.

NOTE: The neutral and ground *must* be electrically isolated. This is also true for any remote panel and all receptacles. The only place they can be connected together is in the main panel where the service ground (ground rod) is located. Some early generators combined them, which led to a whole host of problems, especially with household electronic equipment.



(a)

(b)

FIGURE 90–5 (a) A Chevrolet Volt being charged using the supplied 120-volt charger. (b) Always lay out the entire length of the charging cord before plugging the vehicle into the outlet. If the cord is not kept straight, the current flow can not only create a coil, but the flow of current can overheat the wires and, in some cases, can actually cause the insulation to melt.

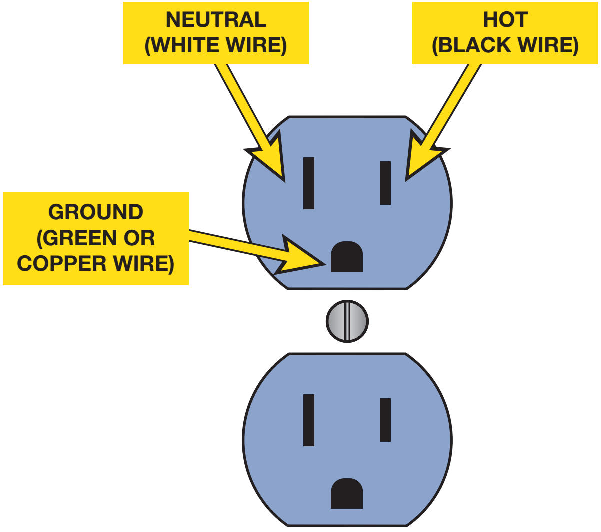


FIGURE 90–6 The electrical outlet must be wired correctly to the house wiring to avoid the possibility of an electrical shock and for proper charging of the vehicle.

CASE STUDY

The Case of the Older House

The owner of a Chevrolet Bolt was visiting a relative who lives in an older home. When visiting, the owner thought that they might as well charge their car even though it was at Level 1 (110/120-volt outlet). At least this could add some range added during the visit. Unfortunately, the house was so old that the electrical outlets did not have a separate ground wire and instead used just a neutral and power (hot) wire. The car knew that the connection did not have a proper ground and the connection was not completed. In this case, the car was smarter than the house.

Summary:

Complaint—A Chevrolet Bolt would not charge when connected to a 110-volt outlet.
Cause—The outlet did not have a ground terminal.
Correction—The vehicle did not allow charging because of the missing ground terminal. This is normal operation and a safety feature of electric vehicles and no correction was needed.

vehicle, the following safety precautions should be adhered to preventing personal injury or property damage:

- Uncoil the cord before connecting the plug to an electrical outlet. If the cord is kept on the charger reel, heat can build up during charging that can cause the insulation to melt. Always unroll the entire length of the charge cord before charging.
- Plug the charging cord directly into a dedicated 110/120-volt, 20-ampere outlet. Do not use an extension cord.

LEVEL 2 CHARGING

HIGHER VOLTAGE EQUALS FASTER CHARGING Level 2 chargers uses 208/240 volts to charge the same vehicle in about 4 hours. Level 2 chargers can be added to most houses, making recharging faster (up to 80 amperes) when at home, and are the most commonly used charging stations available at stores and colleges. A 208/240-volt Level 2 charger rated at 30 amperes will deliver 7.2 kW (240 × 30/1000). In one hour, that will send 7.2 kWh of electricity to a plug-in vehicle, so it will be fine to service vehicles with onboard chargers rated at 7.2 kW or less. Adding a Level 2 charging outlet to the garage or parking location can cost from $500 to $2,000 or more, depending on the location and the wiring of the house or condo. Level 2 charging adds about 25 miles of **range per hour (RPH)**, labeled as **miles per hour (MPH)** on the dash display of a Nissan Leaf. For Level 2 (220/240VAC) charging, vehicles have between a 3 kW and 10 kW onboard chargers, which is usually the limiting factors as to how many kWh of charging is actually achieved. ● **SEE FIGURE 90–7**.

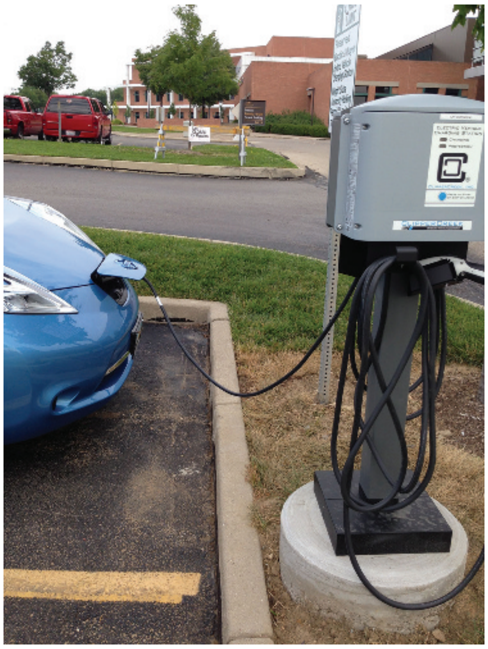

FIGURE 90–7 Nissan Leaf plugged into a Level 2 charging station at a college.

ONBOARD CHARGERS The Level 1 and 2 AC charging is done by the onboard charger. The charging station tells the vehicle the voltage and the maximum current available, and the vehicle will limit itself to no more than that current. Following that handshake (communications between the charging station and the vehicle), the charging station just switches on the power.

NOTE: For Level 3, the vehicle tells the charger how much voltage it can handle, and the external charger will limit the voltage and then the vehicle will take as much current as it can, up to the max the charger can provide.

FREQUENTLY ASKED QUESTION

What Is That Sound?

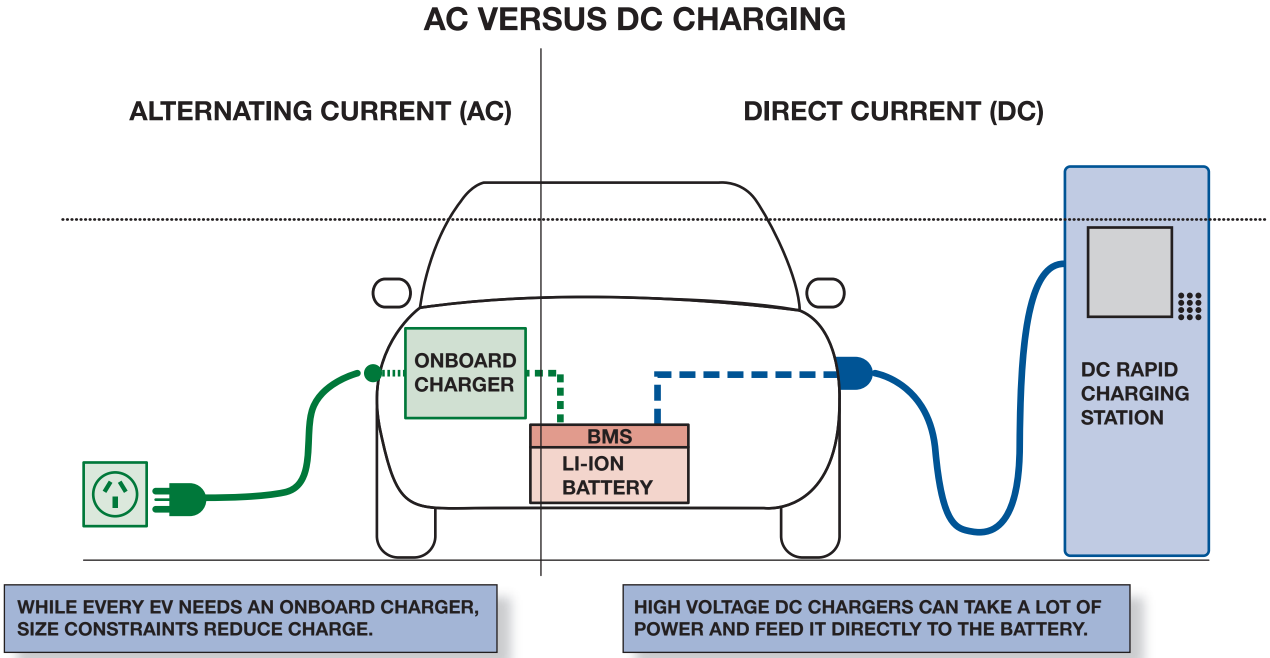
Many electric vehicle owners say that they hear their vehicle making humming sounds while parked in the garage like the climate control fans running. Checking the smartphone app indicated that the climate control was off. While this can cause some concerns to first time owner of electric vehicle, the noise is usually caused by one of the following:

- The fan, which keeps the battery cool, will run especially if charging or having just finished driving.
- A Chevrolet Volt, for example, often makes gurgling noises due to the A/C running to help cool the battery down in the garage on a hot sunny day.

Because these systems are working when the vehicle is stopped and not operating, many experts recommend that the vehicle is plugged in all the time when it is at home. This is what is often referred to as **Always Be Charging (ABC)**.

LEVEL 3 CHARGING

DC FAST CHARGING Level 3 charging stations use 440/480 volts AC input and outputs DC to charge most electric vehicles to 80% charge in less than 30 minutes. This high-charge rate may be harmful to battery life. Always follow the charging instructions and recommendations as stated in the owner's manual of the vehicle being charged. Level 3 chargers charge the vehicle using direct current (DC) at a rate up to 125 amperes. Level 3 chargers are often called a **DCFC (DC Fast Charge)** or *DC Quick Charge (DCQC)*. ● **SEE FIGURE 90–8**.



AC VERSUS DC CHARGING
ALTERNATING CURRENT (AC)
DIRECT CURRENT (DC)
ONBOARD CHARGER
BMS
LI-ION BATTERY
DC RAPID CHARGING STATION
WHILE EVERY EV NEEDS AN ONBOARD CHARGER, SIZE CONSTRAINTS REDUCE CHARGE.
HIGH VOLTAGE DC CHARGERS CAN TAKE A LOT OF POWER AND FEED IT DIRECTLY TO THE BATTERY.

FIGURE 90–8 The difference between Level 1, 2, and 3 charging is that by using AC (Levels 1 and 2) the onboard charger has to convert the alternating current (AC) to direct current (DC) in order to charge the high-voltage battery; using direct current (Level 3) this conversion is not needed so that the DC can be used directly to charge the battery.

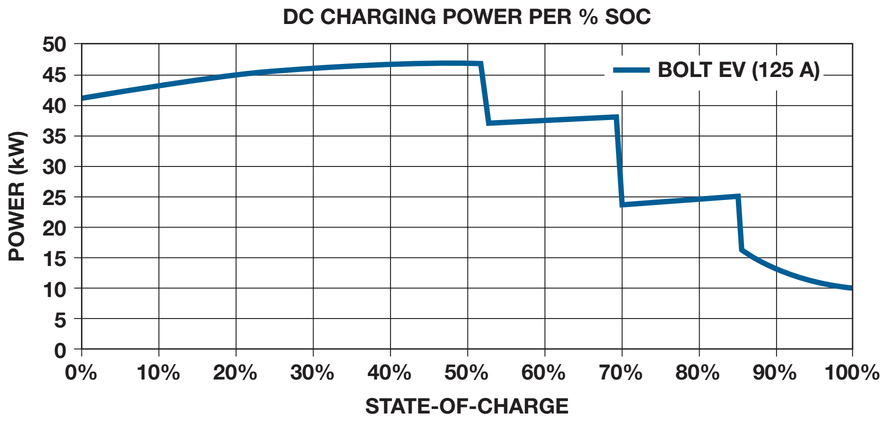


FIGURE 90–9 A chart showing a typical charging rate, which is decreased once the state-of-charge reaches about 70%.

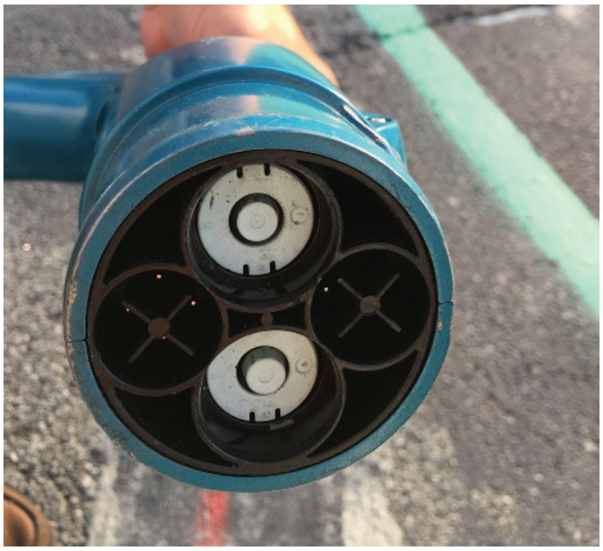

FIGURE 90–10 A close-up view of CHAdeMO Level 3 charging plug.

A Level 3 charger station can cost $50,000 or more, making this type of charger most suitable where facilities will be selling the service of rapidly charging the vehicle. For example, DCFC can provide 60 to 80 miles of range in as little as 20 minutes of charging time. ● **SEE FIGURE 90–9**.

LEVEL 3 ELECTRICAL CONNECTORS There are four different DCFC connectors currently being used by electric vehicle manufacturers all over the world.

- **CHAdeMO**—Nissan and other Japanese companies such as Mitsubishi. ● **SEE FIGURE 90–10**.
- **SAE Combo Charging System (CCS)**—(BMW, Ford, GM, VW, and other vehicle makers). ● **SEE FIGURE 90–11**.
- **Tesla Supercharger**—Tesla standard connector. The Tesla “superchargers” are Level 3 chargers and are free to use by some Tesla owners. Tesla electric vehicles use their own unique plug and supply adaptors if the vehicle is going to be connected to a standard SAE J1772 charging station plug or a 110/120-volt electrical outlet. ● **SEE FIGURE 90–12**.
  ● **SEE CHART 90–2**.

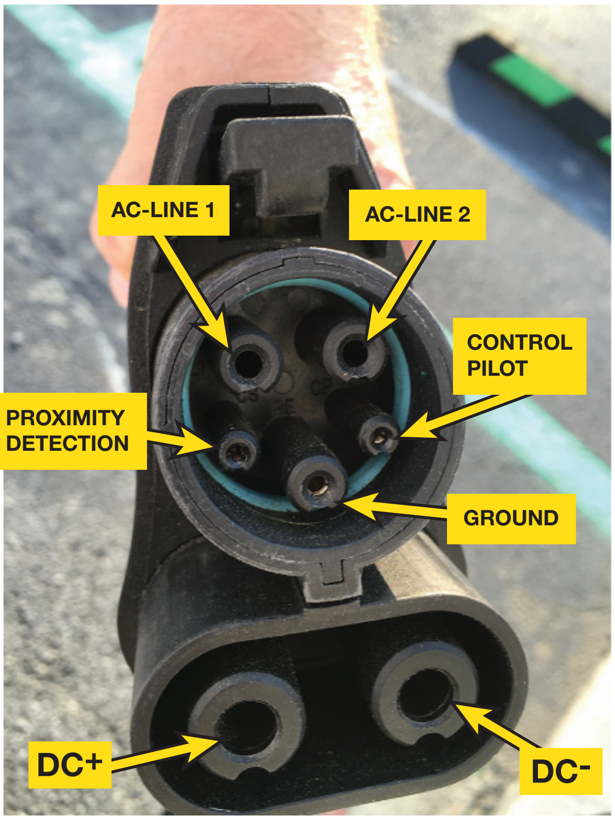

FIGURE 90–11 The SAE Combo Charging System (CCS) is a DCFC connector standard used by BMW, Ford, GM, VW, and other vehicle makers.

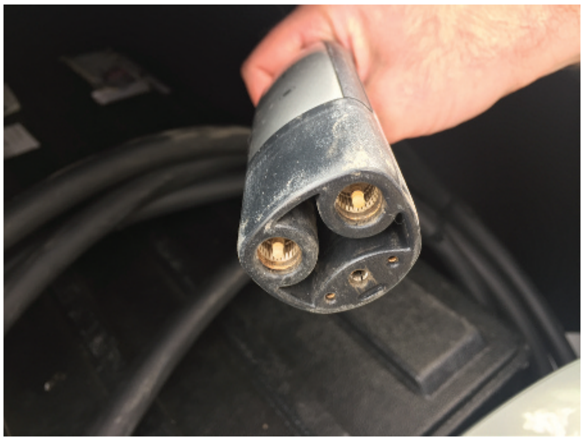

FIGURE 90–12 Tesla vehicles use a unique changing connector that is only used by Tesla.

SUMMARY CHARGING CHART

Level (voltage)	Rate	Time to Fully Charge	Miles per Hour (MPH) Range per Hour (RPH)
Level 1 (110/120 volts)	16 amperes (1.4 to 1.7 kW)	16 hours for 32 kWh battery 40 hours for 80 kWh battery	5 miles per hour
Level 2 (208/210/220 volts)	32–48 amperes (7 to 13 kW)	3.5 hours for 32 kWh battery 8 hours for 80 kWh battery	12 miles per hour with 3.7 kW onboard charger. 25 miles per hour with 6.6 kW onboard charger
Level 3 (440/480 volts DC)	24 kW to 250 kW	Depends, but generally 80% charge in 30 minutes	Up to 200 miles per hour

CHART 90–2

The charge time and range per mile depend upon the voltage and current available during charging.

OWNING AND CHARGING AN EV

TIME-OF-USE For almost all EV owners, choosing a **time-of-use (TOU)** electric rate plan is needed to achieve the largest savings for charging. A TOU plan offers lower electric rates during off-peak periods (usually 11 PM until 5 AM), with higher rates for using electricity during high-demand times. Because most EVs are parked at home overnight, TOU rates are a wise choice for most EV owners.

PUBLIC CHARGING STATIONS (PCS) **Public Charging Stations (PCS)** are available at many locations and most commercial Level 2 charging stations come with added features, which include the following:

- Authentication
- Integrated payment gateways
- Software for remote monitoring

The electric power consumed needs to be billed and payment needs to be collected. The power utilities may also want to manage power drawn by these chargers over time.

NOTE: Some commercial charging stations will stop charging at 80%, whereas others may stop after 30, 45, or 1 hour while others have no limits. Use the website for the charging system being used to check for locations and the charging limits.

WORK PLACE AND DESTINATION CHARGING **Work place charging (WPC)** is very popular because the vehicle owner can

TECH TIP

Speak the Language of Electricity

Most people understand units like inches and feet, meters and kilometers, cups and gallons, milliliters and liters, kilobytes and megabytes and gigabytes, but never learned the basic units of electricity. Many home appliances, such as hair dryers and microwave ovens, have the wattage printed right on the front. There are some people who think electricity is just too complicated. So, when it comes to EVs, manufacturers and charging station operators try to help by stating the miles of range you can get per minute or hour of charging instead of the actual power rating of a charging station. Also, vehicle manufacturers tend to mention just the range that the vehicle can achieve instead of the kWh capacity of the battery. The first battery electric vehicles were equipped with chargers rated at 3.3 kW. They could only accept a maximum of 3.3 kW of electricity each hour they were connected to a 240-volt, or Level 2, power supply. A watt is the basic unit of electricity, and a kilowatt is 1,000 watts. A charging station that could send only 1 kilowatt of electricity to the battery pack in an hour would be a 1 kilowatt-hour (kWh) device. The basic charging capacity of a Tesla, for instance, is 10 kWh, and buyers can order a second onboard charger that doubles the charging speed to 20 kWh. To compute how much electrical current will be delivered to a plugged-in vehicle through any properly installed EVSE, multiply the amperes by the volts and divide by 1,000. Typically, most EVs on a Level 2 charging station can achieve about 25 miles per charging hour.

FREQUENTLY ASKED QUESTION

What Is Plug & Charge?

"Plug & Charge" uses the ISO 15118 international standard, which specifies the secured communication protocol that an EV and the charging stations should use. Plug & charge improves the public charging experience for electric vehicle owners. Until now, networked public EV charging stations required the use of

- an RFID card,
- a smartphone app, and
- a credit card.

Some owners of EV find using a public charging station a frustrating experience. This is because the station often fails to communicate properly and the session either takes a couple of attempts to initiate. Using the plug & charge will simplify public charging and is available for use by many EV makes and models, except Tesla that have their own network.

charge their vehicle while at work and usually for free. Hotels and motels often provide charging stations known as **destination charging**. Hotels are adding chargers to their properties to help attract EV drivers traveling on long trips.

Other charging locations include the following:

- Large factories
- Small businesses
- Museums
- Colleges and universities
- Shopping centers

The usual charging station at these locations is a Level 2 (220/240 volt).

LOCATING A CHARGING STATION Most electric vehicles will display where to charge if a trip is entered into the navigation system. Plus, there are numerous smartphone apps that can be used to locate charging stations. Some of them are as follows:

- Charge Point
- Charge Way
- Electrify America
- Drive the Arc
- EV Match
- Plug Share
- Pod Point

COST TO CHARGE Some businesses provide chargers at no cost to their customers as a way to add value to the service they provide and to help alleviate range anxiety, while others charge a fee. This can either be on a pay-as-you-go basis using a credit card, or via an account with a charging network like ChargePoint or Blink. Blink charges between $0.04 and $0.06 per minute or from $0.39 to $0.79 per kWh, in states where permitted. ● **SEE FIGURE 90–13**.

TECH TIP

Charge to 80% Unless Traveling

Batteries do not have a long service life if the **state-of-charge (SOC)** is above 80% or below 20%. To help protect the high-voltage battery and extend its life, use the menu in the vehicle display main screen to charge to 80% and input the charging stations at work or a free charger used frequently. Usually at 80% SOC, the charging rate drops and then holds steady until 95% where it tapers again. Even when charged to 80%, the display may say fully charged and needs to be manually changed to indicate charge capacity closer to 100%. The only difference will be the number of miles to zero. The two ways that batteries can degrade are as follows:

1. Over discharging starts eating copper once no more lithium is left to move and this action will destroy the battery.
2. Heat created by a high-charge level can cause acid to eat the battery more rapidly.
3. Once the charging station has been inputted, the vehicle will start to precondition the battery in preparation to being charged. Try to charge to 100% only for trips and charge to 80% for daily runs to help protect the battery life.

FREQUENTLY ASKED QUESTION

Why Doesn't My EV Charge at the Rated Output of the Charging Station?

The Bolt owner's manual states to use at least 80 kW to get a full charge in 30 minutes. However, trying to locate a DCFC unit that does in fact supply 80 kW may be a challenge. For example, one Chevrolet Bolt owner was able to locate a DCFC rated at 50 kW, but when using it, the charger was only supplying 35 kW. Other EV owners report the same situation where the rated charger output is not what is actually being supplied to the vehicle. The reasons for this apparent reduced charger include that the vehicle battery may be limiting the amount of current that is be used to charge the battery. This could be the result of the state-of-charge, the battery temperature, or other parameters. As a result of the many factors involved, it is difficult to know what the charging rate will be. Best to use the smartphone app for the vehicle, which will provide the information on charging status.

FREQUENTLY ASKED QUESTION

Can a Solar Panel on the Roof Charge My EV?

While this sounds like a neat idea, it is not practical. If a vehicle's surface was covered with solar panels, they might be able to produce 50-watt hours of electricity. A standard 110/120-volt electrical outlet that takes 8 hours to charge a Chevrolet Volt by supplying about 1,400 watts per hour. A full solar charge would roughly take 350 hours. To answer the question . . . , probably not.

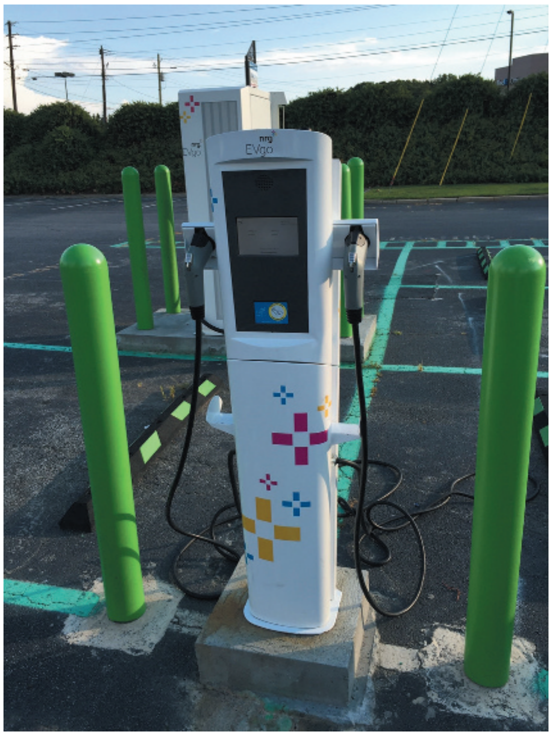

FIGURE 90–13 Commercial charging stations are often located in shopping areas and while most charge a fee, either by the minute of the kWh, some, such as some businesses and schools, are free to use.

REVIEW QUESTIONS

1. What is the difference between a hybrid electric vehicle (HEV) and a plug-in hybrid vehicle (PHEV)?
2. What precautions are needed when charging a vehicle using a Level 1 charging cable that comes with the vehicle?
3. What are the voltage and amperage used to power a Level 2 charger at home?
4. What are the typical charging rates for Level 3 (DCFC) chargers?
5. What are some of the smartphone apps that can be used to locate charging stations?

CHAPTER QUIZ

1. What identifies a plug-in version of a hybrid electric vehicle?
   - **a.** Different badges
   - **b.** An access door for the charging cable in addition to the normal ICE fueling door
   - **c.** Different instrument panel cluster
   - **d.** Any of the above
2. What is true about Level 1 charging?
   - **a.** Uses 110/120 volts
   - **b.** Can supply 2–5 miles per hour of range per hour of charging
   - **c.** Can supply 1.4 to 1.9 kW
   - **d.** All of the above
3. Level 2 charging ___________.
   - **a.** uses J1772 connector
   - **b.** uses 110/120-volt outlet
   - **c.** can supply 1.4 to 1.9 kW
   - **d.** does not need EVSE
4. Level 3 charging ___________.
   - **a.** charges the high-voltage battery using DC
   - **b.** uses 110/120-volt outlet
   - **c.** uses the SAE J1772 connector
   - **d.** Both a and c
5. A typical electric vehicle will consume about ___________ per 100 miles (62 km).
   - **a.** 10 kWh
   - **b.** 20 kWh
   - **c.** 30 kWh
   - **d.** 50 kWh
6. Level 3 chargers use what type of connector?
   - **a.** SAE J1772
   - **b.** SAE Combo Charging System (CCS)
   - **c.** NEMA 14-50
   - **d.** NEMA 6-50
7. Destination charging means ___________.
   - **a.** charging at home
   - **b.** charging at the workplace
   - **c.** charging at a hotel/motel
   - **d.** Any of the above
8. Using a J1772 plug ___________.
   - **a.** can charge most PHEV and EVs
   - **b.** can use 110/120 volts
   - **c.** can use 220/240 volts
   - **d.** All of the above
9. Public Charging Stations (PCS) often charge ___________.
   - **a.** by the hour of usage
   - **b.** by the kWh
   - **c.** by the level of voltage required
   - **d.** Either a or b
10. Charging at 7.2 kW rate is achieved using ___________.
    - **a.** Level 1 charger
    - **b.** Level 2 charger
    - **c.** Level 3 charger
    - **d.** None of the above

Chapter 91

REGENERATIVE BRAKES

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe the principles and operation of regenerative brake systems.
- Discuss the different types of regenerative brake systems, including the components of the system.
- Discuss one-pedal driving.
- Discuss deceleration rates.
- Describe the servicing precautions involved with regenerative brakes.

KEY TERMS:

Inertia 1053 • Kinetic energy 1053 • One-pedal driving 1057 • Regeneration 1054

REGENERATIVE BRAKING IN VEHICLES

INERTIA, FORCE, AND MASS If a moving object has a mass, it has inertia. **Inertia** is the resistance of an object to change its state of motion. In other words, as Newton's first law of motion states: "An object in motion tends to stay in motion, and an object at rest tends to stay at rest unless acted on by an outside force." An electric vehicle (EV) or hybrid electric vehicle (HEV) can reclaim energy by converting the energy of a moving object, called **kinetic energy**, into electric energy. According to basic physics:

A force applied to move an object results in the equation:

$$F = ma$$

where F = force

m = mass

a = acceleration

The faster an object is accelerated, the more force that has to be applied. Energy from the battery (watts) is applied to the coil windings in the motor. These windings produce a magnetic force on the rotor of the motor, which produces torque on the output shaft. This torque is applied to the wheels of the vehicle by use of a coupling of gears and shafts. When the wheel turns, it applies a force to the ground, which, due to friction between the wheel and the ground, causes the vehicle to move along the surface. ● **SEE FIGURE 91–1**.

All vehicles generate torque to move the wheels to drive the vehicle down the road. During this time, it is generating friction and losses. When standard brakes are applied, it is just another friction device that has specially designed material to handle the heat from friction. This friction is applied to the drums and rotors that stop the wheel from turning. The friction between the wheel and the ground actually stops the vehicle. However, the energy absorbed by the braking system is lost in the form of heat and cannot be recovered or stored for use later to help propel the vehicle. The kinetic energy increases with the square of the speed. In other words, if the speed of a vehicle doubles, the kinetic energy is four times higher (speed is doubled (times 2) and the kinetic energy is squared (2 times 2 equals 4)). ● **SEE FIGURE 91–2**.

TRANSFERRING ENERGY BACK TO THE MOTOR Inertia is the fundamental property of physics that is used to reclaim energy from the vehicle. Instead of using 100% friction brakes (base brakes), the braking torque is transferred from the wheels back into the motor shaft. One of the unique things about most electric motors is that electrical energy can be converted into mechanical energy, and mechanical energy can be converted back into

FREQUENTLY ASKED QUESTION

What Is the Difference between Mass and Weight?

Mass is the amount of matter in an object. One of the properties of mass is inertia. Inertia is the resistance of an object to being put in motion, and the tendency to remain in motion once it is set in motion. The weight of an object is the force of gravity on the object and may be defined as the mass times the acceleration of gravity. Therefore, mass means the property of an object and weight is a force.

electrical energy. In both cases, this can be done very efficiently. Through the use of the motor and motor controller, the force at the wheels transfers torque to the electric motor shaft. The magnets on the shaft of the motor (called the rotor—the moving part of the motor) move past the electric coils on the stator (the stationary part of the motor), passing the magnetic fields of the magnets through the coils, producing electricity. This electricity is electrical energy, which is directed to and recharges the high-voltage battery. This process is called **regeneration**, *regen*, or simply "reclaiming energy."

LIMITATIONS OF REGENERATIVE BRAKES There are some limitations that will always affect even the best regenerative braking systems, which include the following:

- It only acts on the driven wheels.
- The system has to be designed to allow for proper use of the antilock braking system (ABS).

FREQUENTLY ASKED QUESTION

Are the Friction Brakes Used during Regenerative Braking?

Yes. Most hybrid vehicles make use of the base (friction) brakes during stopping. The amount of regenerative braking compared to the amount of friction braking is determined by the electronic brake controller. It is important that the base brakes be used regularly to keep the rotors free from rust and ready to be used to stop the vehicle. A typical curve showing the relative proportion of brake usage is shown in ● **FIGURE 91–3**.

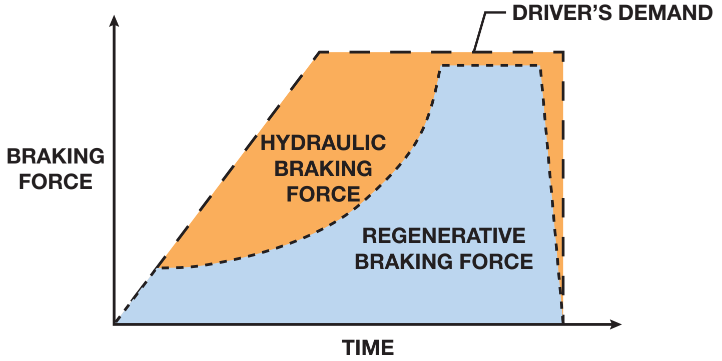

FIGURE 91–3 The regenerative braking system works with the mechanical and hydraulic brake system to provide the necessary braking force to slow and stop the vehicle. Regenerative brakes seldom work at speeds below 10 MPH (16 km/h).

- The batteries are commanded to be kept at a maximum of about 60%, plus or minus 20%, which is best for long battery life and to allow for energy to be stored in the batteries during regenerative braking. If the batteries were allowed to be fully charged, there would be no place for the electrical current to be stored and the conventional friction brakes alone have to be used to slow and stop the vehicle. Charging the batteries over 80% would also overheat the batteries.

BENEFITS OF REGENERATIVE BRAKING SYSTEMS Depending on the type of vehicle, this would reduce fuel consumption by 10% to 25%.

Regenerative braking can be extremely powerful and can recover about 20% of the energy normally wasted as brake heat. Regenerative braking has the following advantages:

- Reduces the drawdown of the battery charge.
- Extends the overall life of the battery pack.
- Reduces fuel consumption.

All production EVs and HEVs use regenerative braking as a method to improve vehicle efficiency, and this feature alone provides the most fuel economy savings. How much energy is reclaimed depends on many factors, including the weight of the vehicle, speed, and the rate of deceleration. ● **SEE FIGURE 91–4.**

FREQUENTLY ASKED QUESTION

When Does Regenerative Braking Not Work?

There is one unusual situation where regenerative braking will not occur. What happens if, for example, the vehicle is at the top of a long hill and the battery charge level is high? In this situation, the controller can only overcharge the batteries. Overcharging is not good for the batteries, so the controller will disable regenerative braking and use the base brakes only. This is one reason why the SOC of the batteries is kept below 80% so regenerative braking can occur.

TYPES OF REGENERATIVE BRAKE SYSTEMS

SERIES REGENERATION In series regenerative braking systems, the amount of regeneration is proportional to the brake pedal position. As the brake pedal is depressed further, the controller that regulates the regenerative braking system computes the torque needed to slow the vehicle, as would occur in normal braking. As the brake pedal is depressed even further, the service brakes are blended into the regenerative braking to achieve the desired braking performance based on brake pedal force and travel. Series regenerative braking requires active brake management to achieve total braking to all four wheels. This braking is more difficult to achieve if the hybrid electric vehicle uses just the front or rear wheels to power the vehicle. This means that the other axle must use the base brakes alone, whereas the drive wheels can be slowed and stopped using a combination of regenerative braking and base brake action. All series regenerative braking systems use an electrohydraulic brake (eHb) system, which includes the hydraulic control unit (ABS modulator) that manages the brake system pressures, as well as the front–rear axle brake balance. Most hybrid vehicles use this type of regenerative braking system. The regenerative braking system mainly uses the regenerative capability, especially at higher vehicle speeds, and gradually increases the amount of the base braking force at low vehicle speeds. ● **SEE FIGURE 91–5.**

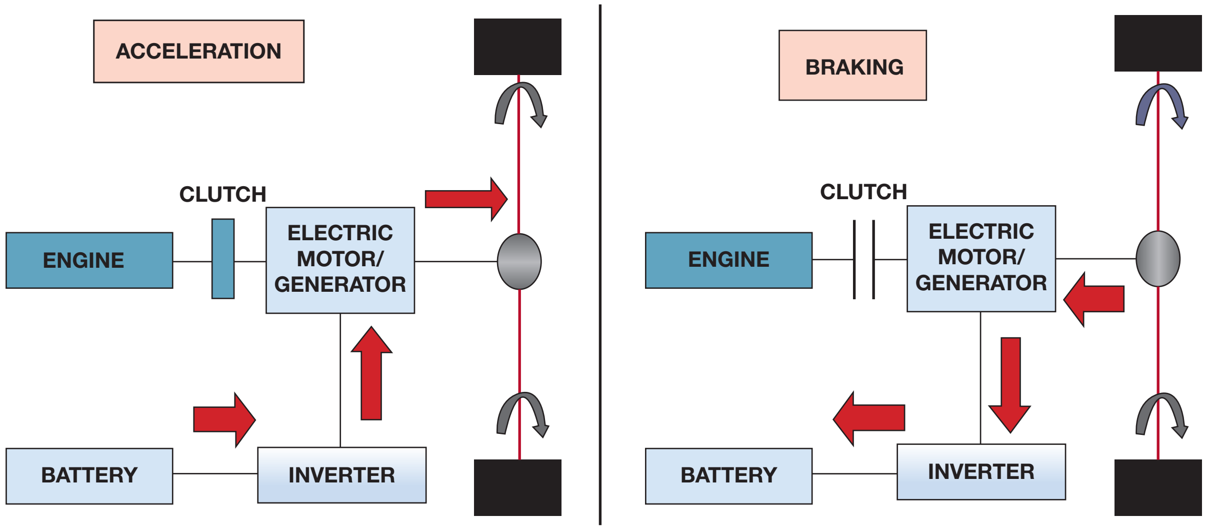

FIGURE 91–4 During acceleration, the ICE and motor/generator are used to propel the vehicle. During deceleration, the energy is returned to the HV battery through the inverter that changes the AC created in the motor/generator to DC to charge the battery.

PARALLEL REGENERATION A parallel regenerative braking system is less complex because the base (friction) brakes are used along with energy recovery by the motors, becoming generators. The controller for the regenerative braking system determines the amount of regeneration that can be achieved based on the vehicle speed. Front and rear brake balance is retained because the base brakes are in use during the entire braking event. The amount of energy captured by a parallel regenerative braking system is less than from a series system. As a result, the fuel economy gains are less.

REGENERATIVE BRAKE COMPONENTS It is the ABS ECU that handles regenerative braking, as well as ABS functions, sending a signal to the hybrid ECU how much regeneration to impose. But how does the ABS ECU know what to do?

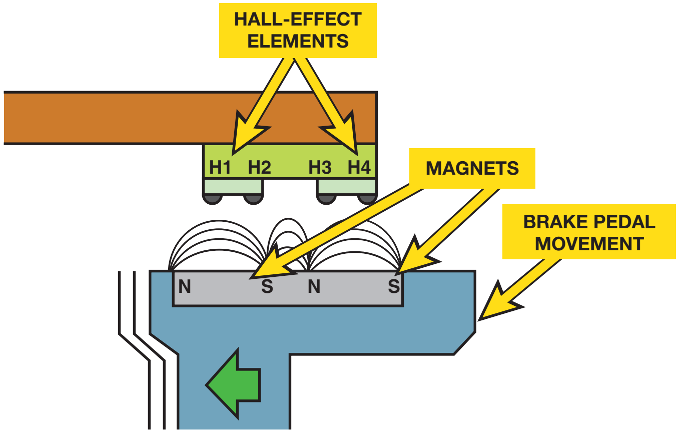

FIGURE 91–6 A contactless BPP sensor uses two Hall-effect elements and magnets to determine not only the position of the brake pedal, but also the speed that the driver is depressing the brake pedal.

Rather than measuring brake pedal travel, which could vary with pad wear, the system uses pressure measuring sensors to detect master cylinder pressure. Some systems use a brake pedal position (BPP) sensor as an input signal to the brake ECU. A typical BBP sensor has two Hall-effect sensor elements on the vacuum booster body and a slide connected to the brake pedal with four Hall magnets. ● **SEE FIGURE 91–6**. The operation includes the following:

- The magnets are connected to the input push rod.
- When the driver presses the brake pedal, the Hall magnets move over the Hall sensors.

This movement (speed and position) is interpreted as a braking request by the brake control system.

The higher the master cylinder pressure, the harder the driver is pushing on the brake pedal. If the driver is pushing only gently, the master cylinder piston displacement will be small and the hydraulic brakes will be only gently applied. In this situation, the ECU knows that the driver wants only gentle deceleration and instructs the hybrid ECU to apply only a small amount of regeneration. However, as master cylinder pressure increases, so does the amount of regeneration that can automatically be applied.

If the electromechanical brake servo and ESC fail at the same time, purely mechanical braking is still possible.

There are four pressure sensors in the braking system and two pressure switches. However, it is the master cylinder pressure sensor that is most important. ● **SEE FIGURE 91–7**.

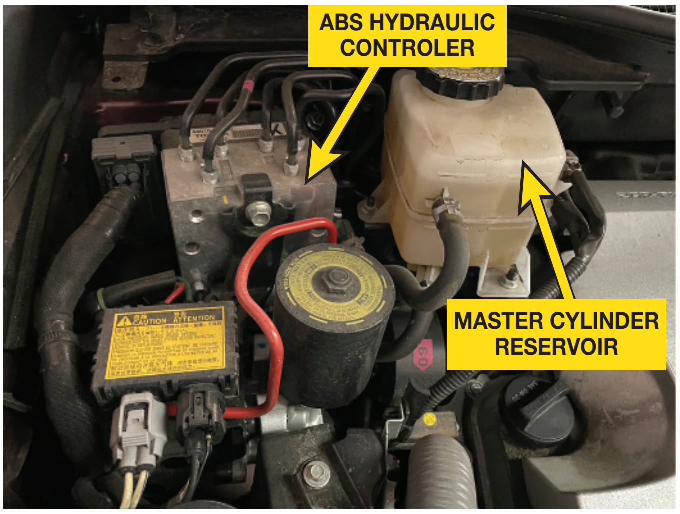

FIGURE 91–7 The components under the hood of a Toyota Highlander hybrid electric vehicle showing the master cylinder reservoir and the ABS controller.

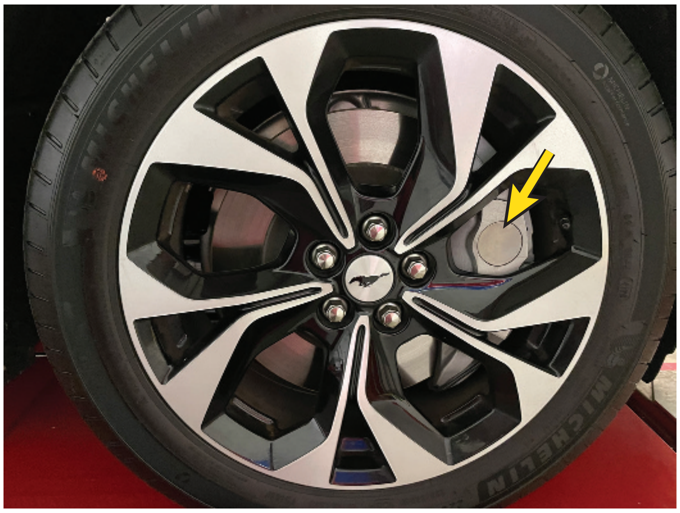

FIGURE 91–8 The front disc brakes on a Mustang Mach E electric vehicle look like most multi-piston front disc brakes used on conventional vehicles.

FREQUENTLY ASKED QUESTION

What Do Regenerative Brakes Look Like?

Regenerative brakes use the rotation of the wheels applied to the electric traction (drive) motor to create electricity. Therefore, the brakes themselves look the same as conventional brakes because the hydraulic brakes are still in place and work the same as conventional brakes. The major difference is that the standard wheel brakes work mostly at low vehicle speeds, whereas conventional brakes work at all speeds. As a result, the brakes on a hybrid electric vehicle should last many times longer than the brakes on a conventional vehicle. ● **SEE FIGURE 91–8**.

FREQUENTLY ASKED QUESTION

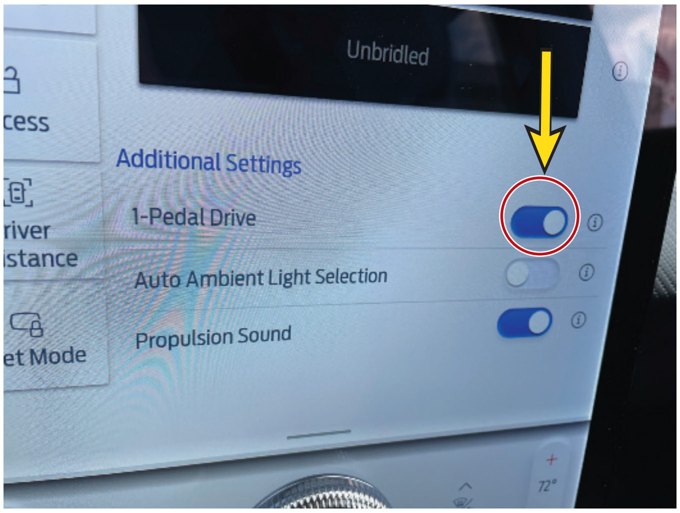
Can an On-Vehicle Brake Lathe Be Used on a Hybrid Electric Vehicle?

Yes. When a brake rotor needs to be machined on a hybrid electric vehicle, the rotor is being rotated. On most hybrids, the front wheels are also connected to the traction motor that can propel the vehicle and generate electricity during deceleration and braking. When the drive wheels are being rotated, the motor/generator is producing electricity. However, unless the high-voltage circuit wiring has been disconnected, no harm will occur.

ONE-PEDAL DRIVING

DEFINITION **One-pedal driving** means that for normal driving, the driver only needs to use the accelerator pedal to accelerate and decelerate. Tesla started using one-pedal driving in 2012 with the Tesla Model S. The brakes on a Tesla are stand alone and are not tied in and blended with the regenerative braking system. One-pedal driving involves the following:

- To accelerate, the driver depresses the accelerator pedal. To accelerate faster, the accelerator pedal is depressed further.



Additional Settings

1-Pedal Drive

Auto Ambient Light Selection

Propulsion Sound

FIGURE 91–9 The display on the dash display of an electric vehicle shows where the one pedal feature can be turned on or off.

- To decelerate (slow down), the driver releases the accelerator pedal and the vehicle speed slows. The faster the driver lets up on the accelerator pedal, the more regenerative braking is achieved and the faster the vehicle slows down. If the deceleration rate is greater than 0.2 Gs, the brake lights come on to warn the driver behind that the vehicle is braking, just as if the driver depressed the brake pedal.

Drivers still have to use the brake pedal to come to a complete stop below 5 to 7 MPH (8 to 11 km/h). In a Nissan Leaf, the car can come to a complete stop in its "e-Pedal" mode. When the car stops totally, it engages the hydraulic brakes to hold it in place. This is not the case with most other vehicles that require the driver to depress the brake pedal to hold the vehicle from moving. ● **SEE FIGURE 91–9**.

EXAMPLES

- The Nissan Leaf has an "L" setting for its drive selector that increases the strength of the regeneration. But it is not strong enough to permit proper one-pedal driving under many circumstances.
- The Volkswagen eGolf and the Chevrolet Bolt EV offer options for one-pedal driving or not depending on the driver needs and desires.
- The Bolt's default "D" position operates like an automatic-transmission car, while the "L" position provides strong regen, eliminating the idle creep, and allows one-pedal driving right down to 0 MPH.
- Audi, while it offers one-pedal driving, the feature has to be selected by the driver. The normal operation of an Audi EV is to allow the vehicle to coast, thereby maintaining the kinetic energy of the moving vehicle without converting that energy back into electrical energy to be stored in the HV battery.
- One-pedal driving seems strange at first, but getting used to it occurs quickly and becomes easy to control the vehicle. The only time that the brake pedal is depressed is for emergency situations or to hold the vehicle from moving, and at very low speeds where regenerative braking is not active.

FREQUENTLY ASKED QUESTION

Is One-Pedal Driving an Advantage?

Some dealers are recommending that their customers do not use one-pedal driving to maximized range. Some electric vehicle manufactures also limit regenerative braking and allow the vehicle to coast, thereby maintaining inertia. Regenerative braking is not 100% efficient. If you are coasting at 60 MPH, regen slows you down to 50, and then accelerates to 60 again, you will lose more energy than if the speed was kept at a steady 60 MPH. Regenerative braking is only useful if used for braking. The most efficient driving mode is the one that is smoothest. That means no hard acceleration or deceleration.

NOTE: When driving in one-pedal mode, the brake light will come on when the accelerator pedal is released and the vehicle starts to slow.

DECELERATION RATES

TERMINOLOGY Deceleration rates are measured in units of "feet per second, per second." What this means is that the vehicle will change in velocity during a certain time interval divided by the time interval.

Deceleration is abbreviated "ft/sec^2" (pronounced "feet per second, per second" or "feet per second squared") or meters per sec^2 (m/s^2) in the metric system.

EXAMPLES Typical deceleration rates include the following:

- Comfortable deceleration is about 8.5 ft/sec^2 (3 m/s^2).
- Loose items in the vehicle will "fly" above 11 ft/sec^2 (3.5 m/s^2).
- Maximum deceleration rates for most vehicles and light trucks range from 16 to 32 ft/sec^2 (5 to 10 m/s^2).

An average deceleration rate of 15 ft/sec^2 (FPSPS) (3 m/s^2) can stop a vehicle traveling at 55 mph (88 km/h) in about 200 ft (61 m) and in less than 4 seconds. Deceleration is also expressed in units called a g. One g is the acceleration of gravity, which is 32 feet per second, per second. With a conventional hydraulic braking system, the driver can brake extremely gently, thereby only imperceptibly slowing the vehicle. A typical hybrid using regenerative braking will normally indicate a 0.1 g (about 3 ft/sec^2) deceleration rate when the throttle is released and the brake pedal has not been applied. This rate is what a driver would normally expect to occur when the accelerator pedal is released. This slight deceleration feels comfortable to the driver, as well as the passengers, because this is what occurs in a non-hybrid vehicle that does not incorporate regenerative braking. When the brake pedal is pressed, the deceleration increases to a greater value than 0.1 g, which gives the driver the same feeling of deceleration that would occur in a conventional vehicle. Maximum deceleration rates are usually greater than 0.8 g and could exceed 1 g in most vehicles. ● **SEE FIGURE 91–10**.

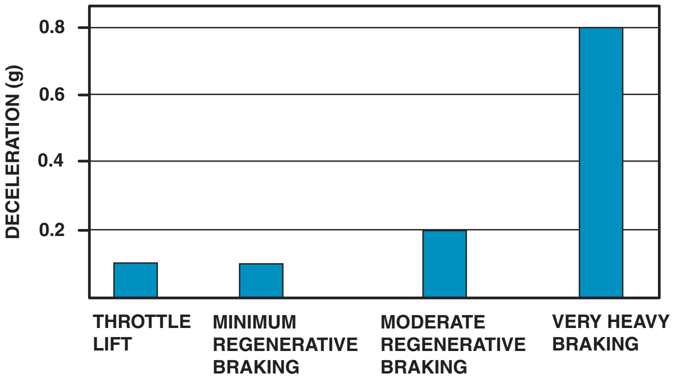


FIGURE 91–10 The graph compares the figures: at the far left, a throttle lift typically giving about 0.1 g deceleration; second from the left, a minimum regenerative braking of about 0.1 g; second from the right, a moderate regenerative braking is about 0.2 g; and on the far right, a hard emergency stop resulting in braking of (at least) 0.8 g, which uses both the regenerative braking system and the base hydraulic brake system.

SERVICING REGENERATIVE BRAKES

UNIQUE MASTER CYLINDERS Most hybrid electric vehicles use unique master cylinders that do not look like conventional master cylinders. Some use more than one brake fluid reservoir and others contain sensors and other components, which are often not serviced separately. ● **SEE FIGURE 91–11**.

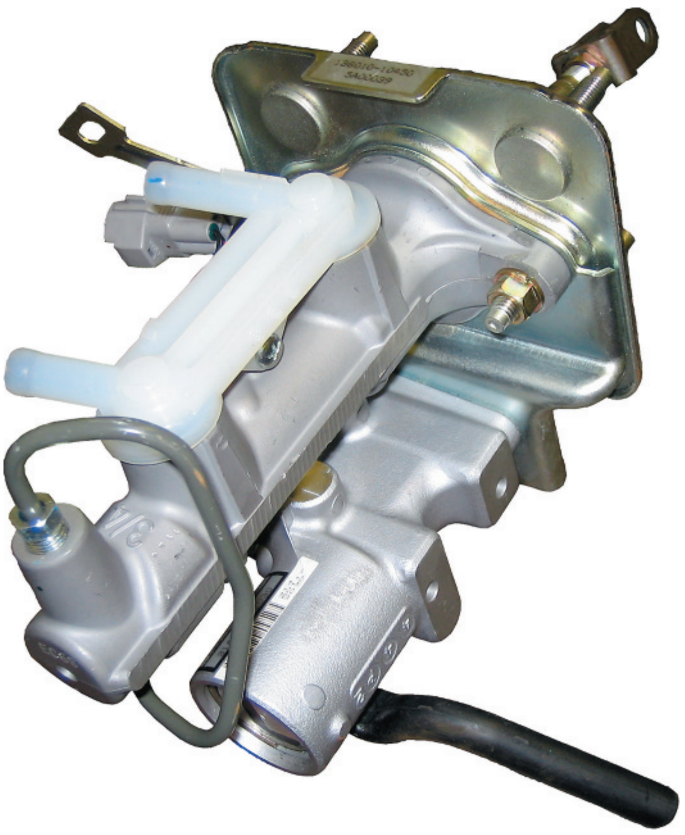

FIGURE 91–11 A master cylinder from a Toyota Highlander hybrid electric vehicle.

Late model GM EVs and PHEVs use an electromechanical brake booster combined with the ABS unit that allows the use of a more conventional master cylinder.

FORD ESCAPE PRECAUTIONS On the Ford Escape hybrid system, the regenerative braking system checks the integrity of the brake system as a self-test. After a certain amount of time, the brake controller will energize the hydraulic control unit and check that pressure can be developed in the system.

- This is performed when a door is opened as part of the wake-up feature of the system.
- The ignition key does not have to be in the ignition for this self-test to be performed.
- This is done by developing brake pressure for short periods of time.

To prevent physical harm or causing damage to the vehicle when servicing the braking system, the technician should do the following:

1. In order to change the brake pads, it is necessary to enter the “Pad Service Mode” on a scan tool and disable the self-test. This will prevent brake pressure from being applied.
2. Disconnect the wiring harness at the hydraulic control unit. ● **SEE FIGURE 91–12**.
3. Check service information regarding how to cycle the ignition switch to enter the Pad Service Mode.

CASE STUDY

Regenerative Brake Warning Message

The owner of an electric vehicle complained to the service department about a message on the dash that stated that the regenerative braking system is degraded. This can be considered normal in cold weather because lithium-ion batteries have no trouble discharging when cold, but do not accept a charge easily when cold. Regenerative braking relies on using the motors as generators, and the battery as the place to store that power. Cold batteries mean limited or no regenerative braking. Once the vehicle was driven and the high-voltage batteries increased in temperature, the regenerative braking system worked normally and the message was no longer displayed on the dash. ● **SEE FIGURE 91–13**.

Summary:

Complaint—Vehicle owner saw a message on the dash warning that the braking system was degraded.
Cause—The high-voltage batteries were cold and could not accept a charge from the regenerative brake system.
Correction—Once the high-voltage batteries increased in temperature, the message was not displayed and is considered to be normal operation at very cold temperatures.

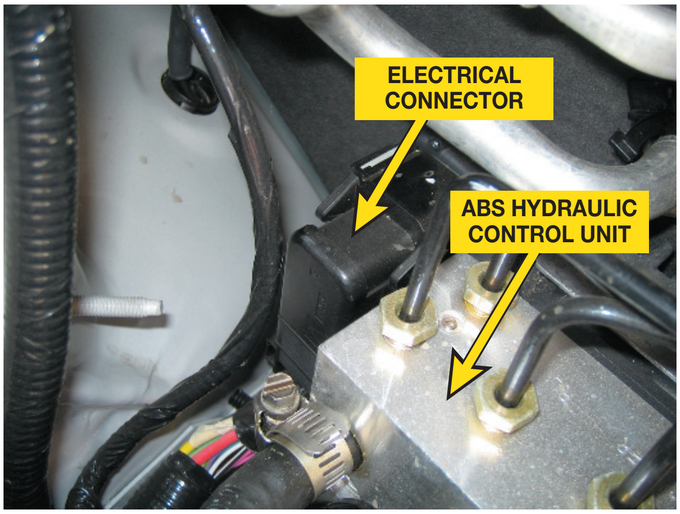

FIGURE 91–12 When working on the brakes on a Ford Escape or Mercury Mariner hybrid vehicle, disconnect the black electrical connector on the ABS hydraulic control unit located on the passenger side under the hood.

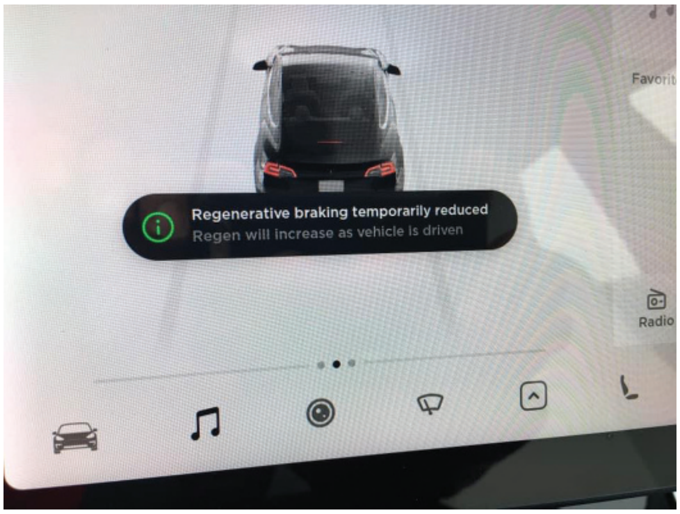

Regenerative braking temporarily reduced
Regen will increase as vehicle is driven

FIGURE 91–13 A notice displayed on the dash informing the driver that the regenerative brakes are degraded or temporarily reduced. When this occurs, the brake pedal feel will change because the system will use more of the base brakes, which may require a higher pedal effort.

REVIEW QUESTIONS

1. What is inertia?
2. What is the difference between series and parallel regenerative braking systems?
3. What happens in the regenerative braking system when the high-voltage batteries are fully charged?
4. What is meant by "one-pedal driving"?
5. What occurs when the driver first releases the accelerator pedal and starts to brake on a hybrid electric vehicle equipped with regenerative braking?

CHAPTER QUIZ

1. Which type of regenerative braking system uses an electro-hydraulic system?
   - **a.** Series
   - **b.** Parallel
   - **c.** Both series and parallel
   - **d.** Neither series nor parallel
2. Kinetic energy is _____________.
   - **a.** the energy that the driver exerts on the brake pedal
   - **b.** the energy needed from the batteries to propel a vehicle
   - **c.** the energy in any moving object
   - **d.** the energy that the motor produces to propel the vehicle
3. Inertia is _____________.
   - **a.** the energy of any moving object that has mass (weight)
   - **b.** the force that the driver exerts on the brake pedal during a stop
   - **c.** the electric motor force that is applied to the drive wheels
   - **d.** the force that the internal combustion engine and the electric motor together apply to the drive wheels during rapid acceleration
4. What are the benefits of regenerative brakes?
   - **a.** They reduce the drawdown of the battery charge.
   - **b.** They extend the overall life of the battery pack.
   - **c.** They reduce fuel consumption.
   - **d.** All of the above
5. During braking on a hybrid electric vehicle equipped with a regenerative braking system, what occurs when the driver depresses the brake pedal?
   - **a.** The friction brakes are only used as a backup and not used during normal braking.
   - **b.** The motors become generators.
   - **c.** The driver needs to apply a braking lever instead of depressing the brake pedal to energize the regenerative braking system.
   - **d.** The batteries are charged to 100% SOC.
6. Technician A says that a front-wheel-drive hybrid electric vehicle can only generate electricity during braking from the front wheel motor(s). Technician B says that antilock braking (ABS) is not possible on a vehicle equipped with a regenerative braking system. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
7. What precaution should be taken when servicing the brakes on a Ford Escape?
   - **a.** Leave a door open.
   - **b.** Put a cover over the master cylinder.
   - **c.** Energize the brake controller.
   - **d.** Put the vehicle in "Pad Service" mode.

8. Two technicians are discussing deceleration rates. Technician A says that a one “g” stop is a gentle slowing of the vehicle. Technician B says that a stopping rate of 8 ft/sec^2 is a severe stop. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
9. One-pedal system means ______________.
   - **a.** the vehicle is not equipped with a separate brake pedal
   - **b.** the accelerator pedal is used to accelerate and decelerate the vehicle
   - **c.** the vehicle uses regenerative braking only and not friction brakes
   - **d.** the vehicle does not use regenerative braking
10. Which of these two is the more efficient type of regenerative braking?
   - **a.** Series regeneration
   - **b.** Parallel regeneration
   - **c.** Both types are equally efficient
   - **d.** A third type, not mentioned, is the most efficient

Chapter 92

FUEL CELLS AND ADVANCED TECHNOLOGIES

LEARNING OBJECTIVES:

After studying this chapter the reader should be able to:

- Explain how a fuel cell generates electricity and the types of fuel cells.
- Discuss hydrogen refueling.
- Discuss fuel cell vehicle systems.
- Explain the purpose and function of fuel cell hybrid vehicles.
- Explain the purpose and function of hydrogen storage.
- Explain how ultracapacitors work in fuel-cell hybrid vehicles.
- Describe the HCCI combustion process.

KEY TERMS:

Electrolysis 1062 • Energy carrier 1062 • Fuel cell 1062 • Fuel-cell hybrid vehicle (FCHV) 1063 • Fuel-cell stack 1064 • Fuel-cell vehicle (FCV) 1063 • Homogeneous Charge Compression Ignition (HCCI) 1069 • Low-grade heat 1065 • Membrane electrode assembly (MEA) 1064 • Polymer electrolyte fuel cell (PEFC) 1064 • Proton exchange membrane (PEM) 1064 • Specific energy 1062 • Ultracapacitor 1069

FUEL-CELL TECHNOLOGY

BACKGROUND A **fuel cell** is an electrochemical device in which the chemical energy of hydrogen and oxygen is converted into electrical energy. The principle of the fuel cell was first discovered in 1639 by Sir William Grove, a Welsh physician. In the 1950s, National Aeronautics and Space Administration (NASA) put this principle to work in building devices for powering space exploration vehicles. Fuel cells are being developed to power homes and vehicles while producing low or zero emissions. ● **SEE FIGURE 92–1**.

PARTS AND OPERATION The chemical reaction in a fuel cell is the opposite of **electrolysis**. Electrolysis is the process in which electrical current is passed through water in order to break it into its components, hydrogen and oxygen. While energy is required to bring about electrolysis, this same energy can be retrieved by allowing hydrogen and oxygen to reunite in a fuel cell. While hydrogen can be used as a fuel, it is *not* an energy source. Instead, hydrogen is only an **energy carrier**, as energy must be expended to generate the hydrogen and store it so it can be used as a fuel.

HYDROGEN-POWERED BATTERY A fuel cell is a hydrogen-powered battery. Hydrogen is an excellent fuel because it has a very high **specific energy** when compared to an equivalent amount of fossil fuel. One kilogram (kg) of hydrogen has three times the energy content as one kilogram of gasoline. Hydrogen is the most common element on earth, but it does not exist by itself in nature. Hydrogen is 14 times lighter than air.

HYDROGEN SOURCES Hydrogen is a low-carbon, non-toxic fuel that is domestically produced from local resources. This is because its natural tendency is to react with oxygen in the atmosphere to form water (H_2O). Hydrogen is also found in many other compounds, such as natural gas or crude oil. In order to store hydrogen for use as a fuel, different processes must be undertaken to separate it from these materials. For example, hydrogen can be produced from water using an electric current to separate the hydrogen from the oxygen using a process called electrolysis. ● **SEE FIGURE 92–2**.

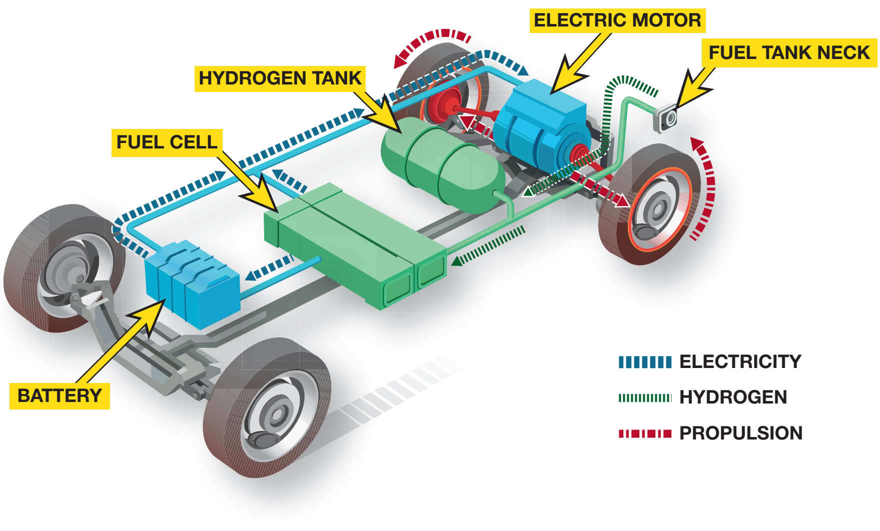

FIGURE 92–1 A fuel cell vehicle uses a fuel cell and a high-voltage battery to provide electrical power to the electric drive motor.

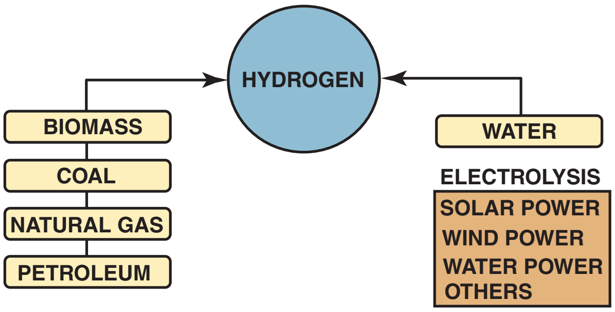

FIGURE 92–2 Hydrogen does not exist by itself in nature. Energy must be expended to separate it from other, more complex materials.

ADVANTAGES OF A FUEL CELL A fuel cell can be used to move a vehicle by generating electricity to power electric drive motors, as well as powering the remainder of the electrical system of the vehicle. Advantages include the following:

- Because they are powered by hydrogen and oxygen, fuel cells by themselves do not generate carbon emissions, such as CO_2. Instead, their only emissions are water vapor and heat, and this makes the fuel cell an ideal candidate for a ZEV (zero-emission vehicle).
- A fuel cell is also much more energy-efficient than a typical internal combustion engine (ICE). While a vehicle powered by an ICE is anywhere from 15% to 20% efficient, a fuel-cell vehicle can achieve efficiencies upward of 40%.
- Fuel cells have very few moving parts and have the potential to be very reliable. Vehicle manufacturers have spent many years and millions of dollars in order to develop a low-cost, durable, and compact fuel cell that operates satisfactorily under all driving conditions.

A **fuel-cell vehicle (FCV)** uses the fuel cell as its only source of power, whereas a **fuel-cell hybrid vehicle (FCHV)** also has an electrical storage device that can be used to power the vehicle. Most new designs of fuel-cell vehicles are now based on a hybrid configuration due to the significant increase in efficiency and drivability that can be achieved with this approach. ● **SEE FIGURE 92–3**.

TOYOTA
FCHV
FUEL CELL HYBRID VEHICLE

FIGURE 92–3 The Toyota FCHV is based on the Highlander platform and uses much of Toyota Hybrid Synergy Drive (HSD) technology in its design.

DISADVANTAGES OF FUEL CELLS While major automobile manufacturers continue to build demonstration vehicles and work on improving fuel-cell system design, no vehicle powered by a fuel cell has been placed into mass production. There are a number of disadvantages of fuel cells, including

- High cost
- Lack of refueling infrastructure
- Safety perception
- Insufficient vehicle range
- Lack of durability
- Cold weather starting problems
- Insufficient power density

All of these problems are being actively addressed by researchers, and significant improvements are being made. Once cost and performance levels meet that of current vehicles, fuel cells may be adopted as a mainstream technology.

FUEL-CELL TYPES There are a number of different types of fuel cells, and these are differentiated by the type of electrolyte

		FUEL-CELL TYPES		
	PEM (POLYMER ELECTROLYTE MEMBRANE)	**PAFC (PHOSPHORIC ACID FUEL CELL)**	**MCFC (MOLTEN CARBONATE FUEL CELL)**	**SOFC (SOLID OXIDE FUEL CELL)**
Electrolyte	Sulfonic acid in polymer	Orthophosphoric acid	Li and K carbonates	Yttrium-stabilized zirconia
Fuel	Natural gas, hydrogen, methanol	Natural gas, hydrogen	Natural gas, synthetic gas	Natural gas, synthetic gas

Types and details of fuel cells, including those most suitable to stationary power generation rather than for use in a vehicle.

that is used in their design. Some electrolytes operate best at room temperature, whereas others are made to operate at up to 1600°F (871°C).

The fuel-cell design that is best suited for automotive applications is the **Proton Exchange Membrane (PEM)**. A PEM fuel cell must have hydrogen for it to operate, and this may be stored on the vehicle or generated, as needed, from another type of fuel. There are several types of fuel cells, and except for the PEM type, however, most of the others are most suitable for use as power-generating units.

● **SEE CHART 92–1** for a comparison of the types of fuel cells and their most common uses.

PEM FUEL CELL OPERATION The Proton Exchange Membrane fuel cell is also known as a **Polymer Electrolyte Fuel Cell (PEFC)**. The PEM fuel cell is known for its lightweight and compact design, as well as its ability to operate at ambient temperatures.

This means that a PEM fuel cell can start quickly and produce full power without an extensive warm-up period. The PEM is a simple design based on a membrane that is coated on both sides with a catalyst, such as platinum or palladium.

- There are two electrodes, one located on each side of the membrane. These are responsible for distributing hydrogen and oxygen over the membrane surface, removing waste heat, and providing a path for electrical current flow.
- The part of the PEM fuel cell that contains the membrane, catalyst coatings, and electrodes is known as the **Membrane Electrode Assembly (MEA)**.
- The negative electrode (anode) has hydrogen gas directed to it, while oxygen is sent to the positive electrode (cathode). Hydrogen is sent to the negative electrode as H_2 molecules, which break apart into H ions (protons) in the presence of the catalyst. The electrons (e) from the H atoms are sent through the external circuit, generating electricity that can be used to perform work.

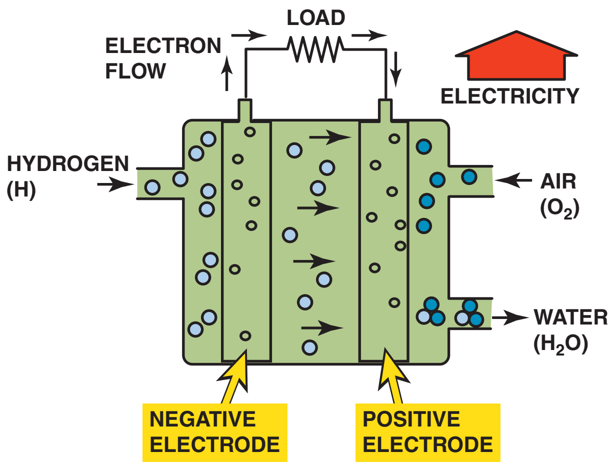

FIGURE 92–4 The polymer electrolyte membrane only allows H^+ ions (protons) to pass through it. This means that electrons must follow the external circuit and pass through the load to perform work.

- These same electrons are then sent to the positive electrode, where they rejoin the H ions that have passed through the membrane and have reacted with oxygen in the presence of the catalyst. This creates H_2O and waste heat, which are the only emissions from a PEM fuel cell. ● **SEE FIGURE 92–4**.

FUEL-CELL STACKS A single fuel cell by itself is not particularly useful as it generates less than 1 volt of electrical potential. It is more common for hundreds of fuel cells to be built together in a **fuel-cell stack**. In this arrangement, the fuel cells are connected in series so that total voltage of the stack is the sum of the individual cell voltages. The fuel cells are placed end-to-end in the stack, much like slices in a loaf of bread. Automotive fuel-cell stacks contain upward of 400 cells in their construction. ● **SEE FIGURE 92–5**.

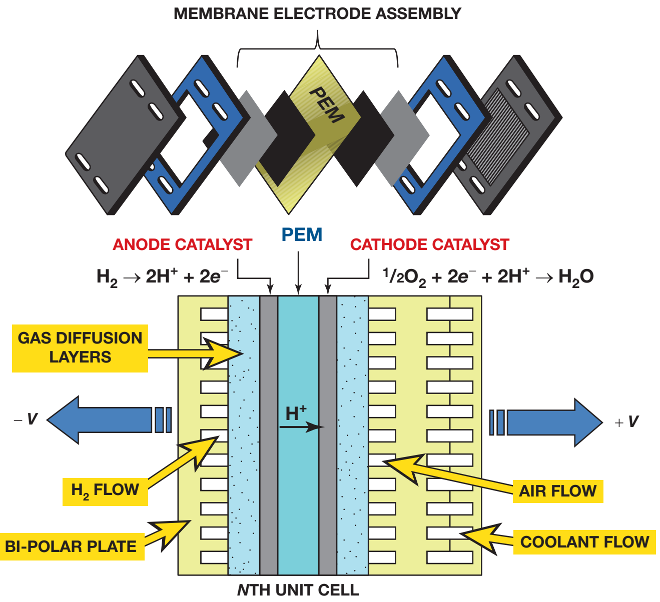

FIGURE 92–5 A fuel-cell stack is made up of hundreds of individual cells connected in series.

TECH TIP

CO Poisons the PEM Fuel-Cell Catalyst

Purity of the fuel gas is critical with PEM fuel cells. If more than 10 parts per million (PPM) of carbon monoxide is present in the hydrogen stream being fed to the PEM anode, the catalyst is gradually poisoned and the fuel cell is eventually disabled. This means that the purity must be "five nines" (99.999% pure). This is a major concern in vehicles where hydrogen is generated by reforming hydrocarbons, such as gasoline, because it is difficult to remove all CO from the hydrogen during the reforming process. In these applications, some means of hydrogen purification must be used to prevent CO poisoning of the catalyst.

The total voltage of the fuel-cell stack is determined by the number of individual cells incorporated into the assembly. The current-producing ability of the stack, however, is dependent on the surface area of the electrodes. Since output of the fuel-cell stack is related to both voltage and current (voltage × current = power), increasing the number of cells or increasing the surface area of the cells increases power output. Some fuel-cell vehicles use more than one stack, depending on power output requirements and space limitations.

REFUELING WITH HYDROGEN

FUELING PROCEDURE Hydrogen is a compressed gas that is stored aboveground at the station. Most hydrogen stations have fuel delivered by a tanker truck, although some stations make their fuel onsite. Like CNG, hydrogen is normally sold by the kilogram (2.2 lb). Filling a vehicle takes just minutes and, to obtain extended driving ranges in fuel-cell electric vehicles (FCEVs), the hydrogen needs to be filled at high pressures. Filling up with hydrogen is very similar to putting propane in a barbeque tank. Just clamp the nozzle onto the receptacle. When the seal is tight, the dispenser pushes high-pressure, gaseous hydrogen into the tank. When the tank is full, the dispenser stops and then the nozzle can be disconnected. To find a hydrogen station, visit the U.S. Department of Energy website: https://www.afdc.energy.gov/stations/#/find/nearest ● **SEE FIGURE 92–6.**

PRESSURES USED The two most commonly used pressures at hydrogen filling stations include

- H35 = 35 MPa (5,000 PSI)
- H70 = 70 MPa (10,000 PSI)

The higher the pressure, the more hydrogen can be added to the onboard storage tank(s). The speed of hydrogen fueling is directly related to the amount of cooling that the dispenser allows to offset the heat of compression. The three temperatures that are used to supply hydrogen include the following:

- T40 station H_2 @ −40°C (−40°F)
- T30 station H_2 @ −30°C (−22°F)
- T20 station H_2 @ −20°C (−4°F)

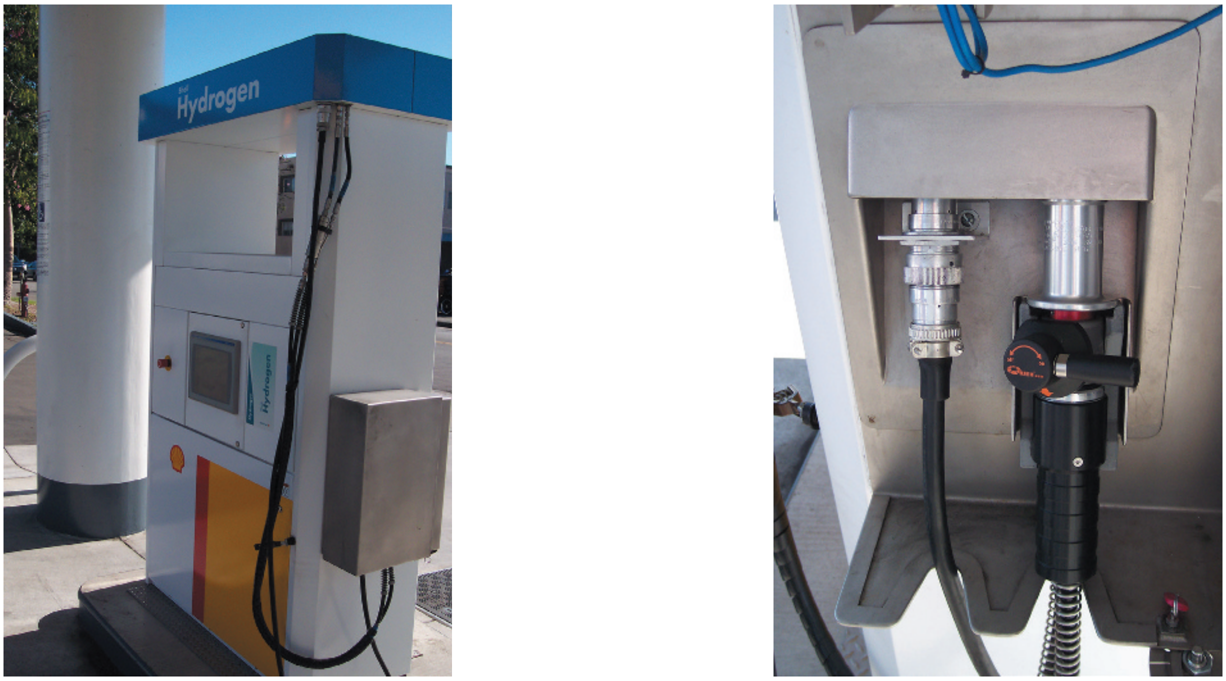
SAE J2601 SAE International-created standard J2601 is the standard for hydrogen-fueling protocol of hydrogen fuel-cell electric vehicles (FCEVs). This standard is used worldwide for hydrogen-fueling stations. The standard J2601 fueling protocol uses a simple control in which the dispenser fuels until the target pressure is reached, based on initial start conditions, giving a consistent hydrogen fueling. Therefore, a H70-T40 (10,000 PSI at −40°F) fueling dispenser enables this fast-fueling by providing hydrogen fuel to the fuel-cell vehicle in usually less than 3 minutes.

FUEL-CELL VEHICLE SYSTEMS

FUEL-CELL HUMIDIFIERS Water management inside a PEM fuel cell is critical. Too much water can prevent oxygen from making contact with the positive electrode; too little water can allow the electrolyte to dry out and lower its conductivity. The amount of water and where it resides in the fuel cell is also critical in determining at how low a temperature the fuel cell starts because water freezing in the fuel cell can prevent it from starting. The role of the humidifier is to achieve a balance where it is providing sufficient moisture to the fuel cell by recycling water that is evaporating at the cathode. The humidifier is located in the air line leading to the cathode of the fuel-cell stack. ● **SEE FIGURE 92–7.**

Some newer PEM designs manage the water in the cells in such a way that there is no need to pre-humidify the incoming reactant gases. This eliminates the need for the humidifier assembly and makes the system simpler overall.

FUEL-CELL COOLING SYSTEMS Heat is generated by the fuel cell during normal operation. Excess heat can lead to a breakdown of the polymer electrolyte membrane, so a liquid cooling system must be utilized to remove waste heat from the fuel-cell stack. One of the major challenges for engineers in this regard is the fact that the heat generated by the fuel cell is classified as **low-grade heat**. This means that there is only a small difference



(a)

(b)

FIGURE 92–6 (a) A hydrogen fueling station located at a Shell gasoline station in Los Angeles, CA. (b) The door on the side is opened to show the fill nozzle with shut-off valve. The hydrogen at this station is made on the roof of the dispenser using water and electricity. An electrical current separates the hydrogen from the oxygen in the water, then compresses the hydrogen, which is then sent to a storage tank, also on the roof.

between the temperature of the coolant and that of the ambient air. Heat transfers very slowly under these conditions, so heat exchangers with a much larger surface area must be used. ● **SEE FIGURE 92–8**.

In some cases, heat exchangers may be placed in other areas of the vehicle when available space at the front of the engine compartment is insufficient. In the case of Toyota FCHV, an auxiliary heat exchanger is located underneath the vehicle to increase the cooling system heat-rejection capacity. ● **SEE FIGURE 92–9**.

An electric water pump and a fan drive motor are used to enable operation of the fuel-cell cooling system. These and other support devices use electrical power that is generated by the fuel cell and, therefore, tend to decrease the overall efficiency of the vehicle.

FIGURE 92–8 The Honda FCX uses one large radiator for cooling the fuel cell, and two smaller ones on either side for cooling drivetrain components.

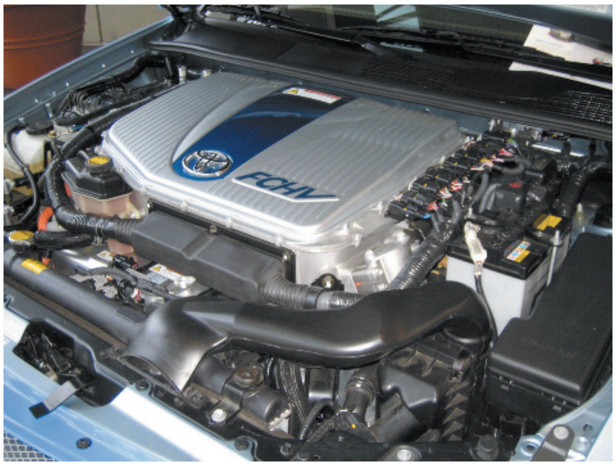

FIGURE 92–9 Space is limited at the front of the Toyota FCHV engine compartment, so an auxiliary heat exchanger is located under the vehicle to help cool the fuel-cell stack.

AIR SUPPLY PUMPS Air must be supplied to the fuel-cell stack at the proper pressure and flow rate to enable proper performance under all driving conditions. This function is performed by an onboard air supply pump that compresses atmospheric air and supplies it to the fuel-cell positive electrode (cathode). This pump is often driven by a high-voltage electric drive motor.

FUEL-CELL HYBRID VEHICLES

PURPOSE AND FUNCTION Hybridization tends to increase efficiency in vehicles with conventional drivetrains, as energy that was once lost during braking, and otherwise normal operation is instead stored for later use in a high-voltage battery. This same advantage can be gained by applying the hybrid design concept to fuel-cell vehicles. Whereas the fuel cell is the only power source in a fuel-cell vehicle, the fuel-cell hybrid vehicle relies on both the fuel cell and an electrical storage device for motive power. Drivability is also enhanced with this design, as the electrical storage device is able to supply energy immediately to the drive motors and overcome any “throttle lag” on the part of the fuel cell.

SECONDARY BATTERIES All hybrid vehicle designs require a means of storing electrical energy that is generated during regenerative braking and other applications. In most FCHV designs, a high-voltage nickel-metal hydride (NiMH) battery pack is used as a secondary battery. This is most often located near the back of the vehicle, either under or behind the rear passenger seat. ● **SEE FIGURE 92–10**.

The secondary battery is built similar to a fuel-cell stack because it is made up of many low-voltage cells connected in series to build a high-voltage battery.

HYDROGEN STORAGE

PURPOSE AND FUNCTION One of the issues with fuel-cell hybrid vehicles is how to store sufficient hydrogen onboard to allow for reasonable vehicle range. Modern drivers have grown accustomed to having a minimum of 300 miles between refueling stops, a goal that is extremely difficult to achieve when fueling the vehicle with hydrogen. Hydrogen has very high energy content on a pound-for-pound basis, but its energy density is less than that of conventional liquid fuels. This is because gaseous hydrogen, even at high pressure, has a very low physical density (mass per unit volume). ● **SEE FIGURE 92–11**.

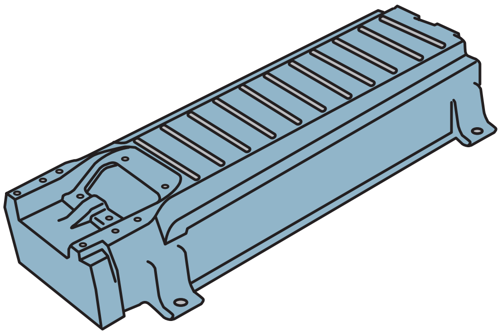

FIGURE 92–10 The secondary battery in a fuel-cell hybrid vehicle is made up of many individual cells connected in series, much like a fuel-cell stack.

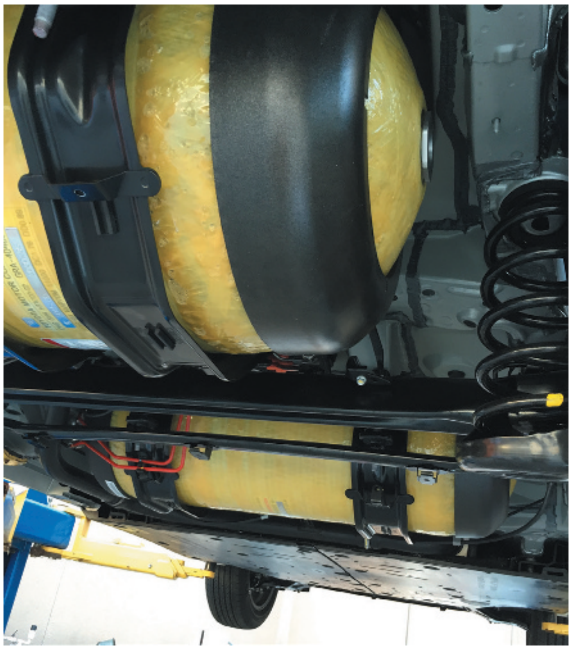

FIGURE 92–11 A photo showing the hydrogen storage tanks underneath a Toyota Mirai fuel-cell vehicle. This vehicle uses two carbon-fiber-reinforced fuel tanks.

A number of methods of hydrogen storage are being considered for use in fuel-cell hybrid vehicles. These include high-pressure compressed gas, liquefied hydrogen, and solid storage in metal hydrides. Efficient hydrogen storage is one of the technical issues that must be solved in order for fuel cells to be adopted for vehicle applications. Much research is being conducted to solve the issue of onboard hydrogen storage.

HIGH-PRESSURE COMPRESSED GAS Most current fuel-cell hybrid vehicles use compressed hydrogen that is stored in tanks as a high-pressure gas. This approach is the least complex of all the storage possibilities, but also has the least energy density. Multiple small storage tanks are often used rather than one large tank in order to fit them into unused areas of the vehicle. One drawback with this approach is that only cylinders can be used to

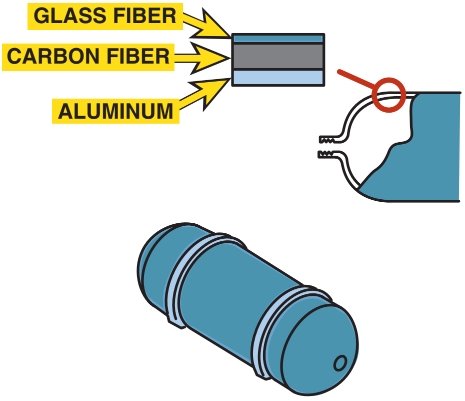

FIGURE 92–12 The Toyota FCHV uses high-pressure storage tanks that are rated at 350 bar. This is the equivalent of 5,000 pounds per square inch.

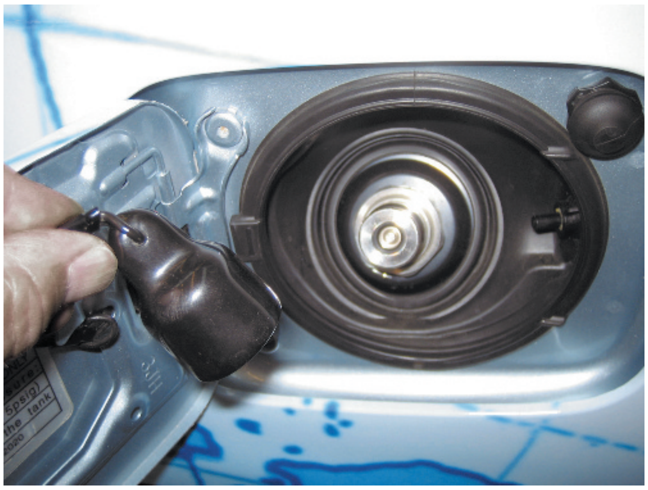

FIGURE 92–13 The high-pressure fitting used to refuel a fuel-cell hybrid vehicle.

store gases at the required pressures. This creates a good deal of unused space around the outside of the cylinders and leads to further reductions in hydrogen storage capacity. It is common for a pressure of 5,000 PSI (350 bar) to be used. ● **SEE FIGURE 92–12**.

Many newer systems use pressures as high as 10,000 PSI (700 bar) to increase the range of the fuel cell-powered vehicle. The tanks used for compressed hydrogen storage are typically made with an aluminum liner wrapped in several layers of carbon fiber and an external coating of fiberglass. In order to refuel the compressed hydrogen storage tanks, a special high-pressure fitting is installed in place of the filler neck used for conventional vehicles. ● **SEE FIGURE 92–13**.

There is also a special electrical connector that is used to enable communication between the vehicle and the filling station during the refueling process. ● **SEE FIGURE 92–14**.

The filling station utilizes a special coupler to connect to the vehicle high-pressure refueling fitting. The coupler is placed on the vehicle fitting, and a lever on the coupler is rotated to seal and lock it into place.

LIQUID HYDROGEN Hydrogen can be liquefied in an effort to increase its energy density, but this requires that it be stored in cryogenic tanks at −423°F (−253°C). This increases vehicle range, but impacts overall efficiency, as a great deal of energy is required to liquefy the hydrogen, and a certain amount of the liquid hydrogen "boils off" while in storage.

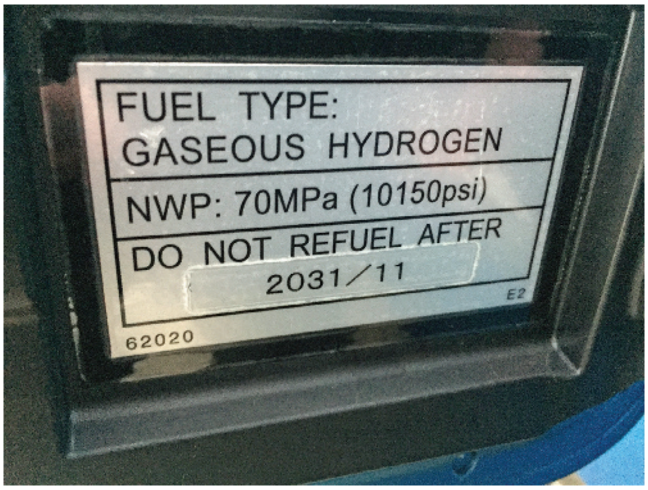

FIGURE 92–14 Note that high-pressure hydrogen storage tanks must be replaced in 2031.

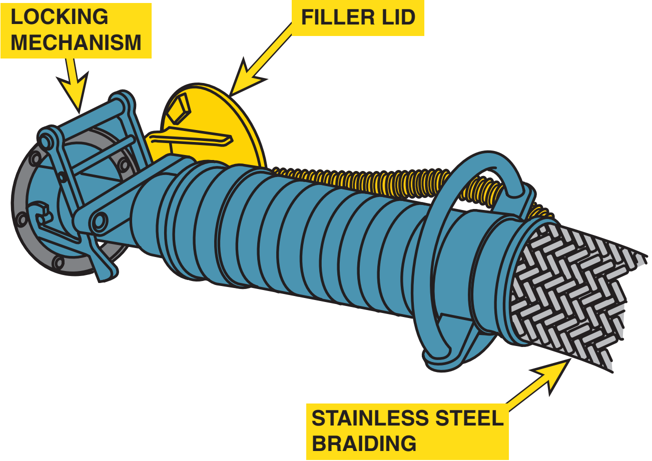

FIGURE 92–15 Refueling a vehicle with liquid hydrogen.

One liter of liquid hydrogen has only one-fourth the energy content of 1 liter of gasoline. ● **SEE FIGURE 92–15**.

SOLID STORAGE OF HYDROGEN One method discovered to store hydrogen in solid form is as a metal hydride, similar to how an NiMH battery works.

A demonstration vehicle features a lightweight fiber-wrapped storage tank under the body that stores about 6.6 pounds (3.3 kg) of hydrogen as a metal hydride at low pressure. The vehicle can travel almost 200 miles with this amount of fuel.

- One kilogram of hydrogen is equal to 1 gallon of gasoline.
- Three gallons of water generates 1 kilogram of hydrogen.

A metal hydride is formed when gaseous hydrogen molecules disassociate into individual hydrogen atoms and bond with the metal atoms in the storage tank. This process uses powdered metallic alloys capable of rapidly absorbing hydrogen to make this occur.

ULTRACAPACITORS

PURPOSE AND FUNCTION An alternative to storing electrical energy in batteries is to use ultracapacitors. A capacitor is best known as an electrical device that blocks DC, but allows AC to pass. However, a capacitor can also be used to store electrical energy, and it is able to do this without a chemical reaction. Instead, a capacitor stores electrical energy using the principle of electrostatic attraction between positive and negative charges.

PARTS AND OPERATION Ultracapacitors are built very different from conventional capacitors. **Ultracapacitor** cells are based on double-layer technology, in which two activated carbon electrodes are immersed in an organic electrolyte. The electrodes have a very large surface area and are separated by a membrane that allows ions to migrate, but prevents the electrodes from touching. ● **SEE FIGURE 92–16**.

Charging and discharging occurs as ions move within the electrolyte, but no chemical reaction takes place. Ultracapacitors can charge and discharge quickly and efficiently, making them especially suited for electric-assist applications in fuel-cell hybrid vehicles.

Ultracapacitors that are used in fuel-cell hybrid vehicles are made up of multiple cylindrical cells connected in parallel. ● **SEE FIGURE 92–17**.

This results in the total capacitance being the sum of the values of each individual cell. For example, ten 1.0-farad capacitors connected in parallel have a total capacitance of 10.0 farads. Greater capacitance means greater electrical storage ability, and this contributes to greater assist for the electric motors in a fuel-cell hybrid vehicle.

ULTRACAPACITOR CAN ARRAY (EXPOSED)

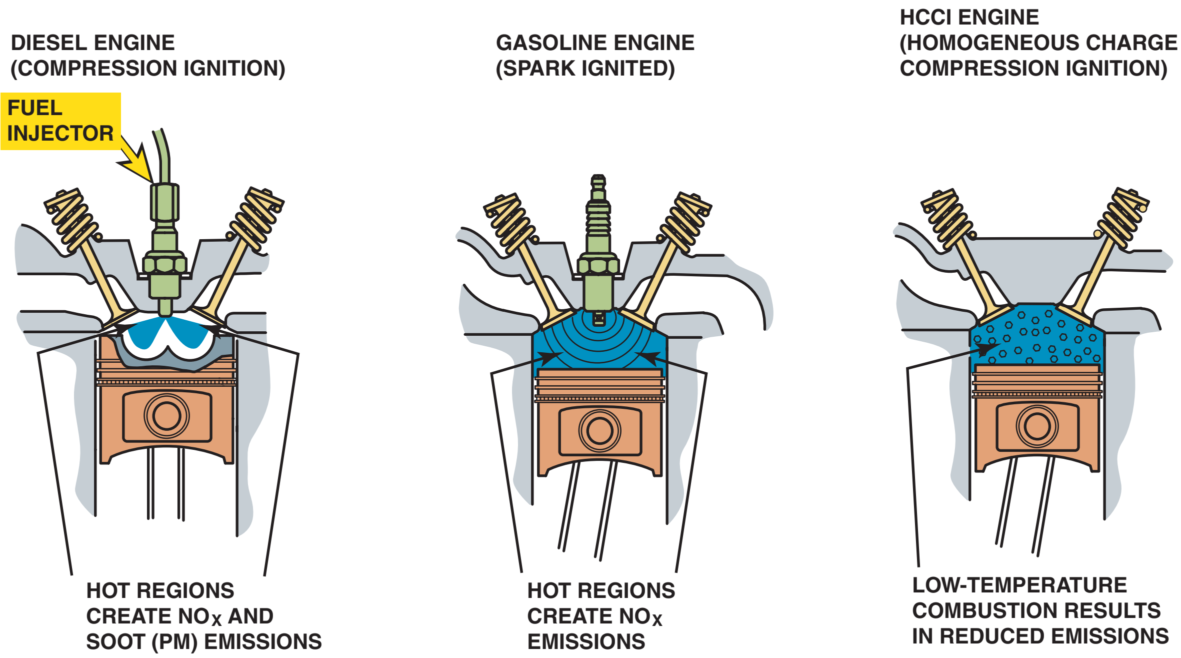
FIGURE 92–17 An ultracapacitor can be used in place of a high-voltage battery in a hybrid electric vehicle. This example is from the Honda FCX fuel-cell hybrid vehicle.

ADVANTAGES Ultracapacitors have excellent cycle life, meaning that they can be fully charged and discharged many times without degrading their performance. They are also able to operate over a wide temperature range and are not affected by low temperatures to the same degree as many battery technologies.

DISADVANTAGES The one major downside of ultracapacitors is a lack of specific energy, which means that they are best suited for sudden bursts of energy, as opposed to prolonged discharge cycles. Research is being conducted to improve this and other aspects of ultracapacitor performance.

HCCI

TERMINOLOGY **Homogeneous Charge Compression Ignition (HCCI)** is a combustion process. HCCI is the combustion of a very lean gasoline air–fuel mixture without the use of a spark ignition. It is a low-temperature, chemically controlled (flameless) combustion process. ● **SEE FIGURE 92–18**.



DIESEL ENGINE (COMPRESSION IGNITION)
FUEL INJECTOR
GASOLINE ENGINE (SPARK IGNITED)
HCCI ENGINE (HOMOGENEOUS CHARGE COMPRESSION IGNITION)
HOT REGIONS CREATE NO_X AND SOOT (PM) EMISSIONS
HOT REGIONS CREATE NO_X EMISSIONS
LOW-TEMPERATURE COMBUSTION RESULTS IN REDUCED EMISSIONS

FIGURE 92–18 Both diesel and conventional gasoline engines create exhaust emissions due to high peak temperatures created in the combustion chamber. The lower combustion temperatures during HCCI operation result in high efficiency with reduced emissions.

HCCI combustion is difficult to control and extremely sensitive to changes in temperature, pressure, and fuel type. While the challenges of HCCI are difficult, the advantages include having a gasoline engine being able to deliver 80% of diesel efficiency (a 20% increase in fuel economy) for 50% of the cost. A diesel engine using HCCI can deliver gasoline-like emissions. Spark and injection timing are no longer a factor as they are in a conventional port-fuel injection system.

FUTURE OF HCCI While much research and development needs to be performed using this combustion process, it has been shown to give excellent performance from idle to mid-load, and from ambient to warm operating temperatures, as well as cold start and run capability. Because the engine operates only in HCCI mode at light throttle settings, such as during cruise conditions at highway speeds, engineers need to improve the transition in and out of the HCCI mode. Work is also being done on piston and combustion chamber shape to reduce combustion noise and vibration that is created during operation in the HCCI operating mode.

Ongoing research is focusing on improving fuel economy under real-world operating conditions, as well as controlling costs.

REVIEW QUESTIONS

1. How does a fuel cell work?
2. What are the advantages and disadvantages of fuel cells?
3. How is hydrogen produced?
4. How does an ultracapacitor work?
5. What are the advantages and disadvantages of using hydrogen?

CHAPTER QUIZ

1. A fuel cell produces electricity from __________.
   a. gasoline/oxygen
   b. nitrogen/hydrogen
   c. hydrogen/oxygen
   d. water/oxygen
2. What are the by-products (emissions) from a fuel cell?
   a. Water vapor
   b. CO
   c. CO_2
   d. Nonmethane hydrocarbon
3. Which type of fuel cell is the most likely to be used to power vehicles?
   a. PAFC
   b. MCFC
   c. PEM
   d. SOFC
4. A disadvantage of a fuel cell vehicle is __________.
   a. limited refueling locations
   b. excessive hydrocarbon exhaust emissions
   c. the fuel is easily obtained
   d. All of the above
5. Which is *not* a function of an ultracapacitor?
   a. Can pass AC
   b. Can be charged with DC
   c. Discharges DC
   d. Can pass DC
6. The commonly used pressures at hydrogen filling stations include __________.
   a. H35
   b. H70
   c. H93
   d. Either a or b
7. Hydrogen storage tanks are usually constructed from __________.
   a. steel
   b. aluminum
   c. carbon fiber
   d. Both b and c
8. HCCI is a process that eliminates what parts or components in a gasoline engine?
   a. Fuel tank
   b. Battery
   c. Fuel injectors
   d. Ignition system
9. Hydrogen can be produced from __________.
   a. water
   b. natural gas
   c. crude oil
   d. Any of the above
10. What does H70-T40 mean when describing a hydrogen filling station?
    a. The type of hydrogen
    b. The temperature and pressure rating
    c. The size of the storage tank
    d. The estimated time needed to fill the tank

BRAKING SYSTEM COMPONENTS AND PERFORMANCE STANDARDS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe the fundamentals of brake systems.
- List the six brake system categories.
- State the purpose of an antilock brake system.
- Discuss federal brake standards.
- Discuss legal aspects of brake repair.

KEY TERMS:

Adjustable pedals 1074 • Antilock brake system (ABS) 1074 • Base brakes 1071 • Disc brakes 1072 • Department of Transportation (DOT) 1075 • Drum brakes 1072 • Electric adjustable pedals (EAP) 1074 • Federal Motor Vehicle Safety Standards (FMVSS) 1075 • Foundation brakes 1071 • Gross vehicle weight rating (GVWR) 1075 • Lightly loaded vehicle weight (LLVW) 1075 • Red brake warning lamp (RBWL) 1074 • Service brakes 1071

FUNDAMENTALS OF BRAKE SYSTEMS

TERMINOLOGY Brakes are by far the most important mechanism on any vehicle because the safety and lives of those riding in the vehicle depend on proper operation of the braking system. It has been estimated that the brakes on the average vehicle are applied 50,000 times a year!

Brakes are an energy-absorbing mechanism that converts vehicle movement into heat while stopping the rotation of the wheels. All braking systems are designed to reduce the speed and stop a moving vehicle and to keep it from moving if the vehicle is stationary. **Service brakes** are the main driver-operated brakes of the vehicle. Service brakes are also called **base brakes** or **foundation brakes**. ● **SEE FIGURE 93–1**.

BRAKE SYSTEM PARTS Most vehicles built since the late 1920s use a brake on each wheel. To stop a wheel, the driver exerts a force on a brake pedal. The force on the brake pedal pressurizes brake fluid in a master cylinder. This hydraulic force (liquid under pressure) is transferred through steel lines and flexible brake lines to a wheel cylinder or caliper at each wheel. Hydraulic pressure to each wheel cylinder or caliper is used to

force friction materials against the brake drum or rotor. The friction between the stationary friction material and the rotating drum or rotor (disc) causes the rotating part to slow and eventually stop. Since the wheels are attached to the drums or rotors, the wheels of the vehicles also stop.

The heavier the vehicle and the higher the speed, the more heat the brakes have to be able to absorb. Long, steep hills can cause the brakes to overheat, reducing the friction necessary to slow and stop a vehicle.

DRUM BRAKES Drum brakes are used on the rear of many rear-wheel-drive, front-wheel-drive, and four-wheel-drive vehicles. When drum brakes are applied, brake shoes are moved outward against a rotating brake drum. The wheel studs for the wheels are attached to the drum. When the drum slows and stops, the wheels also slow and stop.

Drum brakes are economical to manufacture, service, and repair. Parts for drum brakes are generally readily available and reasonably priced. An additional drum brake is used as a parking brake on vehicles equipped with rear disc brakes. ● **SEE FIGURE 93–2**.

DISC BRAKES **Disc brakes** are used on the front of most vehicles built since the early 1970s, and on the rear wheels of many vehicles. A disc brake operates by squeezing brake pads on both sides of a rotor or disc that is attached to the wheel. ● **SEE FIGURE 93–3**.

To summarize, the sequence of events necessary to stop a vehicle includes the following:

1. The driver presses on the brake pedal.
2. The brake pedal force is transferred hydraulically to a wheel cylinder or caliper at each wheel.

BRAKE SYSTEM CATEGORIES

Brake system components can be classified and placed into six subsystem categories, depending on their function. ● **SEE FIGURE 93–4** for an overall view of the entire braking system.

1. **Apply system.** The driver starts the operation of the braking system by pressing on the brake pedal or applying the parking brake. The apply system includes all the levers, pedals, or linkage needed to activate a braking force.
2. **Boost system.** The boost (power brake) system is used on most vehicles to reduce the force that the driver must exert on the brake pedal.
3. **Hydraulic system.** The brake pedal force is transferred to the hydraulic system, where the force is directed through pipes and hoses to the wheel brakes.

FIGURE 93–4 Typical brake system components.

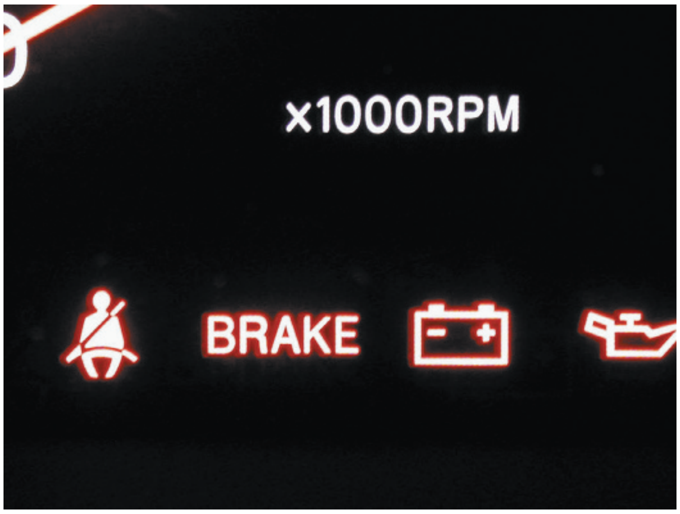

FIGURE 93–5 The red brake warning light remains on after a bulb test if there is a fault with the hydraulic part of the brake system or low brake fluid level has been detected.

4. **Wheel brakes.** Hydraulic pressure from the hydraulic system moves a piston, in either a disc or drum brake system, which uses friction to press material against a rotating drum or rotor. The resulting friction slows the rotation of the wheels.
5. **Brake balance control system.** Mechanical, electrical, and hydraulic components are used to ensure that brakes are applied quickly and with balanced pressure for safe operation. Components in this category include metering valves, proportioning valves, and antilock brake system components.
6. **Brake warning lights.** There are two brake system–related warning lights:
   - The **red brake warning lamp (RBWL)** lights whenever a hydraulic system failure occurs or low brake fluid level has been detected. The red brake warning lamp lights when the ignition is turned on as a bulb check, then goes out, unless a hydraulic fault has been detected. ● **SEE FIGURE 93–5**.

CAUTION: Do not test-drive a vehicle if the red brake warning light is on.

   - The amber ABS warning lamp or dim red brake light indicates an ABS self-test and/or a possible problem in the ABS. This warning light usually flashes several times during a self-test when the engine is first started and then goes out, unless a fault with the antilock brake system is detected. ● **SEE FIGURE 93–6**.

FIGURE 93–6 The ABS warning light is amber.

FREQUENTLY ASKED QUESTION

How Do Adjustable Pedals Work?

Adjustable pedals, also called **electric adjustable pedals (EAP)**, place the brake pedal and the accelerator pedal on movable brackets that are motor operated. A typical adjustable pedal system includes the following components:

- **Adjustable pedal position switch**, which allows the driver to position the pedals.
- **Adjustable pedal assembly**, which includes the motor, threaded adjustment rods, and a pedal position sensor. ● **SEE FIGURE 93–7**.

The position of the pedals, as well as the position of the seat system, is usually included as part of the memory seat function and can be set for two or more drivers.

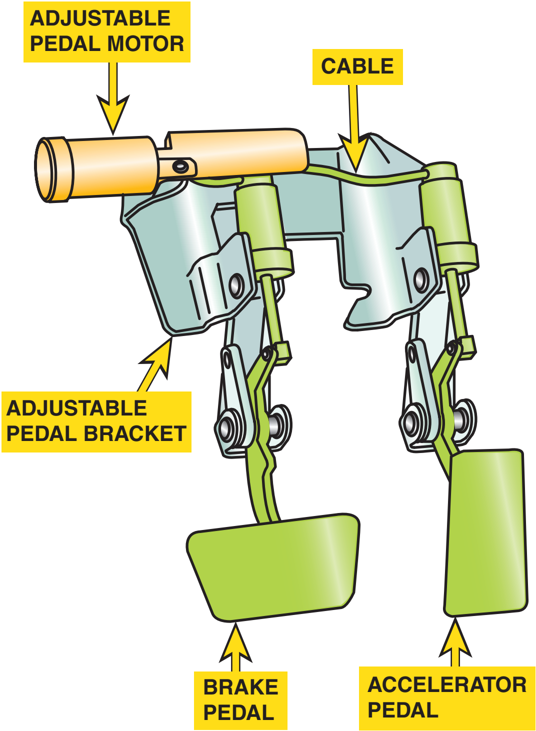

FIGURE 93–7 A typical adjustable pedal assembly. Both the accelerator and the brake pedal can be moved forward and rearward by using the adjustable pedal position switch.

ANTILOCK BRAKE SYSTEM OVERVIEW

The purpose of an **antilock brake system (ABS)** is to prevent the wheels from locking during braking, especially on low-friction surfaces, such as wet, icy, or snowy roads. It is the friction between the tire tread and the road that does the actual stopping of the vehicle. Therefore, ABS does not mean that a vehicle can stop quickly on all road surfaces. ABS uses sensors at the wheels to measure the wheel speed. If a wheel is rotating slower than the others, indicating possible lockup (e.g., on an icy spot), the ABS computer controls the brake fluid pressure to that wheel for a

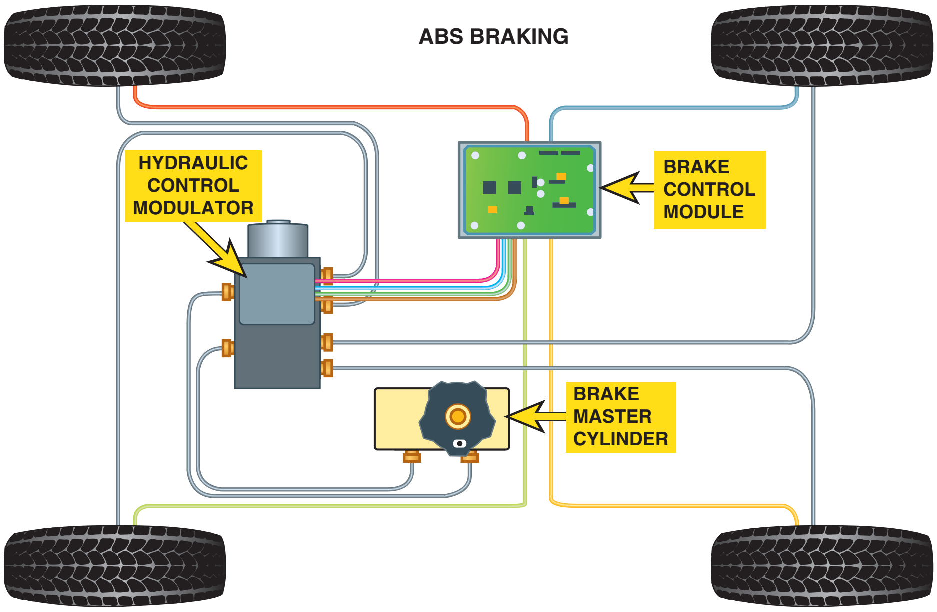

FIGURE 93–8 Typical components of an antilock brake system (ABS) used on a rear-wheel-drive vehicle.

fraction of a second. *A locked wheel has less traction to the road surface than a rotating wheel.*

The ABS computer can reapply the pressure from the master cylinder to the wheel a fraction of a second later. Therefore, if a wheel starts to lock up, the purpose of the ABS is to pulse the brakes on and off to maintain directional stability with maximum braking force. Many ABS units cause the brake pedal to pulse if the unit is working in the ABS mode. When ABS is pulsing the brakes, the driver can steer the vehicle so the driver has more control during braking than a vehicle without ABS. Some ABS units use an isolator valve to prevent brake pedal pulsations during ABS operation. With these types of systems, it is often difficult for the driver to know if and when the ABS unit is working to control a locking wheel. ● **SEE FIGURE 93–8** for an overview of a typical ABS on a rear-wheel-drive vehicle.

Another symptom of normal ABS unit operation is the activation of the hydraulic pressure pump used by many ABS units. In some ABS units, the hydraulic pump is run every time the vehicle is started and moved. Other types of units operate randomly or whenever the pressure in the system calls for the pump to operate.

FEDERAL BRAKE STANDARDS

The statutes pertaining to automotive brake systems are part of the **Federal Motor Vehicle Safety Standards (FMVSS)** established by the U.S. **Department of Transportation (DOT)**. Several standards apply to specific components within the brake system. The overall service and parking brake systems are dealt with in standard 135.

FMVSS 135 was first mandated on September 1, 2000, for passenger vehicles, and September 1, 2002, for multipurpose vehicles, trucks, and buses with a gross vehicle weight rating (GVWR) of 7,716 pounds (3,500 kg) or less. Its purpose is to “ensure safe braking performance under normal and emergency conditions.” FMVSS 135 applies to “passenger vehicles, multipurpose passenger vehicles, trucks, and buses.”

FMVSS 135 deals with brake system safety by establishing specific brake performance requirements. It does not dictate the *design* of the system, although some requirements may make older technologies impractical or obsolete. Only four parts of the brake system are specifically regulated:

- Fluid reservoir and labeling
- Dashboard warning lights
- A method of automatic adjustment
- A mechanically engaging, friction-type parking brake system

The FMVSS 135 tests are used by manufacturers to certify the braking performance of all new vehicles available for public purchase.

FMVSS 135 BRAKE TEST

The overall FMVSS 135 brake test procedure consists of up to 24 steps, depending on the vehicle’s configuration and braking system. The actual performance tests are made with the vehicle loaded to both the manufacturer’s specified **gross vehicle weight rating (GVWR)** and the **lightly loaded vehicle weight (LLVW)**, with certain applied brake forces. There are precise instructions for every step of the test, including the number of times the tests must be repeated, the sequence of the testing, and the allowable stopping distance for the particular type of vehicle. Some highlights of the testing procedure include the following:

- **Burnish Procedure.** The brakes are burnished by making 200 stops from 50 mph (80 km/h) at a fixed rate of deceleration with a controlled cool-down period after each stop. This procedure conditions the friction material.
- **Adhesion Utilization (torque wheel method).** For vehicles not equipped with ABS, this test is to determine if the brake system makes adequate use of the road surface in stopping the vehicle.
- **Cold Effectiveness.** This test is performed to determine if the vehicle has sufficient stopping power when the brake lining materials are not preheated by previous stops.
- **High-Speed Effectiveness.** This test is performed to determine if the brake system provides adequate stopping power for all loading conditions. The allowable stopping distance is calculated from the maximum speed the vehicle can attain.

FREQUENTLY ASKED QUESTION

What Is a GM RPO Code?

The GM regular production code (RPO) is the code used when the vehicle was built, including all optional equipment listed, which includes letters and/or numbers. Most General Motors vehicles have the RPO sticker, also called the Service Parts Identification label, in the trunk, most often on the spare tire cover. Trucks usually have the RPO sticker in the glove box. ● **SEE FIGURE 93–9**.

Before ordering parts, take a photo of the vehicle identification number (VIN) and the RPO sticker. Having these available to answer any questions at the parts counter saves a lot of time and makes sure that the correct part is being ordered for the vehicle. The brake-related RPO codes start with the letter "J" and include the type or rating of the brake system. Some sample brake system–related RPO codes include

J41 BRAKE SYSTEM, PWR, FRT DISC, RR DRUM, CAST IRON
J42 BRAKE SYSTEM, PWR, FRT DISC, RR DRUM, ALUMINUM
J65 BRAKE SYSTEM, PWR, FRT & RR DISC
J85 BRAKE SYSTEM, PWR, FRT & RR DISC
JA1 BRAKE, LIGHT WEIGHT DISC DRUM
JA2 BRAKE, HEAVY WEIGHT DISC DRUM
JA8 BRAKE, MEDIUM WEIGHT DISC DRUM
JB3 BRAKE, POWER, DISC/DRUM, 4,600 LBS
JB5 BRAKE, POWER, DISC/DRUM, 6,400 LBS
JB6 BRAKE, POWER, DISC, DRUM 7,200 LBS
JB7 BRAKE, POWER, DISC, DRUM 8,400 L85
JB8 BRAKE, POWER, DISC, DRUM 10,000 LBS
JB9 BRAKE, LIGHT WEIGHT, DISC/DISC
JC4 BRAKE, POWER, DISC, DRUM 5,600 LBS
JC5 BRAKE, VAC POWER, 4-WHEEL DISC, 7,200 LBS
JD3 BRAKE, HYD POWER, DISC/DRUM
JE5 BRAKE, SYSTEM, PWR, ANTILOCK, FRT & RR WHL
JF9 BRAKE, HYD POWER, 4 WHEEL DISC
JH5 BRAKE, HYD POWER, 4-WHEEL DISC, 7,200 LBS
JH6 BRAKE, HYD POWER, 4-WHEEL DISC, 9,900 LBS
JL8 FRONT & REAR DISC BRAKES
JM5 BOOSTER, BRAKE, 200MM TANDEM, HIGH FLOW
JM8 BRAKE SYSTEM PWR, FRT DISC RR DRUM, ALUMINUM.

FREQUENTLY ASKED QUESTION

Do the FMVSS 135 Standards Apply to Replacement Brake Performance?

No. The Federal Motor Vehicle Safety Standard 135 applies to new vehicles. Replacement parts used during a brake repair or replacement may or may not permit the vehicle to achieve the same standards as when new.

To help ensure like-new braking performance, the service technician should always use quality brake parts from a known manufacturer.

- **Stops with the Engine Off.** This test is for vehicles equipped with brake power assist units. The vehicle, loaded to GVWR, must stop within 230 ft (70 m), from a speed of 62 mph (100 km/h). This test must be repeated six times.
- **Antilock Functional Failure.** This test ensures that service brakes function correctly in the event of an antilock functional failure, and the brake system warning indicator is activated when an ABS electrical function failure occurs.
- **Variable Brake Proportioning System.** This test is performed on vehicles equipped with either a mechanical or an electrical variable proportioning system. It ensures that, in the event of a failure, the vehicle can still come to a stop in an acceptable distance.
- **Hydraulic Circuit Failure.** This test is performed to ensure that the driver is alerted via the brake warning system indicator that a failure has occurred, and that the vehicle can still be stopped in an acceptable distance.
- **Brake Power Assist Unit Inoperative.** This test makes sure the service brake can stop the vehicle in an acceptable distance with the brake power assist unit in an inoperative state. It is performed on vehicles with brake power assist units turned off or inoperative.
- **Parking Brake.** The parking brake alone holds the vehicle stationary in either the forward or reverse direction on a 20% grade for a period of at least five minutes.
- **Brake Heat Test.** This procedure heats the brake system by making a series of 15 stops from a high speed. The vehicle is loaded to GVWR, with rapid acceleration between each stop to minimize cooling the brakes.
- **Hot Performance.** After the brake system has been heated by a series of heating snubs, the hot performance test is immediately performed. The vehicle is loaded to GVWR and two stops are made. The stopping distance must be within acceptable limits as specified in the test. This test ensures that the brake system on the vehicle does not fade following a series of high-speed stops at GVWR.

Although these tests may seem extreme, they are only a minimum standard of performance. Any brake repair work should also leave the brake system capable of meeting FMVSS 135.

BRAKE REPAIR AND THE LAW

Once a vehicle leaves the factory, the responsibility for maintaining the designed-in level of braking performance falls on the owner of the vehicle. Owners look to trained automotive technicians to service their brake systems. Many states have laws that regulate brake work to help ensure safe repairs. These laws vary from one area to another, but they may require special licensing for brake technicians, or special business practices when selling brake work. In some cases, the laws provide the consumer with specific warranties and the right to outside arbitration in cases of defective or substandard repairs.

Regardless of whether there are specific laws governing brake repair, a technician is always liable for damage or injuries resulting from repairs performed in an unprofessional or unworkman-like manner. Considering the lives and property that depend on good brakes, there is only one acceptable goal when making brake system repairs: to restore the system and its component parts so they perform to original specifications. In other words, *the purpose of any repair is to restore like-new performance.*

REVIEW QUESTIONS

1. List the differences between drum brakes and disc brakes.
2. List the six brake subsystem categories.
3. Explain how ABS units prevent wheel lockup.
4. List 10 of the brake tests performed under the Federal Motor Vehicle Safety Standard (FMVSS) 135.
5. What is the purpose of any brake repair?

CHAPTER QUIZ

1. Disc brakes use replaceable friction material called ________.
   a. linings
   b. pads
   c. core
   d. web
2. Drum brakes use replaceable friction material called ________.
   a. shoes
   b. pads
   c. core
   d. web
3. Technician A says that a power-assisted brake reduces stopping distances compared with a nonpower-assisted brake system. Technician B says that the power-assisted brake system reduces the force that the driver must exert on the brake pedal. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. What is the color of the antilock brake system (ABS) warning lamp?
   a. Red
   b. Amber
   c. Yellow
   d. Green
5. If a vehicle is equipped with antilock brakes, this means that ________.
   a. the vehicle is able to be steered during hard braking
   b. the brake pedal pulsates during normal braking
   c. the vehicle is able to stop in a shorter distance, regardless of road conditions
   d. All of the above
6. The FMVSS 135 standards determine ________.
   a. the design of the braking system
   b. the performance of the braking system
   c. the materials used in the braking system
   d. All of the above
7. An owner of a vehicle equipped with ABS brakes complained that whenever they tried to stop on icy or slippery roads, the brake pedal would pulse up and down rapidly. Technician A says that this is normal for many ABS units. Technician B says that the ABS unit is malfunctioning. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
8. Which of the following will turn on the red brake warning lamp (RBWL)?
   a. Hydraulic system failure
   b. Low brake fluid level
   c. During a bulb check
   d. All of the above
9. All of the following are specified by the FMVSS 135 *except* ________.
   a. brake burnish procedure
   b. variable brake proportioning system
   c. brake noise levels
   d. cold effectiveness
10. What is the purpose of any brake repair?
    a. Reduce noise during braking
    b. Replace pads and linings
    c. Restore proper brake pedal height
    d. Restore like-new performance

Chapter 94

BRAKING PRINCIPLES AND FRICTION MATERIALS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss the energy principles that apply to brakes.
- Discuss inertia as it applies to brakes.
- Discuss the friction principles that apply to brakes.
- Describe how brakes can fade due to excessive heat.
- Describe how deceleration rates are measured.
- Describe brake friction materials.
- Discuss asbestos as it applies to brakes.
- Describe semimetallic friction materials.
- Discuss non-asbestos/ceramic friction materials.
- Explain brake pad environmental concerns.
- Discuss the use of edge codes on friction materials.

KEY TERMS:

Asbestos 1083 • Brake fade 1080 • Ceramic 1084 • Coefficient of friction 1080 • Copper 1084 • Edge codes 1085 • Energy 1078 • Kinetic energy 1078 • Leaf mark 1085 • Lining fade 1081 • Mechanical fade 1081 • Mu (μ) 1080 • Non-asbestos 1083 • Non-asbestos organic (NAO) 1083 • Non-asbestos synthetic (NAS) 1083 • Semimetallic 1083 • Weight bias 1080 • Work 1078

ENERGY AND WORK

ENERGY **Energy** is the ability to do work. There are many forms of energy, but chemical, mechanical, and electrical energy are the most familiar kinds involved in the operation of an automobile. ● **SEE FIGURE 94–1**.

WORK **Work** is the transfer of energy from one physical system to another—especially the transfer of energy to an object through the application of force. This is precisely what occurs when a vehicle's brakes are applied: The force of the actuating system transfers the energy of the vehicle's motion to the brake drums or rotors where friction converts it into heat energy and stops the vehicle.

KINETIC ENERGY **Kinetic energy** is a fundamental form of mechanical energy. It is the energy of mass in motion. Every moving object possesses kinetic energy, and the amount of that energy is determined by the object's mass and speed. The greater the mass of an object and the faster it moves, the more kinetic energy it possesses. Even at low speeds, a moving vehicle has enough kinetic energy to cause serious injury and damage. The purpose and function of the brake system is to dispose of that

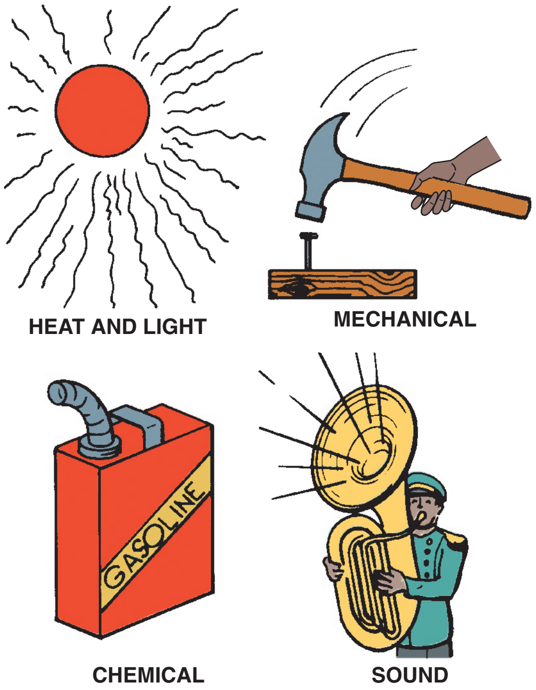

FIGURE 94–1 Energy, which is the ability to perform work, exists in many forms.

energy in a safe and controlled manner. Engineers calculate kinetic energy using the following formula:

$$\frac{mv^2}{29.9} = E_k$$

where

m = **mass or weight of the vehicle in pounds (lb)**

v = **velocity of the vehicle in miles per hour**

E_k = **kinetic energy in foot-pounds (ft-lb)**

NOTE: Mass is how much material something contains, whereas weight is the effect of gravity on an object.

Another way to express this equation is as follows:

$$\frac{\text{weight} \times \text{speed}^2}{29.9} = \text{kinetic energy}$$

KINETIC ENERGY EXAMPLE #1 A 3,000 lb vehicle traveling at 30 MPH is compared with a 6,000 lb vehicle, also traveling at 30 MPH. ● **SEE FIGURE 94–2**.

The equations for computing their respective kinetic energies look like this:

$$\frac{3{,}000 \text{ lb} \times 30^2 \text{ MPH}}{29.9} = 90{,}301 \text{ ft-lb}$$

$$\frac{6{,}000 \text{ lb} \times 30^2 \text{ MPH}}{29.9} = 180{,}602 \text{ ft-lb}$$

The results show that

- When the weight of a vehicle is doubled from 3,000 to 6,000 lb, its kinetic energy is also doubled from 90,301 to 180,602 ft-lb.
- In mathematical terms, kinetic energy increases *proportionally* as weight increases. In other words, if the weight of a moving object doubles, its kinetic energy also doubles.
- If the weight quadruples, the kinetic energy becomes four times as great.

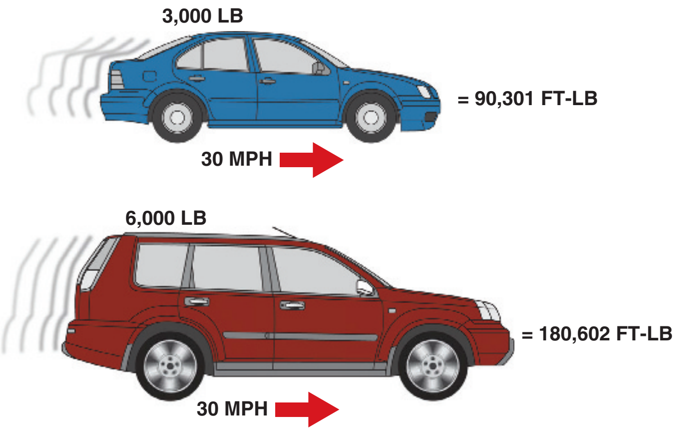

FIGURE 94–2 Kinetic energy increases in direct proportion to the weight of the vehicle.

TECH TIP

Brakes Stop Wheels, Not the Vehicle

Brakes are used to slow and stop the rotation of the wheels. The tires are attached to the wheels, and the friction between the tire tread and the pavement is what actually stops the vehicle. If the vehicle is on a slippery surface, such as gravel or snow, the wheels may be stopped by the brakes, but the vehicle can continue without slowing if there is a lack of traction between the tires and the ground.

KINETIC ENERGY EXAMPLE #2 A 3,000 lb vehicle traveling at 30 MPH is compared with the same vehicle, traveling at 60 MPH. ● **SEE FIGURE 94–3**.

$$\frac{3{,}000 \text{ lb} \times 30^2 \text{ MPH}}{29.9} = 90{,}301 \text{ ft-lb}$$

$$\frac{3{,}000 \text{ lb} \times 60^2 \text{ MPH}}{29.9} = 361{,}204 \text{ ft-lb}$$

The results show that the vehicle traveling at 30 MPH has over 90,000 ft-lb of kinetic energy, but at 60 MPH the figure increases to over 350,000 ft-lb.

- At twice the speed, the vehicle has exactly four times as much kinetic energy.
- If the speed were doubled again to 120 MPH, the amount of kinetic energy grows to almost 1,500,000 ft-lb! In mathematical terms, kinetic energy increases as the *square of its speed*.
- In other words, if the speed of a moving object doubles (2), the kinetic energy becomes four times as great ($2^2 = 4$). And if the speed quadruples (4), say from 15 to 60 MPH, the kinetic energy becomes 16 times as great ($4^2 = 16$). This is the reason speed has such an impact on kinetic energy.

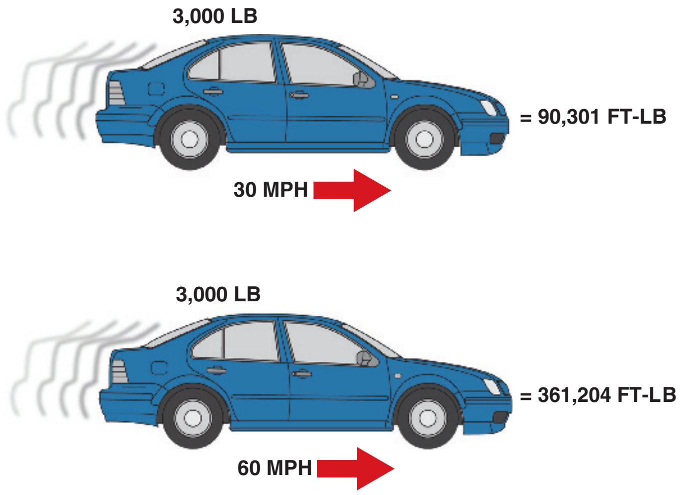

FIGURE 94–3 Kinetic energy increases as the square of any increase in vehicle speed.

INERTIA

DEFINITION Inertia is defined by Isaac Newton's first law of motion, which states that a body at rest tends to remain at rest, and a body in motion tends to remain in motion in a straight line unless acted upon by an outside force.

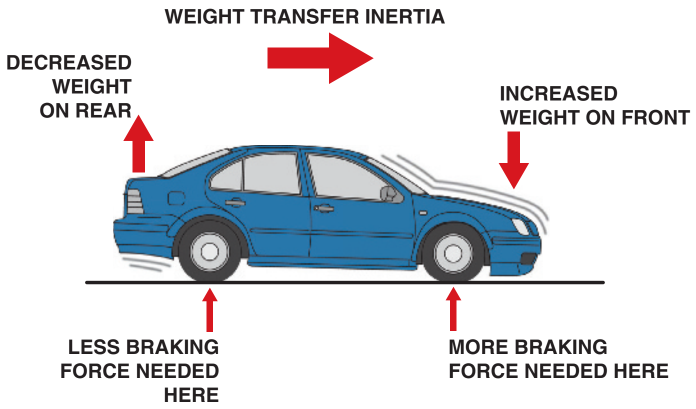
WEIGHT TRANSFER Inertia, in the form of weight transfer, plays a major part in braking performance. Newton's first law of motion states, if applied to a vehicle:

> A moving vehicle remains in motion unless acted upon by an outside force.

The sequence that occurs when the brakes are applied includes

- The vehicle brakes provide that outside force, but when the brakes are applied at the wheel friction assemblies, only the wheels and tires begin to slow immediately.
- The rest of the vehicle, all of the weight carried by the suspension, attempts to remain in forward motion.
- The result is that the front suspension compresses, the rear suspension extends, and the weight is transferred toward the front of the vehicle. ● **SEE FIGURE 94–4**.

WEIGHT BIAS The total weight of the vehicle does not change during a brake application, only the amount supported by each axle. To compound the problem of weight transfer, most vehicles also have a forward **weight bias**, which means that even when stopped, more than 50% of their weight is supported by the front wheels. This occurs because the engine, transmission, and most other heavy parts are located toward the front of the vehicle. ● **SEE FIGURE 94–5**.



WEIGHT TRANSFER INERTIA
DECREASED WEIGHT ON REAR
INCREASED WEIGHT ON FRONT
LESS BRAKING FORCE NEEDED HERE
MORE BRAKING FORCE NEEDED HERE

FIGURE 94–4 Inertia creates weight transfer that requires the front brakes to provide most of the braking force.

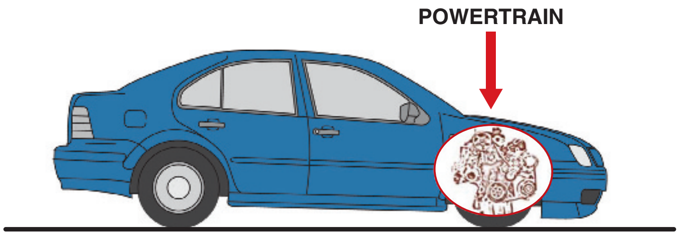


FIGURE 94–5 Front-wheel-drive vehicles have most of their weight over the front wheels.

Front-wheel-drive (FWD) vehicles, in particular, have a forward weight bias. Whenever the brakes are applied, weight transfer and weight bias greatly increase the load on the front wheels, while the load on the rear wheels is reduced. This requires the front brakes to provide 60% to 80% of the total braking force. To deal with the extra load, the front brakes are much more powerful than the rear brakes.

COEFFICIENT OF FRICTION

DEFINITION The amount of friction between two objects or surfaces is commonly expressed as a value called the **coefficient of friction** and is represented by the Greek letter **mu (μ)**, pronounced "mYOO." The coefficient of friction, also referred to as the *friction coefficient*, is determined by dividing tensile force by weight force. The tensile force is the pulling force required to slide one of the surfaces across the other. The weight force is the force pushing down on the object being pulled. The complete friction assembly (including lining and backing) is often called a *brake pad* or *brake shoe*. The friction coefficient (μ) for most standard brake pads is usually in the range of 0.25 to 0.55.

STATIC AND KINETIC FRICTION There are actually two measurements of the coefficient of friction: the static friction coefficient and the kinetic friction coefficient. The static value is the coefficient of friction with the two friction surfaces at rest. The kinetic value is the coefficient of friction while the two surfaces are sliding against one another. The coefficient of static friction is always higher than that of kinetic friction, which explains why it is harder to *start* an object moving than to *keep* it moving. ● **SEE FIGURE 94–6**.

It takes 100 pounds of tensile force to start the wooden block sliding, but once in motion, it takes only 50 pounds to keep it sliding. The relatively high static friction is harder to overcome than the somewhat lower kinetic friction. The static and kinetic friction coefficients for several combinations of materials are shown in ● **CHART 94–1**.

The difference between static and kinetic friction explains why parking brakes, although much less powerful than service brakes, are still able to hold a vehicle in position on a hill. The job of the parking brakes is relatively easy because

- The stationary vehicle has no kinetic energy.
- The brake lining and drum or discs are not moving when they are applied.
- To start the vehicle moving, enough force has to be applied to overcome the relatively high static friction of the parking brakes.

The service brakes, however, have a much more difficult job. The moving vehicle has a great deal of kinetic energy, and the fact that the brake friction surfaces are in relative motion means that kinetic friction makes them less efficient.

BRAKE FADE

DEFINITION If repeated hard stops are performed, the brake system components can overheat and lose effectiveness, or possibly fail altogether. This loss of braking power is called **brake fade**.

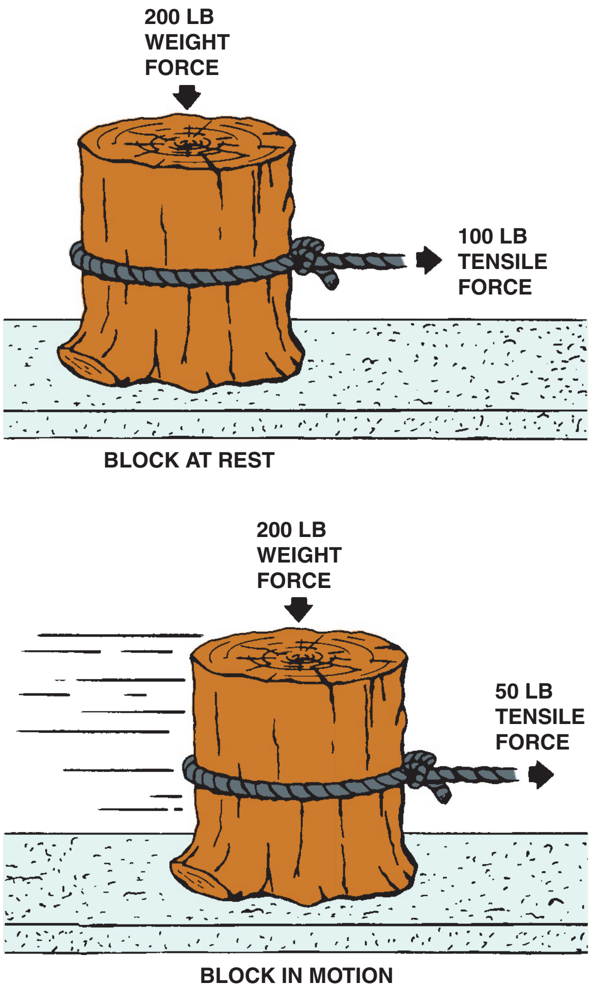

FIGURE 94–6 The static coefficient of friction of an object at rest is higher than the kinetic (dynamic) friction coefficient once in motion.

CONTACTING SURFACES	STATIC COEFFICIENT OF FRICTION	KINETIC COEFFICIENT OF FRICTION
Steel on steel (dry)	0.6	0.4
Steel on steel (greasy)	0.1	0.05
Teflon on steel	0.04	0.04
Brass on steel (dry)	0.5	0.4
Brake lining on cast iron	0.4	0.3
Rubber tires on smooth pavement (dry)	0.9	0.8

CHART 94–1

Every combination of materials has different static and kinetic friction coefficients.

MECHANICAL FADE **Mechanical fade** occurs when a brake drum overheats and expands away from the brake lining. To maintain braking power, the brake shoes must move farther outward, which requires additional brake pedal travel. When the drum expands to a point where there is not enough pedal travel to keep the lining in contact with the drum, brake fade occurs. Mechanical fade is not a problem with disc brakes because as a brake rotor heats up, it expands toward the brake pads, rather than away from them.

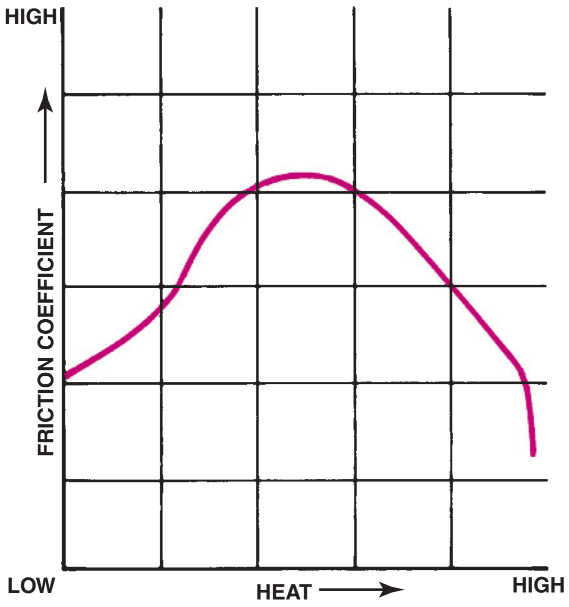

FIGURE 94–7 Some heat increases the coefficient of friction, but too much heat can cause it to drop off sharply.

LINING FADE **Lining fade** affects both drum and disc brakes and occurs when the friction material overheats to the point where its coefficient of friction drops off. ● **SEE FIGURE 94–7**.

When lining fade occurs on drum brakes, partial braking power can sometimes be restored by increasing pressure on the brake pedal, although this may only make matters worse, since the extra pressure increases the amount of heat and fade. With disc brakes, lining fade is possible, but is less of a problem because of disc brakes' superior ability to dissipate heat. The rotor friction surfaces are exposed to the passing air, and most rotors have internal ventilation passages that further aid in cooling.

GAS FADE Gas fade is a relatively rare type of brake fade that occurs under very hard braking when a thin layer of hot gases and dust particles builds up between the brake drum or rotor and linings. The gas layer acts as a lubricant and reduces friction. ● **SEE FIGURE 94–8**.

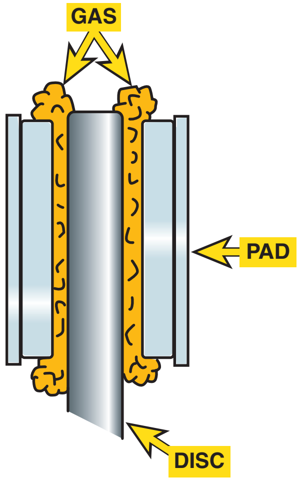

FIGURE 94–8 One cause of brake fade occurs when the phenolic resin, a part of the friction material, gets so hot that it vaporizes. The vaporized gas from the disc brake pads gets between the rotor (disc) and the friction pad. Because the friction pad is no longer in contact with the rotor, no additional braking force is possible.

- As with lining fade, greater application force at the brake pedal is required to maintain a constant level of stopping power.
- Gas fade becomes more of a problem as the size of the brake lining increases because gases and particles have a harder time escaping from under a drum brake shoe than a disc brake pad.
- Some high-performance brake shoes and pads have slotted linings to provide paths for gas and particles to escape.

In most cases, brake fade is a temporary condition and the brakes return to normal once they have all been allowed to cool.

WATER FADE If a vehicle is driven through deep water or during a severe rainstorm, water can get between the brake drum and the linings. When this occurs, no stopping power is possible until the water is pushed out and normal friction is restored. While water fade is most likely to occur with drum brakes, it can also occur on disc brakes. After driving through deep water, the wise driver should lightly apply the brakes to check the operation and to help remove any water trapped between the friction material and the rotor or drum.

DECELERATION RATES

TERMINOLOGY Deceleration rates are measured in units of "feet per second per second" (No, this is not a misprint). What it means is that the vehicle changes in velocity during a certain time interval divided by the time interval. Deceleration is abbreviated "ft/sec^2" (pronounced "feet per second per second" or "feet per second squared") or meters per sec^2 (m/sec^2) in the metric system.

TECH TIP

How to Reduce Possible Brake Fade?

To help prevent possible brake fade while descending long hills, place the gear selector into a lower drive range, such as "2," or even "1," if going slowly enough. This action allows for additional engine braking and takes the load off of the wheel brakes. ● **SEE FIGURE 94–9**.

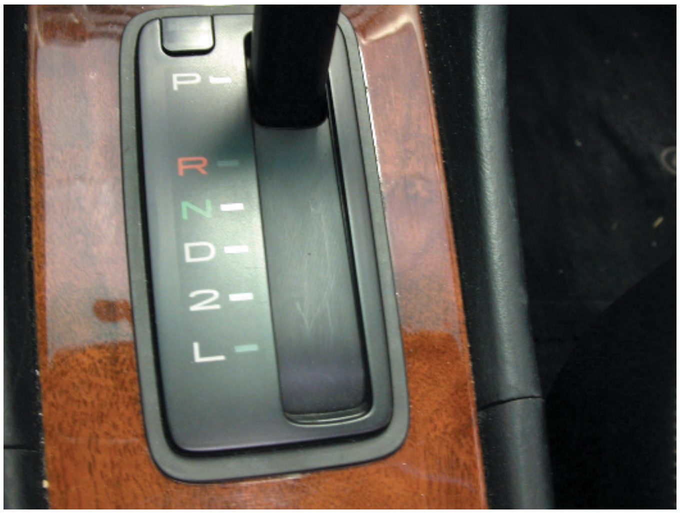

FIGURE 94–9 The gear selector is often called the "PRNDL," pronounced "prindle," regardless of the actual letters or numbers used. Move the gear selector to a low range when descending long steep grades to avoid overheating the brakes.

FIGURE 94–10 Rapid braking causes the brake friction material to wear more compared to gentle, less aggressive, braking.

TYPICAL DECELERATION RATES Typical deceleration rates include the following:

- Comfortable deceleration is about 8.5 ft/sec^2 (3 m/sec^2).
- Loose items in the vehicle "fly" above 11 ft/sec^2 (3.5 m/sec^2).
- Maximum deceleration rates for most vehicles and light trucks range from 16 to 32 ft/sec^2 (5 to 10 m/sec^2).

An average deceleration rate of 15 ft/sec^2 (3 m/sec^2) can stop a vehicle traveling at 55 MPH (88 km/h) in about 200 ft (61 m) in less than four seconds. ● **SEE FIGURE 94–10**.

BRAKE TEMPERATURE Temperatures at the front brake pads can reach

- 1,300°F (700°C) or higher during normal driving
- as high as 1,800°F (980°C) during braking from a high speed or during long descents

Brake fluid and rubber components may reach 300°F (150°C) or higher.

BRAKE FRICTION MATERIALS

PURPOSE AND FUNCTION Brake friction materials are composed of relatively soft, but tough, and heat-resistant material to provide the friction between the moveable part of the braking system (drum or rotor) and the stationary part of the braking system. The brake friction material has to provide the friction needed to slow and stop the vehicle quietly, and still provide a long service life.

BRAKE LINING COMPOSITION Brake shoes and pads operate under the most extreme conditions in the entire brake system and are subject to wear. Friction materials, such as disc brake pads or drum brake shoes, contain a mixture of ingredients. These materials include a binder, such as

- thermosetting resin
- fibers (for reinforcement)
- friction modifiers (to obtain a desired coefficient of friction)

BRAKE BLOCKS The various ingredients in brake lining are mixed and molded into the shape of the finished product. The fibers in the material are the only thing holding this mixture together. A large press is used to force the ingredients together to form a brake block, which eventually becomes the brake lining/pads.

ASBESTOS

DEFINITION **Asbestos** is the term used to describe naturally occurring silicate minerals that consist of long fibers. Asbestos mining began more than 4,000 years ago, but did not start large scale until the end of the nineteenth century when manufacturers and builders began using asbestos for

- sound absorption
- its resistance to fire, heat, electrical, and chemical damage
- affordability

It was used in such applications as electrical insulation for hotplate wiring and in building insulation. When asbestos is used for its resistance to fire or heat, the fibers are often mixed with cement or woven into fabric or mats. These desirable properties made asbestos a very widely used material, and its use continued to grow throughout most of the twentieth century until the carcinogenic (cancer-causing) effects of asbestos were discovered, which caused its effective demise as a mainstream construction and fireproofing material in most countries.

ASBESTOS HAZARDS Asbestos exposure can cause scar tissue to form in the lungs. This condition is called asbestosis. It gradually causes increasing shortness of breath, and the scarring to the lungs is permanent. Even low exposures to asbestos can cause mesothelioma, a type of fatal cancer of the lining of the chest or abdominal cavity. Asbestos exposure can also increase the risk of lung cancer, as well as cancer of the voice box, stomach, and large intestine. It usually takes 15 to 30 years or more for cancer or asbestos lung scarring to show up after exposure.

ASBESTOS BRAKE LININGS Asbestos was a popular component for vehicle brakes because of its heat resistance and strength. Brake friction materials that used asbestos were called *organic* linings/pads. The U.S. Environmental Protection Agency (EPA) has not banned the use of asbestos in drum brake linings or disc brake pads, even though it has banned its use in corrugated paper, roll board, commercial paper, specialty paper, and flooring felt.

The concentration of asbestos in brake lining was estimated at 30% to 50%. The routine tasks of "blowing out" brake surfaces (using an air hose to clean the surfaces) were considered to be the most common way workers were exposed. The use of asbestos for brake linings was never abandoned completely. ● **SEE CHART 94–2**.

INGREDIENT	TYPICAL FORMULA RANGE
Phenolic resin (binder)	9% to 15%
Asbestos fiber	30% to 50%
Organic friction modifiers (rubber scrap)	8% to 19%
Inorganic friction modifiers (barites, talc, whiting)	12% to 26%
Abrasive particles (alumina)	4% to 20%
Carbon	4% to 20%

CHART 94–2

Typical brake compositions for asbestos (organic) lining.

TECH TIP

Competitively Priced Brakes

The term "competitively priced" means lower cost. Most brake manufacturers offer "premium" as well as lower-price linings to remain competitive with other manufacturers, or with importers of brake lining material produced overseas by U.S. or foreign companies. Organic asbestos brake lining is inexpensive to manufacture. In fact, according to warehouse distributors and importers, the box often costs more than the brake lining inside. Professional brake service technicians should only install brake linings and pads that give braking performance equal to that of the original factory brakes. For best results, always purchase high-quality brake parts from a known brand-name manufacturer.

SEMIMETALLIC FRICTION MATERIALS

DEFINITION The term **semimetallic** refers to brake lining material that uses metal, rather than asbestos, in its formulation. It still uses resins and binders and is, therefore, not 100% metal, but rather semimetallic. Semimetallic pads are commonly called "semi-mets."

CONSTRUCTION The metal in most metallic linings is made from metal particles that have been fused together without melting. This process is called *sintering* and the result is called *sintered metal linings*. Most semimetallic linings do not contain asbestos. Semimetallic linings require a very smooth finish on the rotor because the metal in the lining does not conform to the surface of the rotor, as does asbestos lining. A major disadvantage of semimetallic disc brake pads is that it causes a lot of brake dust, which discolors the vehicle wheels. ● **SEE CHART 94–3**.

NON-ASBESTOS/CERAMIC FRICTION MATERIALS

TERMINOLOGY Brake pads and linings that use synthetic material, such as aramid fibers, instead of steel are usually referred to as

- **non-asbestos**
- **non-asbestos organic (NAO)**
- **non-asbestos synthetic (NAS)**

INGREDIENT	FORMULA RANGE
Phenolic resin	15% to 40%
Graphite or carbon particles	15% to 40%
Steel fibers	0% to 25%
Ceramic powders	2% to 10%
Steel, copper, brass metal powders	15% to 40%
Other modifiers (rubber scrap)	0% to 20%

CHART 94–3

Typical brake compositions for semimetallic disc brake pads.

INGREDIENT	FORMULA RANGE
Phenolic resin	15% to 40%
Graphite or carbon	20% to 30%
Copper	0% to 22% (Being phased out)
Ceramic powders	5% to 30%
Aluminum, barium, calcium, iron, potassium, magnesium, sodium	Each <2%
Fillers (barium sulfate, aramid fibers, ceramic fibers, other mined mineral powders)	5% to 10%

CHART 94–4

Typical compositions for NAO/ceramic friction materials.

These friction materials are often called **ceramic** in the American aftermarket because they include ceramic fibers, which are usually potassium titanite.

CONSTRUCTION Linings are called synthetic because synthetic fibers are used. These linings use aramid fiber instead of metal as the base material. Aramid is the generic name for aromatic polyamide fibers. Kevlar is the Dupont brand name of aramid and a registered trademark of E.I. Dupont de Nemours and Company.

- Non-asbestos linings are often quieter than semimetallic pads and cause less wear to brake rotors, as do semimetallic pads.
- Brake dust from NAO disc brake pads is less than from semimetallic pads. ● **SEE CHART 94–4**.

CARBON FIBER FRICTION MATERIALS Carbon fiber brake lining is the newest and most expensive of the lining materials.

Carbon fiber material is often called CFRC (carbon fiber-reinforced carbon). It is composed of a carbon mix into which reinforcing carbon fibers are embedded. CFRC is commonly used in the brakes of jet aircraft and racing cars. CFRC brakes provide constant friction coefficient whether cold or hot, low wear rates, and low noise development.

BRAKE PADS AND ENVIRONMENTAL CONCERNS

USE OF COPPER IN BRAKE PADS **Copper** is a soft metal with very high thermal and electrical conductivity and is used in most brake lining/pads because it

- Helps transfer heat efficiently and increases brake effectiveness in cold weather
- Helps prevent brakes from squeaking and shuddering
- Adds strength to the brake pad material
- Helps reduce fade so that brakes remain effective through extended braking events.

FREQUENTLY ASKED QUESTION

What Are Ceramic Pads Exactly?

NAO/Ceramic friction materials contain some ceramic powders or fibers. They are not "ceramic matrix composites," but rather they are an organic matrix composite molded using a phenolic resin. NAO materials typically exhibit low friction and/or high wear rates at high temperatures. To counteract this behavior, they sometimes contain many other raw materials (such as abrasives and metal sulfides) to maintain thermal stability. Metal sulfides generally provide lubrication and reduce noise created by these friction materials. Ceramic compounds provide much quieter braking because the ceramic compound helps dampen noise by generating a frequency beyond the human hearing range.

Another characteristic that makes ceramic materials attractive is the absence of noticeable dust. All brake pads produce dust as they wear. The ingredients in ceramic compounds produce a light-colored dust that is much less noticeable and less likely to stick to the wheels. Ceramic pads meet or exceed all original equipment standards for durability, stopping distance, and noise.

This is quite an improvement over organic and semimetallic brake materials that typically sacrifice pad life to reduce noise, or vice versa.

FREQUENTLY ASKED QUESTION

What Do D^{3}EA and BEEP Mean?

Original equipment brake pads and shoes are required to comply with the Federal Motor Vehicle Safety Standard (FMVSS) 135, which specifies maximum stopping distances. There is also a requirement for fade resistance, but no standard for noise or wear. Aftermarket (replacement) brake pads and shoes are not required to meet the FMVSS standard. However, several manufacturers of replacement brake pads and shoes are using a standardized test that closely matches the FMVSS standard and is called the "Dual Dynamometer Differential Effectiveness Analysis" or D^{3}EA. This test is currently voluntary and linings that pass the test can have a "D^{3}EA certified" seal placed on the product package. BEEP stands for "Brake Effectiveness Evaluation Procedure" and is a series of tests on aftermarket brake components that is similar to the FMVSS tests and SAE J2430 standards.

Not all brake pads contain copper. Copper content varies from manufacturer to manufacturer, and even among pads made by the same manufacturer for different applications.

ENVIRONMENTAL CONCERN Tiny amounts of copper from brakes fall onto the streets and parking lots every time the brakes are used. Copper is a pollutant because

- It is toxic to certain sensitive species of algae (phytoplankton) that form the base of the aquatic food chain.
- Copper also directly damages the sensory capabilities of salmon, making it difficult for them to avoid predators or find their way back to their spawning grounds.

Copper is not necessarily harmful to the environment because it is vital to the health of both plants and animals. Copper from brakes account for anywhere from 35% to 60% of copper in California's urban watershed runoff. In some urban watersheds, this added copper may be enough to cause water concentrations to exceed the water quality standard for copper. This led to determining a course of action that addresses the issue.

LEGAL REQUIREMENTS TO REDUCE COPPER The issue of copper in the environment has been under consideration since the 1990s when cities south of San Francisco were having trouble meeting Clean Water Act (CAA) requirements to reduce copper in urban runoff flowing into San Francisco Bay. Studies indicated that brake pads were a major source of copper in that runoff. California and Washington in 2010 passed laws mandating a reduction in the amount of copper used in automotive brake pads. Both bills mandate that brake pads sold in each state contain no more than 0.5% of copper by weight and must meet all applicable safety standards. The laws differ in timing. In California, the law takes effect no later than January 1, 2025.

LEAF MARK Washington State legislation mandates that all brake pads and shoes manufactured after January 1, 2015, are required to have a **leaf mark** icon indicating the level of compliance with state friction material content legislation. To demonstrate brake manufacturers' compliance with new state regulations, the Brake Manufacturers Council (BMC) of the Automotive Aftermarket Suppliers Association and the Motor and Equipment Manufacturers Association (MEMA) have selected NSF International to serve as its official registrar. NSF International is an independent organization that writes standards, tests, and certifies products for the food, water, and consumer goods industries to minimize adverse health effects and protect the environment (www.nsf.org). In addition to copper, all of the new standards restrict the following from brake friction materials:

- Asbestos fibers, less than 0.1% by weight
- Cadmium and its compounds, less than 0.01% by weight
- Chromium (VI)-salts, less than 0.1% by weight
- Lead and its compounds, less than 0.1% by weight
- Mercury and its compounds, less than 0.1% by weight

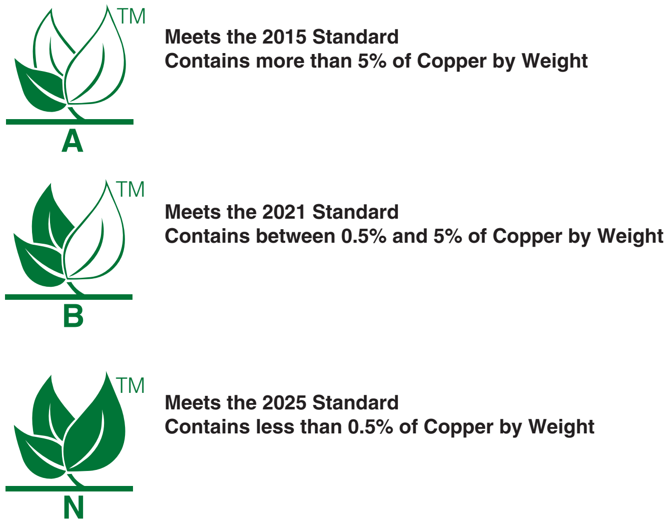
The leaf marks refer to the following ratings:

- **Level "A" standard (one leaf)**: Contains more than 5% of copper by weight (2015 Standard)
- **Level "B" standard (two leafs)**: Contains between 0.5% and 5% of copper by weight (2021 Standard)
- **Level "N" standard (three leafs)**: Contains less than 0.5% of copper by weight (2025 Standard)

● **SEE FIGURE 94–11**.

EDGE CODES

PURPOSE Starting in 1964, brake linings have been using a standardized way to identify the brake lining materials. The edge codes follow the Society of Automotive Engineers (SAE) Standard J866a.



TM
A
Meets the 2015 Standard
Contains more than 5% of Copper by Weight
TM
B
Meets the 2021 Standard
Contains between 0.5% and 5% of Copper by Weight
TM
N
Meets the 2025 Standard
Contains less than 0.5% of Copper by Weight

FIGURE 94–11 All boxes of brake linings and pads should be labeled with the leaf mark, which gives a visual clue as to the standard under which the brake friction materials meet certain state laws regarding the amount of copper.

EDGE CODE INFORMATION After January 1, 2014, all brake shoes and pads were required to have manufacturer's **edge codes**, which indicate all of the following:

- Company code
- Pad number
- Formulation code
- Vendor number
- Friction code
- Week number that the brakes were made
- Environmental code (A, B, or N)
- Year of manufacture

Because these edge codes now contain so much information, many manufacturers of brake friction material print this information on the backing of the friction material instead of on the edge of the lining to make it easier to see and read. ● **SEE FIGURES 94–12 AND 94–13**.

COEFFICIENT OF FRICTION EDGE CODE The edge codes for the coefficient of friction include letters that represent a range of coefficient of friction. ● **SEE CHART 94–5**.

COLD AND HOT COEFFICIENT OF FRICTION There are always two letters used side by side; the first letter indicates the coefficient of friction when brakes are cold (250°F/121°C), and the

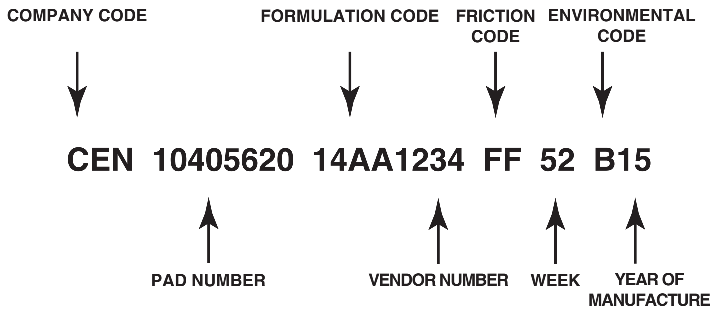


FIGURE 94–12 The edge codes include a lot of information about the brake friction material.

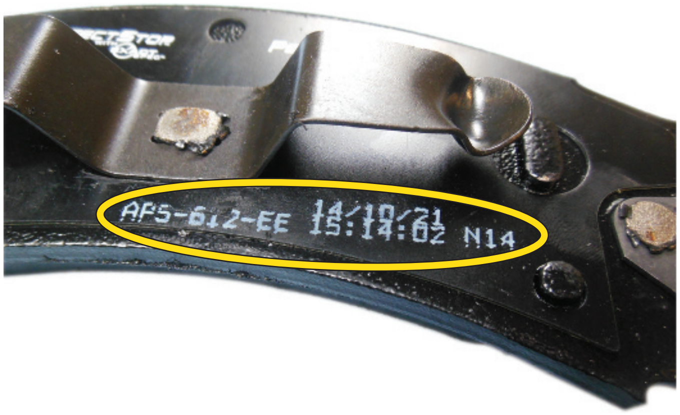

FIGURE 94–13 The “edge codes” are now printed on the backing of the brake pad because there is so much required information that it often does not fit on the edge of the brake pad or shoe.

TECH TIP

Edge Codes Do Not Represent Quality

The coefficient of friction letters do not mean the relative quality of the lining material. Lining wear, fade resistance, tensile strength, heat recovery rate, wet friction, noise, and coefficient of friction must be considered when purchasing high-quality linings. For best brake performance, always purchase the best-quality brake pads and lining from a well-known brand name.

second letter indicates the coefficient of friction of the brake lining when the brakes are hot (600°F/316°C). For example, FF indicates that the brake lining material has a coefficient of friction between 0.35 and 0.45 when both cold and hot. ● **SEE FIGURE 94–14**.

CODE LETTER	COEFFICIENT OF FRICTION RANGE
Code C	0.00–0.15
Code D	0.15–0.25
Code E	0.25–0.35
Code F	0.35–0.45
Code G	0.45–0.55
Code H	0.55 and above
Code Z	Ungraded

CHART 94–5

Edge code letters represent a range of coefficient of friction of the linings.

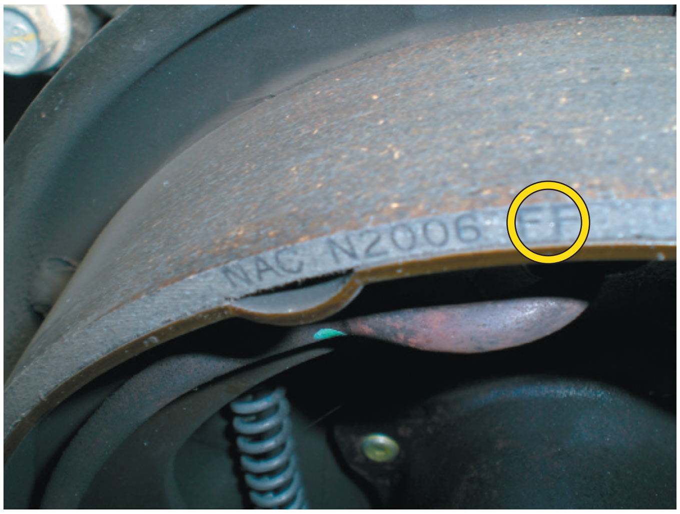

FIGURE 94–14 Typical drum brake lining edge codes, showing the coefficient of friction codes for cold and hot circled.

REVIEW QUESTIONS

1. What is kinetic energy?
2. What is inertia?
3. What is the coefficient of friction?
4. Why is copper being removed from brake friction material?
5. What is the meaning of the friction code letter printed on the edge of brake linings and pads?

CHAPTER QUIZ

1. Which Greek letter is used to represent the coefficient of friction?
   - **a.** Mu (μ)
   - **b.** Omega (Ω)
   - **c.** Delta (Δ)
   - **d.** Pi (Π)
2. The amount of asbestos in brake friction material is being restricted because ___________.
   - **a.** it does not transfer heat to the drum/rotor
   - **b.** it is a health hazard
   - **c.** asbestos worn from brakes contaminates rivers and streams
   - **d.** it causes excessive brake drum/rotor wear
3. What type of binder is used in all brake friction materials?
   - **a.** Rubber scrap
   - **b.** Carbon
   - **c.** Phenolic resin
   - **d.** Ceramic powders
4. An edge code reading for coefficient of friction is EF. This means ___________.
   - **a.** the coefficient of friction is 0.50
   - **b.** the coefficient of friction is higher when the brakes are cold
   - **c.** the coefficient of friction is higher when the brakes are hot
   - **d.** a higher quality brake has a code of FF
5. Brake pads and linings that use synthetic material, such as aramid fibers, instead of steel are usually referred to as ___________.
   - **a.** NAO
   - **b.** NAS
   - **c.** Ceramic
   - **d.** Any of the above

6. What can the driver do to reduce the possibility of brake fade caused by heat?

- **a.** Ride the brakes to keep the shoes and pads against the drum or rotor
- **b.** Pump the brake pedal while descending a steep hill
- **c.** Select a lower transmission gear
- **d.** Shift the transmission into neutral and allow the vehicle to coast down long or steep hills

7. Brake fade can occur due to ____________.

- **a.** mechanical fade
- **b.** gas fade
- **c.** water fade
- **d.** Any of the above

8. Why is copper being reduced in brake friction materials?

- **a.** Because it is a health concern when it becomes airborne
- **b.** Because it can affect life in rivers and streams
- **c.** To help reduce the weight of the vehicle
- **d.** To help reduce the cost of the brake linings/pads

9. The kinetic energy of a vehicle traveling at 60 MPH is ____________ when compared to the same vehicle traveling at 30 MPH.

- **a.** twice as much
- **b.** three times higher
- **c.** four times as much
- **d.** ten times higher

10. Disc brake pads can reach temperatures as high as ____________.

- **a.** 300°F (150°C)
- **b.** 1,000°F (540°C)
- **c.** 1,300°F (700°C)
- **d.** 1,800°F (980°C)

Chapter

BRAKE HYDRAULIC SYSTEMS

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Explain how the noncompressibility of liquids is used in brake systems.
- State Pascal's law.
- Describe the function, purpose, operation, and types of master cylinders.
- Describe the process of diagnosing and troubleshooting master cylinders.
- Discuss the different valves and switches used in the brake hydraulic system, including the fluid level switch, proportioning valve, and metering valve.
- Explain electronic brake proportioning (EBP).
- List the components included in a combination valve.
- Describe how a brake light switch works.

KEY TERMS:

Brake pedal position sensor (BPP) 1105 • Breather port 1091 • Combination valve 1104 • Compensating port 1091 • Dynamic rear proportioning (DRP) 1103 • Electronic brake proportioning (EBP) 1103 • Filler port 1091 • Height-sensing proportioning valve 1102 • Master cylinder 1090 • Metering valve 1104 • Pascal’s law 1088 • Pedal free play 1097 • Pedal height 1097 • Proportioning valve 1100 • Replenishing port 1091 • Slope 1102 • Split point 1102 • Vent port 1091

HYDRAULIC PRINCIPLES

NEED FOR HYDRAULICS In addition to the mechanical advantage provided by leverage at the brake pedal assembly, all vehicles use hydraulic pressure to help increase brake application force. All braking systems require that a driver’s force is transmitted to the drum or rotor attached to each wheel. ● **SEE FIGURE 95–1**.

The force that can be exerted on the brake pedal varies due to the strength and size of the driver. Engineers design braking systems to require less than 150 pounds of force (68 kg) from the driver, yet provide the force necessary to stop a heavy vehicle from high speed.

NONCOMPRESSIBILITY OF LIQUIDS Hydraulic systems use liquids to transmit motion. For all practical purposes, a liquid cannot be compressed. No matter how much pressure or force is placed on a quantity of liquid, its volume remains the same. This fact enables liquids in a closed system to transmit motion. ● **SEE FIGURE 95–2**.

If piston A is moved a distance of 1 inch, the liquid is displaced ahead of it and piston B moves 1 inch as well. Liquids cannot be compressed, but any air trapped in the system can be compressed.

In ● **FIGURE 95–3**, the simple hydraulic system has been contaminated with air. Even though piston A is moved a distance of 1 inch, piston B does not move if the load on it is greater than the pressure of the air in the system. For example, if the load on piston B is 50 pounds per square inch (PSI), the movement of piston A must compress the air in the system to that same pressure before piston B begins to move. A brake hydraulic system must be air free or the brakes do not operate correctly and the driver feels a spongy brake pedal that is also often lower than normal.

PASCAL’S LAW

DEFINITION The hydraulic principles that permit a brake system to function were discovered by a French physicist, Blaise Pascal (1632–1662). **Pascal’s law** states:

> When force is applied to a liquid confined in a container or an enclosure, the pressure is transmitted equally and undiminished in every direction.

EXAMPLE OF PASCAL’S LAW To help understand this principle, assume that a force of 10 pounds is exerted on a piston

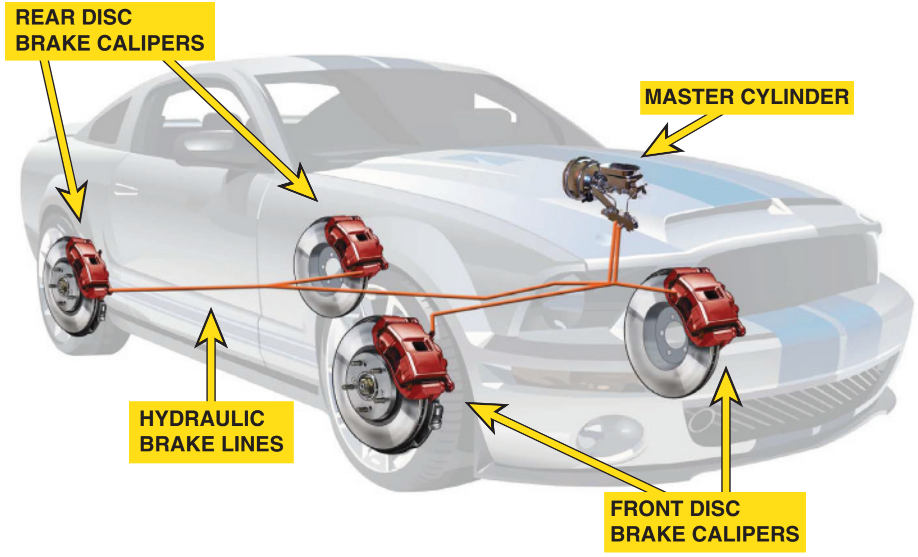

FIGURE 95–1 Hydraulic brake lines transfer the brake effort to each brake assembly attached to all four wheels.

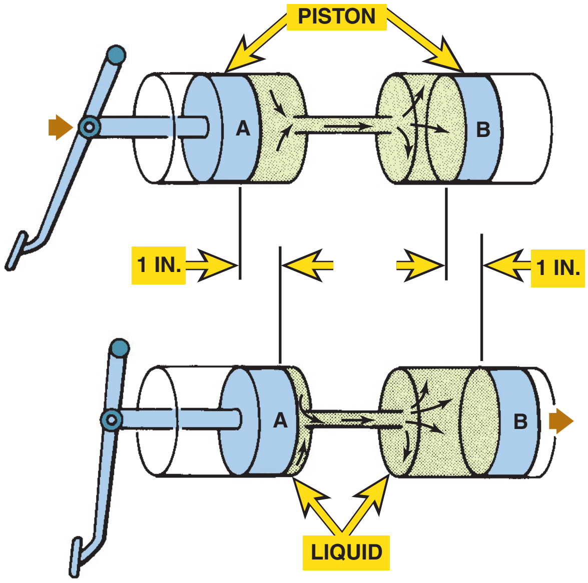

FIGURE 95–2 Because liquids cannot be compressed, they are able to transmit motion in a closed system.

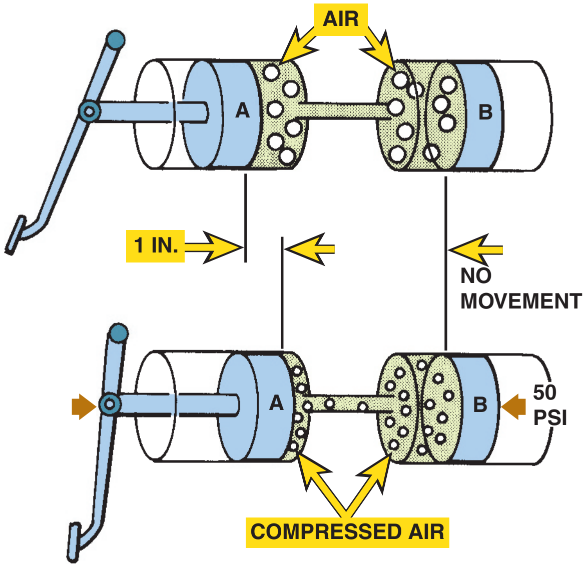

FIGURE 95–3 Hydraulic system must be free of air to operate properly. If air is in the system, the air is compressed when the brake pedal is depressed and the brake fluid does not transmit the force to the wheel brakes.

with a surface area of 1 square inch. Since this *force* measured in lb or Newtons (N) is applied to a piston with an area measured in square inches (sq. in.), the *pressure* is the force divided by the area or "10 PSI." It is this "pressure" that is transmitted, without loss, throughout the entire hydraulic system. ● **SEE FIGURE 95–4**.

F = P × A (force is equal to the pressure multiplied by the area)

P = F ÷ A (pressure is equal to the force divided by the area)

A = F ÷ P (area is equal to the force divided by the pressure)

where the capital letters mean:

F **= force (lb) (Newtons)**

P **= pressure in lb per sq. in. (kilo Pascals [kPa])**

A **= area in sq. in. (cm^2)**

If two out of the three factors are known, then the other one can be calculated by using this formula. A practical example involves a master cylinder with a piston area of 1 sq. in., one wheel cylinder with an area of 1 sq. in., and one wheel cylinder with a piston area of 2 sq. in. ● **SEE FIGURE 95–5**.

BRAKE HYDRAULIC FORCES The real "magic" of a hydraulic brake system is the fact that different forces can be created at different wheel cylinders. More force is necessary for front brakes than for rear brakes because, as the brakes are applied, the weight of the vehicle moves forward.

Larger (area) pistons are used in brake calipers on the front wheels to increase the force used to apply the front brakes. Not only can hydraulics act as a "force machine" (by varying piston size), but the hydraulic system also can be varied to change piston stroke distances. On a typical vehicle, a driver-input force of 150 lb (660 Newtons) is boosted both mechanically (through the brake pedal linkage) and by the power booster to a fluid pressure of about 1,700 PSI (11,700 kPa).

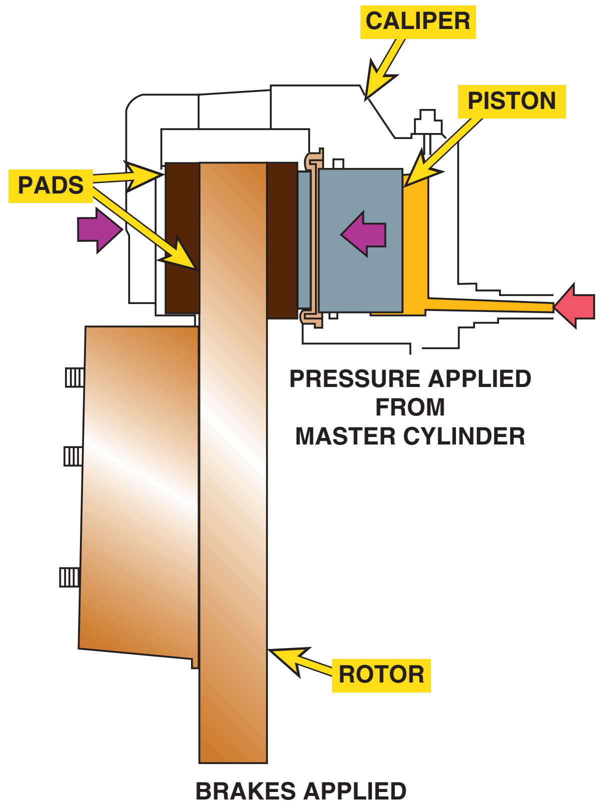
FREQUENTLY ASKED QUESTION

How Much Brake Fluid Is Moved When the Brake Pedal Is Depressed?

During a typical brake application, only about 1 teaspoon (5 ml or cc) of brake fluid actually is moved from the master cylinder and into the hydraulic system to cause the pressure buildup to occur.



CALIPER
PISTON
PADS
PRESSURE APPLIED
FROM
MASTER CYLINDER
ROTOR
BRAKES APPLIED

FIGURE 95–6 The brake pad (friction material) is pressed on both sides of the rotating rotor by the hydraulic pressure of the caliper.

- With a drum brake, the wheel cylinder expands and pushes the brake shoes against a brake drum. The distance the shoes move is only about 0.005 to 0.012 inch (5 to 12 thousandths of an inch) (0.015 to 0.30 mm).
- With a disc brake, brake fluid pressure pushes on the piston in the caliper a small amount and causes a clamping of the disc brake pads against both sides of a rotor (disc). The typical distance the pads move is only about 0.001 to 0.003 inch (1 to 3 thousandths of an inch) (0.025 to 0.076 mm). ● **SEE FIGURE 95–6**.

MASTER CYLINDERS

PURPOSE AND FUNCTION The **master cylinder** is the heart of the entire braking system. No braking occurs until the driver depresses the brake pedal. The brake pedal linkage is used to apply the force of the driver's foot into a closed hydraulic system.

MASTER CYLINDER RESERVOIRS Most vehicles built since the early 1980s are equipped with see-through master cylinder reservoirs, which permit owners and service technicians to check the brake fluid level without having to remove the top of the reservoir. Some countries have laws that require this type of reservoir. ● **SEE FIGURE 95–7**.

- The reservoir capacity is great enough to allow for the brakes to become completely worn out and still have enough reserve for safe operation.
- The typical capacity of the entire braking system is usually 2 to 3 pints (1 to 1.5 L). Vehicles equipped with four-wheel disc brakes usually hold 4 pints (2 L) or more.

CASE STUDY

Bigger Is Not Better

A vehicle owner wanted better braking performance from his off-road race vehicle. Thinking that a larger master cylinder would help, a technician replaced the original 1 inch bore-diameter master cylinder with a larger 1 1/8 inch bore-diameter master cylinder.

After bleeding the system, the technician was anxious to test-drive the “new” brake system. During the test-drive, the technician noticed that the brake pedal “grabbed” much higher than with the original master cylinder. This delighted the technician. The owner of the vehicle was also delighted until they tried to stop from highway speed. The driver had to use both feet to stop!

The technician realized, after the complaint, that the larger master cylinder was able to move more brake fluid, but with less pressure to the wheel cylinders. The new master cylinder gave the impression of better brakes because the fluid was moved into the wheel cylinders (and calipers) quickly, and the pads and shoes contacted the rotor and drums sooner because of the greater volume of brake fluid moved by the larger pistons in the master cylinder. To calculate the difference in pressure between the original (stock) master cylinder and the larger replacement, the technician used Pascal’s law with the following results:

Original Master Cylinder (1 Inch Bore)	**Replacement Master Cylinder (1 1/8 Inch Bore)**
$\text{Pressure} = \frac{\text{Force}}{\text{Area}}$	$\text{Pressure} = \frac{\text{Force}}{\text{Area}}$
$\text{PSI} = \frac{450 \text{ lb}}{\text{Area}}$ (typical)	$\text{PSI} = \frac{450 \text{ lb}}{\text{Area}}$ (typical)
$\text{Area} = \pi r^2 = 3.14 \times 0.5^2$ (1/2 of 1 inch)	$\text{Area} = \pi r^2 = 3.14 \times 0.5625^2$ (1/2 of 1 1/8 inch)
$\text{Area} = 3.14 \times 0.25$	$\text{Area} = 3.14 \times 0.316$
$\text{Area} = 0.785$ sq. in.	$\text{Area} = 0.992$ sq. in.
$\text{Pressure} = \frac{450}{0.785} = 573 \text{ PSI}$	$\text{Pressure} = \frac{450}{0.992} = 454 \text{ PSI}$

The difference in pressure is 119 PSI less with the larger master cylinder ($573 - 454 = 119$).

The stopping power of the brakes was reduced because the larger-diameter master cylinder piston produced lower pressure (the same force was spread over a larger area and this means that the pressure [PSI] is less). All master cylinders are sized correctly from the factory for the correct braking effort, pressure, pedal travel, and stopping ability. A technician should never change the sizing of any hydraulic brake component on any vehicle.

Summary:

Complaint—Customer wanted better brakes for racing.
Cause—A larger-diameter master cylinder was tried, but it required more driver effort to stop.
Correction—The original master cylinder was reinstalled which restored proper vehicle braking.

TECH TIP

Don’t Fill the Master Cylinder without Seeing Me!

The boss explained to the beginning technician that there are two reasons why the customer should be told not to fill the master cylinder reservoir when the brake fluid is down to the “minimum” mark, as shown in ● **FIGURE 95–8**.

1. If the master cylinder reservoir is low, there may be a leak that should be repaired.
2. As the brakes wear, the disc brake piston moves outward to maintain the same distance between friction materials and the rotor. Therefore, as the disc brake pads wear, the brake fluid level goes down to compensate.

Therefore, if the brake fluid is low, the vehicle should be serviced—either for new brakes or to repair a leak.

MASTER CYLINDER OPERATION The master cylinder is the heart of any hydraulic braking system. Brake pedal movement and force are transferred to the brake fluid and directed to wheel cylinders or calipers. ● **SEE FIGURE 95–9**.

The master cylinder is also separated into two pressure-building chambers (or circuits) to provide braking force to one-half of the brake in the event of a leak or damage to one circuit. ● **SEE FIGURE 95–10**.

Both pressure-building sections of the master cylinder contain two holes from the reservoir. According to the Society of Automotive Engineers (SAE), the terms used include

- The forward (tapered) high-pressure hole is the **vent port**, also called the **compensating port**.
- The rearward straight drilled low-pressure hole is called the **replenishing port**, also called the inlet port, bypass port, **filler port**, or the **breather port**.
  ● **SEE FIGURE 95–11**.

AT-REST POSITION The primary sealing cups are between the compensating port hole and the inlet port hole. In this position, the brake fluid is free to expand and move from the calipers, wheel cylinders, and brake lines up into the reservoir through the vent port (compensation port) if the temperature rises and the fluid expands. If the fluid was trapped, the pressure of the brake fluid would increase with temperature, causing the brakes to self-apply. The pistons (primary and secondary) are retained by a clip at the pushrod end and held in position by return springs. ● **SEE FIGURE 95–12**.

APPLIED POSITION When the brake pedal is depressed, the pedal linkage forces the pushrod and primary piston down the bore of the master cylinder. ● **SEE FIGURE 95–13**.

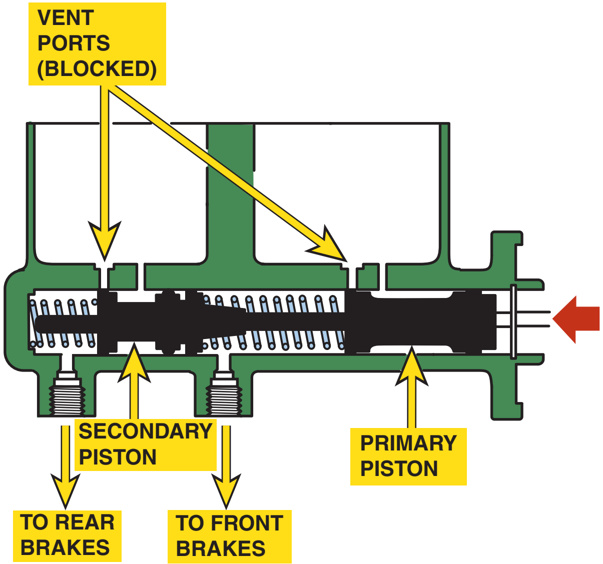
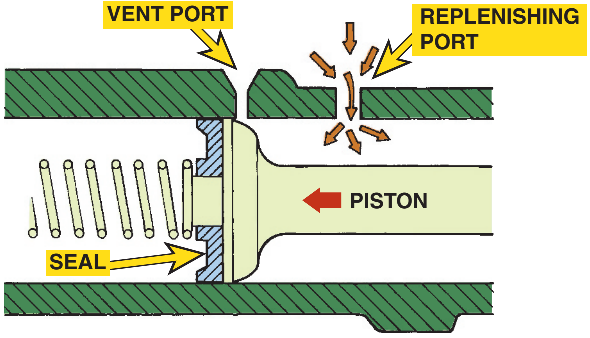
FIGURE 95–12 The vent ports must remain open to allow brake fluid to expand when heated by the friction material and transferred to the caliper and/or wheel cylinder. As the brake fluid increases in temperature, it expands. The heated brake fluid can expand and flow back into the reservoir through the vent ports.



VENT PORTS (BLOCKED)
SECONDARY PISTON
PRIMARY PISTON
TO REAR BRAKES
TO FRONT BRAKES

FIGURE 95–13 As the brake pedal is depressed, the pushrod moves the primary piston forward, closing off the vent port. As soon as the port is blocked, pressure builds in front of the primary sealing cup, which pushes on the secondary piston. The secondary piston also moves forward, blocking the secondary vent port and building pressure in front of the sealing cup.

- As the piston moves forward, the primary sealing cup covers and blocks off the vent port (compensating port).
- Hydraulic pressure builds in front of the primary seal as the pushrod moves forward. The back of the piston is kept filled through the replenishing port. This stops any suction (vacuum) from forming behind the piston. ● **SEE FIGURE 95–14**.
- The secondary piston is moved forward as pressure is exerted by the primary piston. If, for any reason, such as a leak, the primary piston cannot build pressure, a mechanical link on the front of the primary piston touches the secondary piston and moves it forward, as the primary piston is pushed forward by the pushrod and brake pedal.

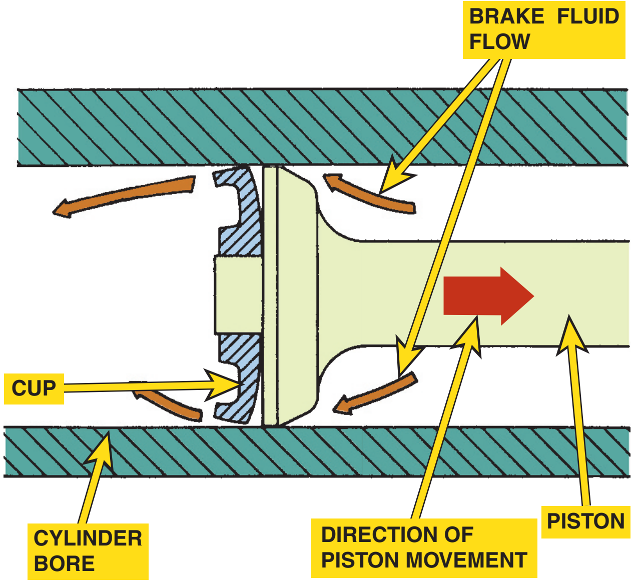


VENT PORT
REPLENISHING PORT
PISTON
SEAL

FIGURE 95–14 The purpose of the replenishing port is to keep the volume behind the primary piston filled with brake fluid from the reservoir as the piston moves forward during a brake application.

RELEASED POSITION Releasing the brake pedal removes the pressure on the pushrod and master cylinder pistons.

- A spring on the brake pedal linkage returns the brake pedal to its normal at-rest (up) position. The spring in front of the master cylinder piston expands, pushing the pistons rearward.
- At the same time, pressure is released from the entire braking system and the released brake fluid pressure is exerted on the master cylinder pistons, forcing them rearward.
- As the piston is pushed back, the lips of the seal fold forward, allowing fluid to quickly move past the piston. Some pistons have small holes that allow the fluid to move more quickly. Once the primary seal passes the vent port, the remaining hydraulic pressure forces any excess fluid into the reservoir. ● **SEE FIGURE 95–15**.



BRAKE FLUID FLOW
CUP
CYLINDER BORE
DIRECTION OF PISTON MOVEMENT
PISTON

FIGURE 95–15 When the brake pedal is released, the master cylinder piston moves rearward. Some of the brake fluid is pushed back up through the replenishing port, but most of the fluid flows past the sealing cup. Therefore, when the driver pumps the brake pedal, the additional fluid in front of the pressure-building sealing cup is available quickly.

FRONT/REAR SPLIT MASTER CYLINDERS Used on rear wheel drive vehicles, front/rear split master cylinders use two separate pressure-building sections. One section operates the front brakes and the other section operates the rear brakes. ● **SEE FIGURE 95–16**.

The nose end of the master cylinder is the closed end toward the front of the vehicle. The open end is often called the pushrod end of the master cylinder. ● **SEE FIGURE 95–17**.

TECH TIP

Too Much Is Bad

Some vehicle owners or inexperienced service people may fill the master cylinder to the top. Master cylinders should only be filled to the "maximum" level line or about 1/4 inch (6 mm) from the top to allow room for expansion when the brake fluid gets hot during normal operation. If the master cylinder is filled to the top, the expanding brake fluid has no place to expand and can leak out of the top of the reservoir. The spilled brake fluid removes paint and can cause corrosion of any electrical wiring or components located under the master cylinder.

HYDRAULIC FAILURE If the rear section of the hydraulic system fails, the primary piston does not build pressure to operate the secondary piston. To permit the operation of the secondary piston (nose end piston) in the event of a hydraulic failure of the rear section, the primary piston extension mechanically contacts and pushes on the secondary piston. ● **SEE FIGURE 95–18**.

If there is a failure of the front-section hydraulic system, the primary piston (pushrod end) operates normally and exerts pressure on the secondary piston. The secondary piston, however, is not able to build pressure because of the leak in the system.

DIAGONAL SPLIT MASTER CYLINDERS With front-wheel-drive vehicles, the weight of the entire power train is on the front wheels and 80% to 90% of the braking force is achieved by the front brakes. This means that only 10% to 20% of the braking force is being handled by the rear brakes. If the front brakes fail, the rear brakes alone cannot provide adequate braking force. The solution is the use of a diagonal split master cylinder. ● **SEE FIGURE 95–19**.

- In a diagonal split braking system, the left front brake and the right rear brake are on one circuit, and the right front with the left rear is another circuit of the master cylinder.
- If one circuit fails, the remaining circuit can still stop the vehicle in a reasonable fashion because each circuit has one front brake.
- To prevent this one front brake from causing the vehicle to pull toward one side during braking, the front suspension is designed with negative scrub radius geometry. This effectively eliminates any handling problem in the event of a brake circuit failure.

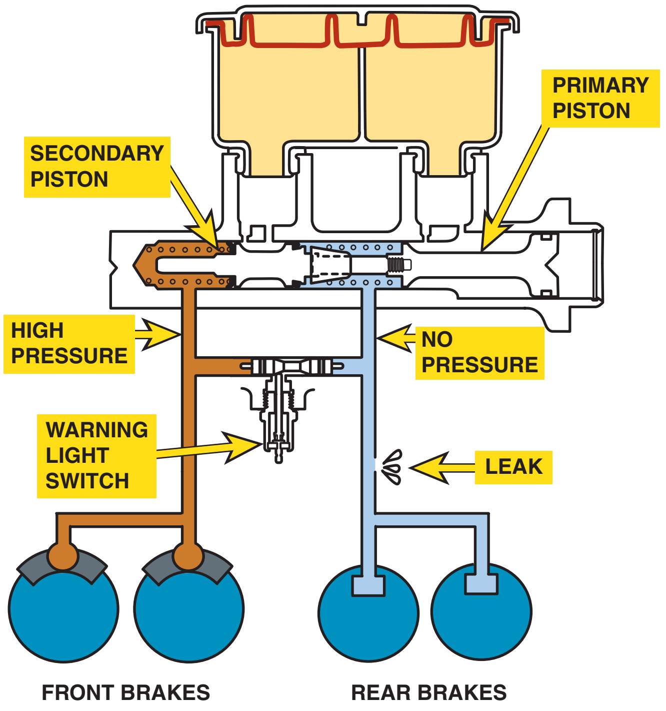
TECH TIP

Always Check for Venting (Compensation)

Whenever diagnosing any braking problem, start the diagnosis at the master cylinder—the heart of any braking system. Remove the reservoir cover and observe the brake fluid for spurting while an assistant depresses the brake pedal.

- **Normal operation (movement of fluid observed in the reservoir)** There should be a squirt or movement of brake fluid out of the vent port of both the primary and secondary chambers. This indicates that the vent port is open and that the sealing cup is capable of moving fluid upward through the port before the cup seals off the port as it moves forward to pressurize the fluid.
- **No movement of fluid observed in the reservoir in the primary piston** This indicates that brake fluid is not being moved as the brake pedal is depressed. This can be caused by the following:
  a. Incorrect brake pedal height—brake pedal or pushrod adjustment could be allowing the primary piston to be too far forward, causing the seal cup to be forward of the vent port. Adjust the brake pedal height to a higher level and check for a too-long pushrod length.
  b. A defective or swollen rubber sealing cup on the primary piston could cause the cup itself to block the vent port.

NOTE: If the vent port is blocked for any reason, the brakes of the vehicle may self-apply when the brake fluid heats up during normal braking. Since the vent port is blocked, the expanded hotter brake fluid has no place to expand and instead increases the pressure in the brake lines. The increase in pressure causes the brakes to apply. Loosening the bleeder valves and releasing the built-up pressure is a check that the brakes are self-applying. Then check the master cylinder to see if it is "venting."



PRIMARY PISTON
SECONDARY PISTON
HIGH PRESSURE
NO PRESSURE
WARNING LIGHT SWITCH
LEAK
FRONT BRAKES
REAR BRAKES

FIGURE 95–18 In the event of a primary system failure, no hydraulic pressure is available to push the second piston forward. As a result, the primary piston extension contacts the secondary piston and pushes on the secondary piston mechanically, rather than hydraulically. The loss of pressure in the primary system is usually noticed by the driver by a lower-than-normal brake pedal and the lighting of the red brake warning lamp.

DIAGNOSING MASTER CYLINDERS

VISUAL INSPECTION A thorough visual inspection is important when inspecting any master cylinder. The visual inspection should include checking the following items:

1. Check the brake fluid for proper level and condition. Brake fluid should not be rusty, thick, or contaminated.

TECH TIP

The Brake Pedal Depressor Trick

The master cylinder can be used to block the flow of brake fluid. Whenever any hydraulic brake component is removed, brake fluid tends to leak out because the master cylinder is usually higher than most other hydraulic components, such as wheel cylinders and calipers.

To prevent brake fluid loss that can easily empty the master cylinder reservoir, simply depress the brake pedal slightly or prop a stick or other pedal depressor to keep the brake pedal down. When the brake pedal is depressed, the piston sealing cups move forward, blocking off the reservoir from the rest of the braking system. The master cylinder stays full and the brake fluid stops dripping out of brake lines that have been disconnected. ● **SEE FIGURE 95–20**.

NOTE: Try this—put a straw into a glass of water. Use a finger to seal the top of the straw and then remove the straw from the glass of water. The water remains in the straw because air cannot get into the top of the straw. This is why the brake pedal depressor trick works to prevent the loss of brake fluid from the system, even if the brake line is totally disconnected.

2. Check that the vent holes in the reservoir cover are open and clean.
3. Check for any external leaks at the lines or at the pushrod area. ● **SEE FIGURE 95–21**.

TECH TIP

Quick and Easy Brake Reserve Test

Brake pedal reserve distance can be easily checked by depressing the brake pedal with the right foot and attempting to slide your left foot under the brake pedal. ● **SEE FIGURE 95–22**.

FIGURE 95–19 Front-wheel-drive vehicles use a diagonal split master cylinder. In this design, one section of the master cylinder operates the right front and the left rear brake and the other section operates the left front and right rear. In the event of a failure in one section, at least one front brake still functions.

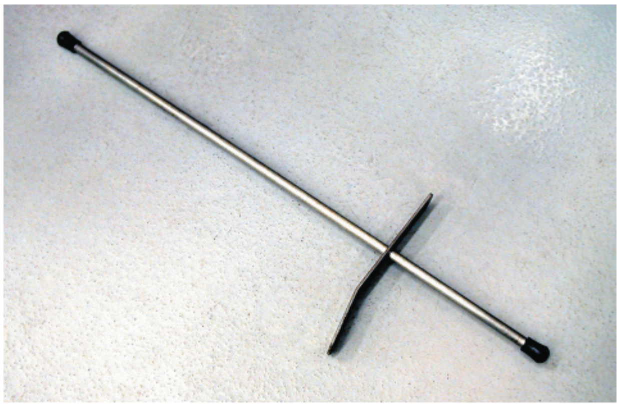

FIGURE 95–20 A brake pedal depressor like this can be used during brake service to block the flow of brake fluid from the master cylinder during service work on the hydraulic system.

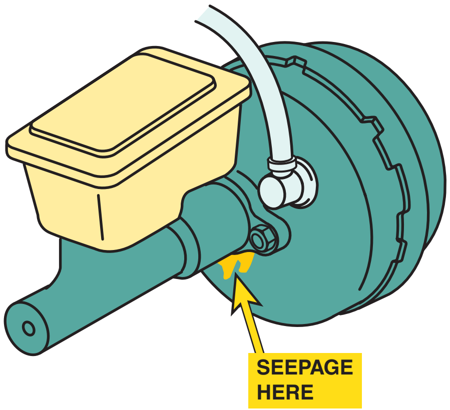

FIGURE 95–21 Seepage at the booster indicates a leaking secondary (end) seal.

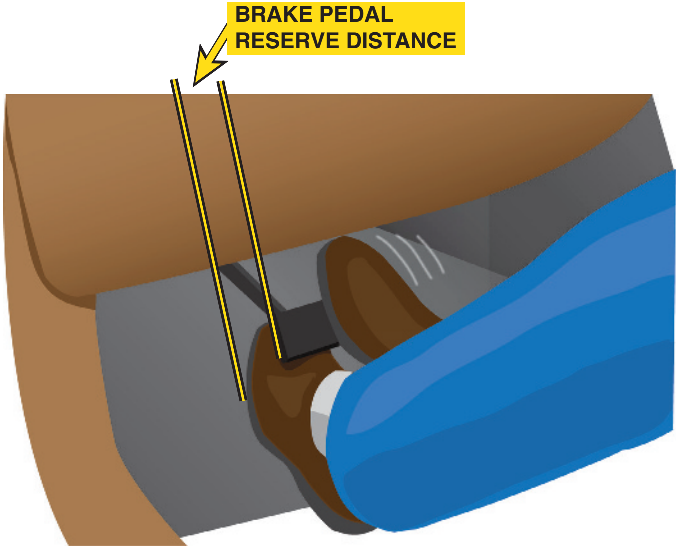

FIGURE 95–22 Pedal height is usually measured from the floor to the top of the brake pedal. Always follow the manufacturer's recommended procedures and measurements.

BRAKE PEDAL HEIGHT Proper brake **pedal height** is important for the proper operation of the stop (brake) light switch. If the pedal is not correct, the pushrod may be in too far forward, preventing the master cylinder cups from uncovering the compensation port. If the pedal is too high, the free play is excessive. ● **SEE FIGURE 95–23**.

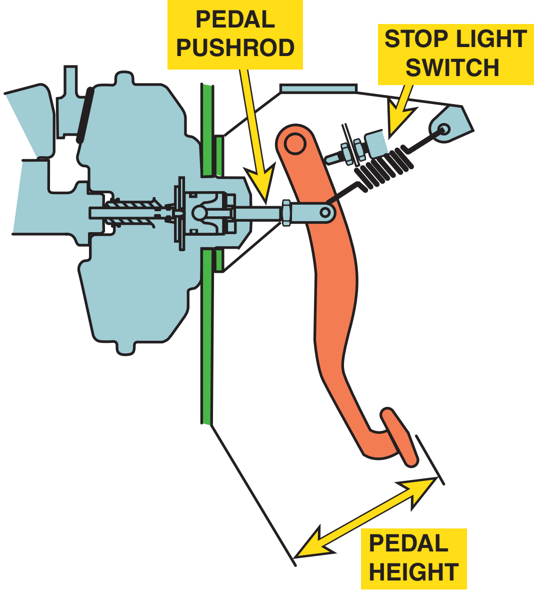

FIGURE 95–23 Pedal height is usually measured from the floor to the top of the brake pedal. Always follow the manufacturer's recommended procedures and measurements.

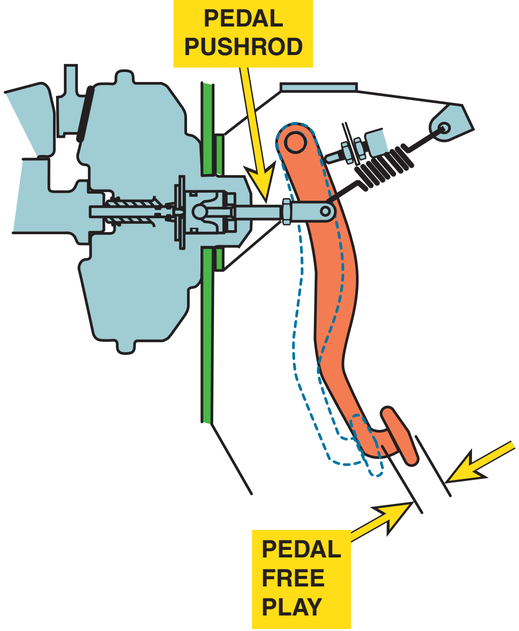

FIGURE 95–24 Brake pedal free play is the distance between the brake pedal fully released and the position of the brake pedal when braking resistance is felt.

BRAKE PEDAL FREE PLAY **Pedal free play** is the distance the brake pedal travels before the primary piston in the master cylinder moves. Most vehicles require brake pedal free play between 1/8 and 1 1/2 inch (3 to 38 mm). Too little or too much free play can cause braking problems that can be mistakenly attributed to a defective master cylinder. Check service information for the exact specifications and testing procedures for the vehicles being tested. ● **SEE FIGURE 95–24**.

BRAKE PEDAL TRAVEL A more accurate measurement is obtained using a pedal pressure gauge and ruler, following these steps:

STEP 1 With the ignition off, pump the brake pedal until it becomes firm (depletes power booster reserve).

STEP 2 Measure and record the distance from the brake pedal to the lower rim of the steering wheel. ● **SEE FIGURE 95–25**.

STEP 3 Apply the brakes with 100 pounds of pressure. Use a brake pedal pressure gauge, if available, to help ensure accurate test results.

STEP 4 While holding the pedal with 100 pounds of force, measure and record the distance from the pedal to the lower rim of the steering wheel. ● **SEE FIGURE 95–26**.

STEP 5 Subtract the applied measurement from the unapplied measurement to get the total travel.

Compare the pedal travel with the specification found in service information. As an example, a typical specification is 2.0 inches (5 cm).

NOTE: The brake pedal travel checks on many hybrid electric vehicles are different from this procedure. Refer to service information before checking these vehicles.

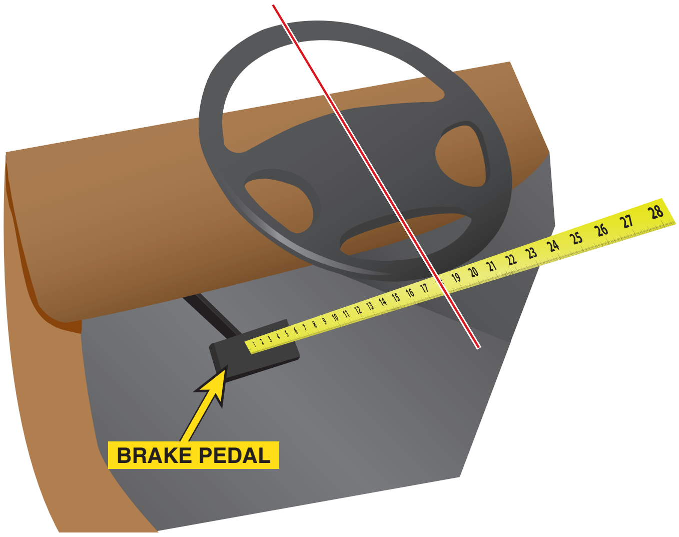

FIGURE 95–25 Measure the unapplied distance between the brake pedal and the steering wheel.

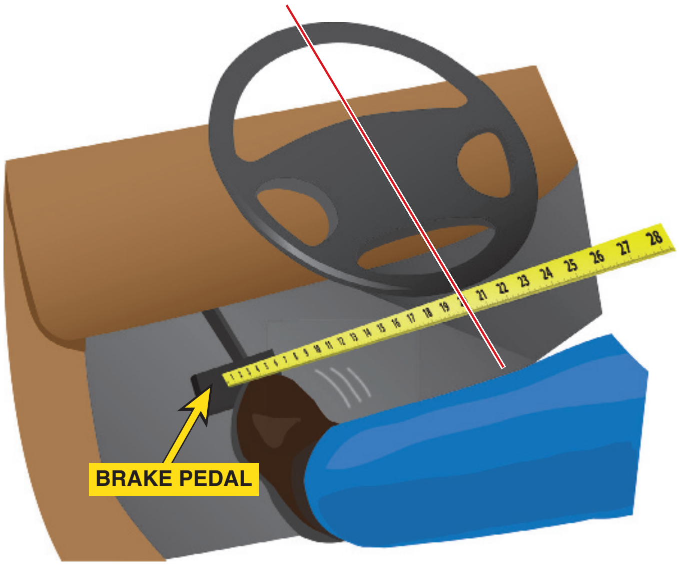

FIGURE 95–26 Apply the brakes and measure the distance again.

MASTER CYLINDER SYMPTOMS

Some common master cylinder fault symptoms include

- **Spongy brake pedal.** A spongy pedal with a larger-than-normal travel indicates air in the lines. Check for leaks and bleed the air from the system, as discussed later in this chapter.
- **Lower-than-normal brake pedal.** A brake pedal that travels downward more than normal and then gets firm is an indication that one circuit of the dual-circuit hydraulic system is probably not working. Check for leaks in the system and repair as necessary. Another possible reason is an out-of-adjustment drum brake allowing too much pedal travel before the shoes touch the brake drum.

NOTE: A lower-than-normal brake pedal may also be an indication of air in the hydraulic system.

- **Sinking brake pedal.** If the brake pedal sinks all the way to the floor especially when the vehicle is not moving, suspect a defective master cylinder that is leaking internally. This internal leakage is often called bypassing because the brake fluid is leaking past the sealing cups, allowing pressure from one chamber to leak into the other chamber.

INSTALLING THE MASTER CYLINDER

After the master cylinder has been bench bled, it can be installed in the vehicle. Tighten the fasteners to factory specifications. Bleed the system as needed. Bench bleed the master cylinder before installing. ● **SEE FIGURE 95–27**.

NOTE: Brake fluid can drip from the outlet of the master cylinder and could drip onto the vehicle. Brake fluid is very corrosive and can remove paint. Use fender covers and avoid letting brake fluid touch any component of the vehicle. ● **SEE FIGURE 95–28**.

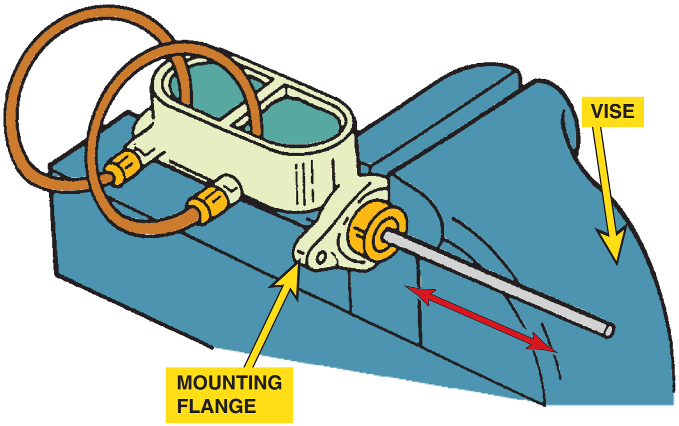

FIGURE 95–27 Bleeding a master cylinder before installing it on the vehicle. The master cylinder is clamped into a bench vise while using a rounded end of a dowel rod to push on the pushrod end with bleeder tubes down into the brake fluid. Master cylinders should be clamped on the mounting flange, as shown, to prevent distorting the master cylinder bore.

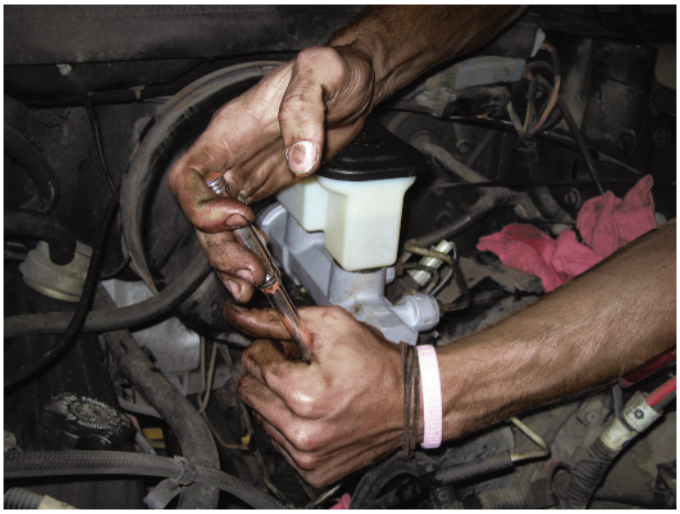

FIGURE 95–28 Installing a master cylinder. Always tighten the retaining fasteners and brake lines to factory specifications.

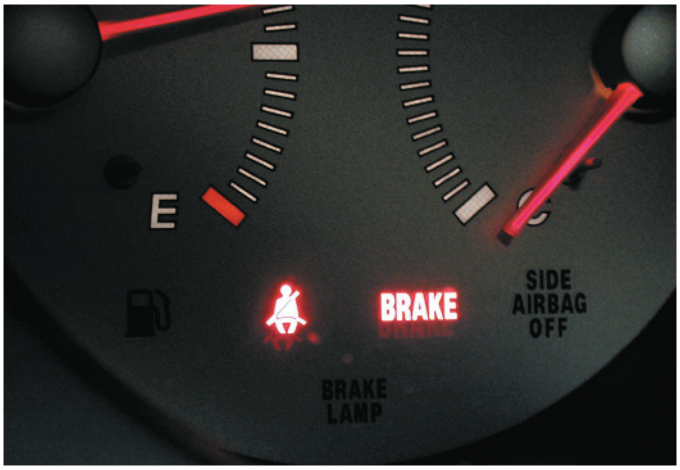
HYDRAULIC VALVES AND SWITCHES

PRESSURE-DIFFERENTIAL SWITCH (BRAKE WARNING SWITCH) A pressure-differential switch is used on vehicles built after 1967 with front/rear master cylinders to warn the driver of a loss of pressure in one of the two separate systems by lighting the dashboard red brake warning indicator lamp. This system was used until it was replaced with the brake fluid level sensors used on newer vehicles. ● **SEE FIGURE 95–29**.

The brake lines from both the front and the rear sections of the master cylinder are sent to this switch, which lights the brake warning indicator lamp in the event of a "difference in pressure" between the two sections. A failure in one part of the brake system does not result in a failure of the entire hydraulic system. ● **SEE FIGURE 95–30**.



E
BRAKE
SIDE AIRBAG OFF
BRAKE LAMP

FIGURE 95–29 A red brake warning lamp.

PRESSURE-DIFFERENTIAL SWITCH RESET After the hydraulic system has been repaired and bled, moderate pressure on the brake pedal centers the piston in the switch and turns off the warning lamp.

If the lamp remains on, it may be necessary to do the following:

1. Apply light pressure to the brake pedal.
2. Momentarily open the bleeder valve on the side that did not have the failure.

This procedure should center the pressure-differential switch valve in those vehicles that are not equipped with self-centering springs. If the lamp still remains on, it means that the plunger inside the differential valve is stuck in place. The whole assembly should be replaced, if this is the case.

FIGURE 95–30 A leak in the hydraulic system causes unequal pressures between the two different brake circuits. This difference in pressures causes the plunger inside the pressure-differential switch to move, which completes the electrical circuit for the red brake warning lamp.

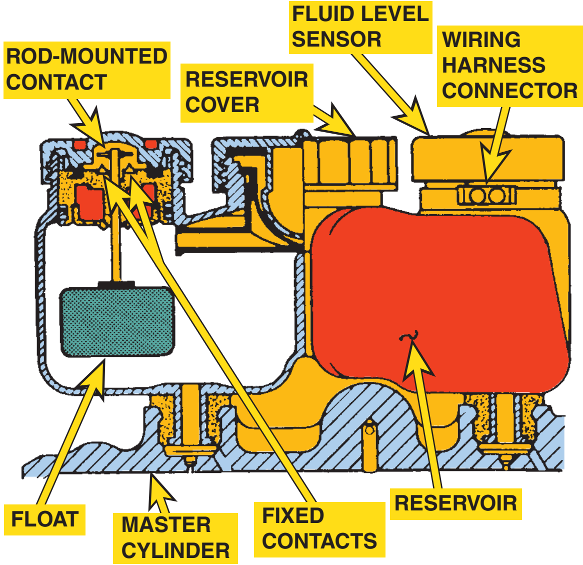

FIGURE 95–31 A movable contact brake fluid level switch.

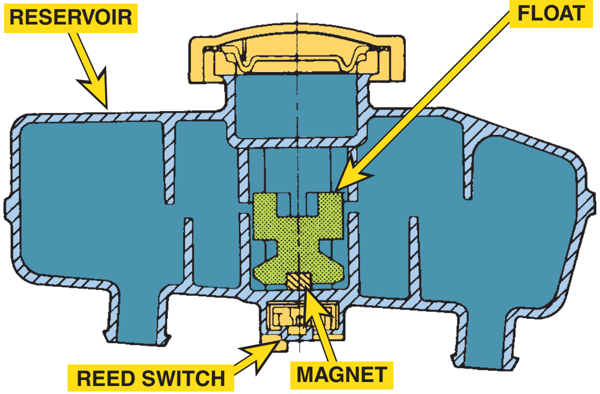

FIGURE 95–32 A magnetic brake fluid level switch.

BRAKE FLUID LEVEL SENSOR Since the late 1990s, master cylinders use a brake fluid level sensor or switch in the master cylinder reservoir. This sensor lights the red brake warning lamp (RBWL) on the dash if low brake fluid level is detected. A float-type sensor or a magnetic reed switch is commonly used and provides a complete electrical circuit when the brake fluid level is low. After refilling the master cylinder reservoir to the correct level, the RBWL should go out. ● **SEE FIGURES 95–31 AND 95–32**.

DIAGNOSING A RED "BRAKE" WARNING LAMP The RBWL can be on for several reasons, including

- **Parking brake on**. The same dash warning lamp is used to warn the driver that the parking brake is on.
- **Low brake fluid**. This condition causes the red dash warning lamp to come on if the vehicle is equipped with a master cylinder reservoir brake fluid level switch.
- **Unequal brake pressure**. The pressure-differential switch is used on older vehicles with a front/rear brake split system to warn the driver whenever there is low brake pressure to either the front or rear brakes.
- **Worn brake pads**. Vehicles equipped with electronic pad wear sensors can turn on the light when the pads wear out.

NOTE: Brake systems use either a pressure-differential switch or a low brake fluid switch to light the dash red "brake" lamp, but not both.

TECH TIP

Check Service Information for the Red Brake Light Input

Older vehicles control the red brake warning lamp using straight wiring and switches. It is becoming more common for this function to be controlled by onboard computers and data systems instead. The brake fluid level switch is often an input to a body control module (BCM) and the dash lamp is the output. ● **SEE FIGURE 95–33**.

The most likely cause of the RBWL being on is low brake fluid caused by worn-out brake pads or a leaking brake line, wheel cylinder, or caliper. Therefore, the first step is to determine the cause of the lamp being on, then to repair the problem.

STEP 1 **Check the Level of the Brake Fluid**. If low, carefully inspect the entire hydraulic brake system for leaks and repair, as necessary. Don't forget that the fluid level normally goes down as the brake pads wear. Badly worn pads can drop the fluid level low enough to turn on the warning light.

STEP 2 **Disconnect the Wire from the Pressure-Differential Switch**. If the lamp is still "on," the problem is due to the parking brake lever switch being "on" or grounded, or the wire going to the switch is shorted to ground. If the red brake warning lamp is "off" after being disconnected from the pressure-differential switch, then the problem is due to a hydraulic failure (a low pressure in either the front or the rear system that creates a difference in pressure of at least 150 PSI).

PROPORTIONING VALVE A **proportioning valve** improves brake balance during hard stops by limiting hydraulic pressure to the rear brakes. ● **SEE FIGURE 95–34**.

A proportioning valve is necessary because inertia creates weight shift toward the front of the vehicle during braking. The weight shift unloads the rear axle, which reduces traction between the tires and the road, and limits the amount of stopping power that can be delivered. Unless application pressure to the rear wheels is limited, the brakes lock, making the vehicle unstable and likely to skid. The best overall braking performance is achieved when the front brakes lock just before the rear brakes. Vehicles with front disc and rear drum brakes require a proportioning valve for two reasons:

1. Disc brakes require higher hydraulic pressure for a given stop than do drum brakes. In a disc/drum system, the front brakes always need more pressure than the rear brakes.
2. Once braking has begun, drum brakes require less pressure to maintain a fixed level of stopping power than they did to establish that level. In a disc/drum system, the rear brakes always need less pressure than the front brakes.

A proportioning valve can be either one part used to control both rear brakes or two parts, one part of each rear brake.

PROPORTIONING VALVE OPERATION The proportioning valve does not work at all times. During light or moderate braking, there is insufficient weight transfer to make rear wheel locking a problem.

The command to turn on the red brake warning light is sent from the BCM to the IPC through the data lines, shown by the two parallel arrows.

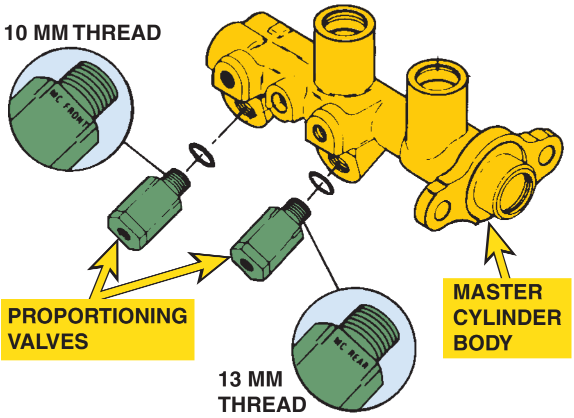

FIGURE 95–34 Some proportioning valves are mounted directly to the master cylinder in the outlet to the rear brakes.

- Before proportioning action begins, brake system hydraulic pressure must reach a minimum level, called the **split point**. Below the split point, full system pressure is supplied to the rear brakes. ● **SEE FIGURE 95–35**.
- Above the split point, the proportioning valve allows only a portion of the pressure through to the rear brakes. The proportioning valve gets its name from the fact that it regulates pressure to the rear brakes in proportion to the pressure applied to the front brakes.
- Once system hydraulic pressure exceeds the split point, the rear brakes receive a fixed percentage of any further increase in pressure.
- Brake engineers refer to the ratio of front-to-rear brake pressure proportioning as the **slope**. Full system pressure to the rear brakes equals a slope of 1, but if only half the pressure is allowed to reach the rear brakes, the proportioning valve is said to have a slope of 0.50. The proportioning valves on most vehicles have a slope between 0.25 and 0.50. ● **SEE FIGURES 95–36 AND 95–37**.

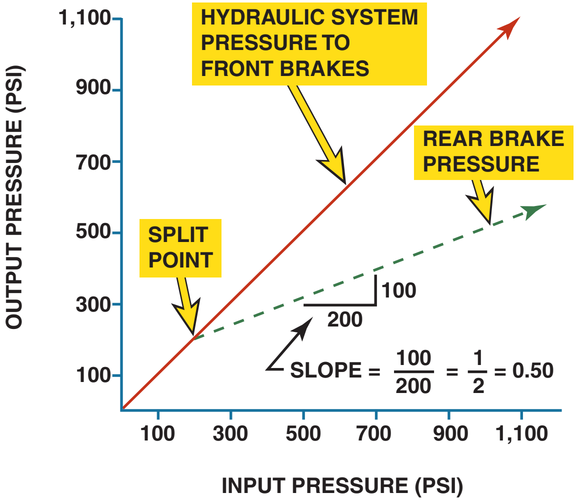

FIGURE 95–35 Typical proportioning valve pressure relationship. Note that, at low pressures, the pressure is the same to the rear brakes as is applied to the front brakes. After the split point, only a percentage (called the slope) of the master cylinder pressure is applied to the rear brakes.

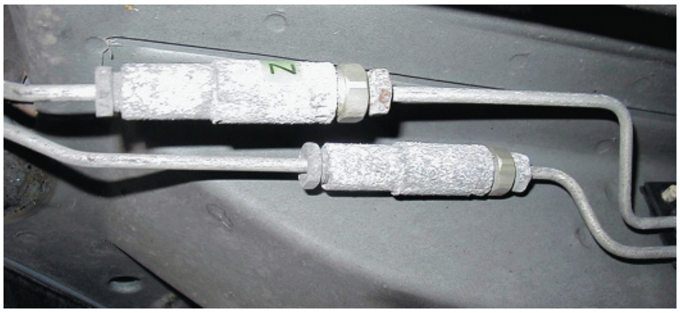

FIGURE 95–36 These two proportioning valves are found under the vehicle on this Dodge minivan.

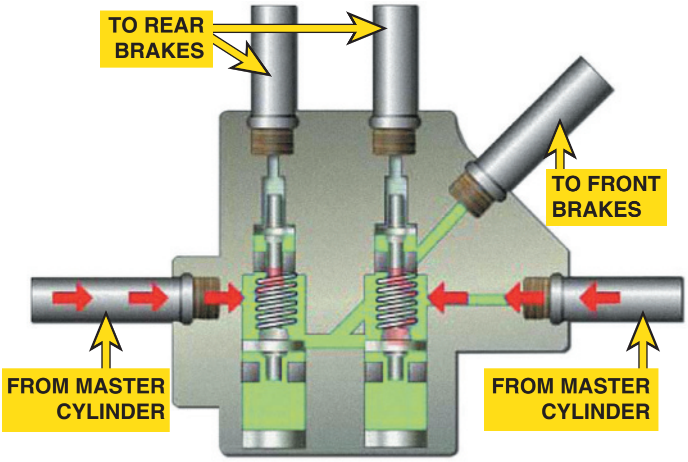

FIGURE 95–37 A vehicle with a diagonal split braking system often uses a one-piece proportioning valve with two pistons, one for each rear wheel.

HEIGHT-SENSING PROPORTIONING VALVES

Many vehicles use a proportioning valve that varies the amount of pressure that can be sent to the rear brakes, depending on the height of the rear suspension. This type of valve is called a **height-sensing proportioning valve**.

- If the vehicle is lightly loaded, the rear suspension is high, especially during braking. In this case, the amount of pressure allowed to the rear brakes is reduced. This *helps* prevent rear-wheel lockup and possible skidding. Besides, a lightly loaded vehicle requires less braking force to stop than a heavily loaded vehicle.
- When the vehicle is loaded, the rear suspension is forced downward. The lever on the proportioning valve moves and allows a greater pressure to be sent to the rear brakes. This greater pressure allows the rear brakes to achieve more braking force, helping to slow a heavier vehicle. When a vehicle is heavily loaded in the rear, the chances of rear-wheel lockup are reduced. ● **SEE FIGURES 95–38 AND 95–39**.

CAUTION: Some vehicle manufacturers warn that service technicians should never install replacement air lift shock absorbers or springs that may result in a vehicle height different than specified by the vehicle manufacturer. If the ride height is increased, the front-to-rear brake proportional relationship is changed and could reduce stopping distances.

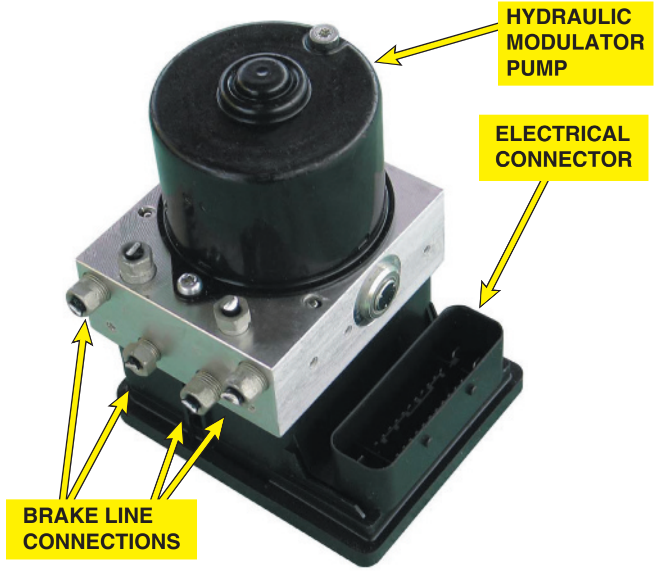
ELECTRONIC BRAKE PROPORTIONING

PURPOSE AND FUNCTION Most new vehicles with antilock brake systems have eliminated the need for a conventional brake proportioning valve. Instead, this becomes a function of the antilock brake system controller. Often referred to as **dynamic rear proportioning (DRP)** or **electronic brake proportioning (EBP)**, this system removes the need for a mechanical proportioning valve.

PARTS AND OPERATION Most proportioning valves are calibrated to reduce pressure to the rear brakes by a fixed amount, which may increase the risk of rear-wheel lockup if the vehicle is loaded differently or is braking on a wet or slick surface. Dynamic rear proportioning uses the ABS controller software and the rear wheel hydraulic control circuits to maintain optimum front-to-rear balance under all conditions.

Electronic brake proportioning (EBP) in the ABS is accomplished by monitoring brake switch input and front- and rear-wheel speeds, and reducing pressure to the rear brakes as needed using the ABS solenoids when there is a difference in wheel deceleration rates. The controller energizes the inlet valve solenoids for both rear brakes to hold pressure in the lines and then energizes both rear outlet valve solenoids to release pressure, as needed. ● **SEE FIGURE 95–40**.



HYDRAULIC MODULATOR PUMP
ELECTRICAL CONNECTOR
BRAKE LINE CONNECTIONS

FIGURE 95–40 The ABS control module performs the functions of the metering and proportioning valves on most ABS-equipped vehicles.

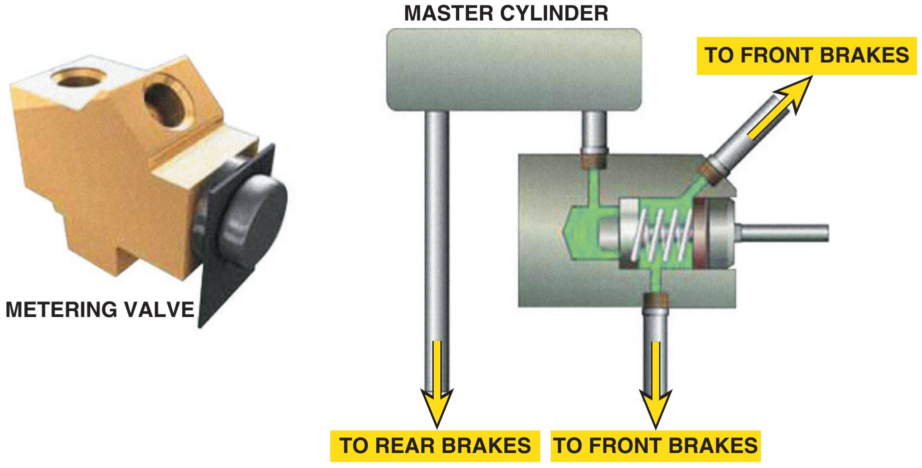


FIGURE 95–41 The metering valve may be a separate component or part of the combination valve.

METERING VALVE (HOLD-OFF) OPERATION A **metering valve** is used on many front-disc, rear-drum-brake-equipped vehicles. The metering valve prevents the full operation of (holds off) the disc brakes until between 75 to 125 PSI is sent to the rear drum brakes to overcome rear-brake return spring pressure. This allows the front and rear brakes to apply at the same time for even stopping. Most metering valves also allow for the pressure to the front brakes to be gradually blended up to the metering valve pressure to prevent front brake locking under light pedal pressures on icy surfaces. ● **SEE FIGURE 95–41**.

SYSTEMS WITHOUT METERING VALVES Braking systems that are diagonal split, such as those found on most front-wheel-drive vehicles, do *not* use a metering valve. A metering valve is only used on front/rear split braking systems, such as those found on most rear-wheel-drive vehicles.

TECH TIP

Push-In or Pull-Out Metering Valve?

Whenever bleeding the air out of the hydraulic brake system using pressure bleeding equipment, the metering valve should be bypassed. The metering valve stops the passage of brake fluid to the front wheels until pressure exceeds about 125 PSI (860 kPa). To bypass the metering valve, the service technician has to push or pull a small button located on the metering valve. An easy way to remember whether to push in or to pull out is to inspect the button itself.

- *If the button is rubber coated, then push in.*
- *If the button is steel, then pull out.*

Special tools allow the metering valve to be held in the bypass position. Failure to remove the tool after bleeding the brakes can result in premature application of the front brakes before the rear drum brakes have enough pressure to operate.

Most rear-wheel-drive vehicles without metering valves are equipped with four-wheel disc brakes. Because the clearance between the pads and rotors is approximately the same at all four wheels, there is no need to delay front brake actuation.

COMBINATION VALVES

Most vehicle manufacturers combine the function of a proportioning valve with one or more other valves into one unit, called a **combination valve**. On a rear-wheel-drive vehicle, a combination valve consists of the following components all in one replaceable unit:

- Metering valve
- Proportioning valve
  Pressure-differential switch
  ● **SEE FIGURES 95–42 AND 95–43**.

Some combination valves have only two functions and contain just

- the pressure differential and
- metering valve.

Other units combine the pressure differential with the proportioning valve. ● **SEE FIGURE 95–44**.

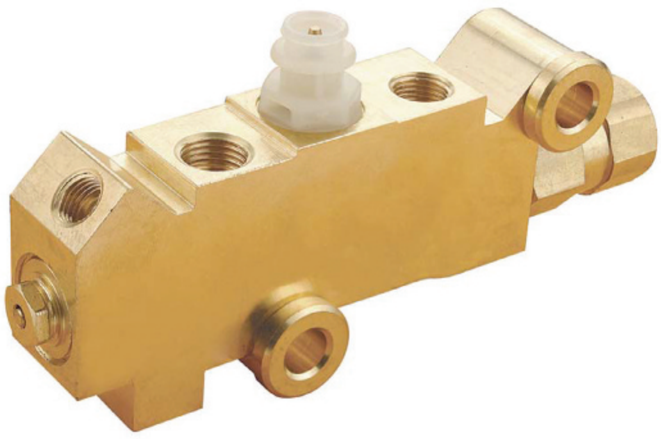

FIGURE 95–42 This combination valve contains the pressure-differential valve, the metering valve, and the proportioning valve.

FIGURE 95–43 Combination valve containing metering, pressure-differential (warning switch), and proportioning valves all in one unit. This style is often called a "pistol grip" design because the proportioning valve section resembles the grip section of a handgun.

BRAKE PEDAL POSITION SWITCH
STEERING COLUMN

FIGURE 95–45 The brake pedal position (BPP) sensor (switch) and arm mounts to the brake pedal, under the dash.

BRAKE PEDAL POSITION SENSOR/SWITCH

PURPOSE AND FUNCTION On older vehicles, the brake switch was used to turn on the brake lights. Most new vehicles use the **brake pedal position (BPP) sensor** or switch as an input to the body computer for many functions, including the following:

- Brake lights
- ABS input signal
- Traction control is disabled when the brake pedal is depressed
- Electronic stability control (ESC) system input signal

Vehicles with ABS and ESC may also use a brake pedal position sensor in addition to the brake pedal switch. This sensor is a three-wire potentiometer that returns a variable voltage signal to the ABS controller to indicate the position of the brake pedal. ● **SEE FIGURE 95–45**.

BRAKE LIGHT SWITCH TESTING The brake light switch or sensor is most easily checked with the use of a scan tool. Both the powertrain data list and the ABS data list show the brake switch as an "ON/OFF" status when the pedal is pressed. A DMM (digital multimeter) set to ohms can be used to check a brake switch on or off the vehicle. Access the two wires from the switch and back probe the connectors with the meter test leads. ● **SEE FIGURES 95–46 AND 95–47**.

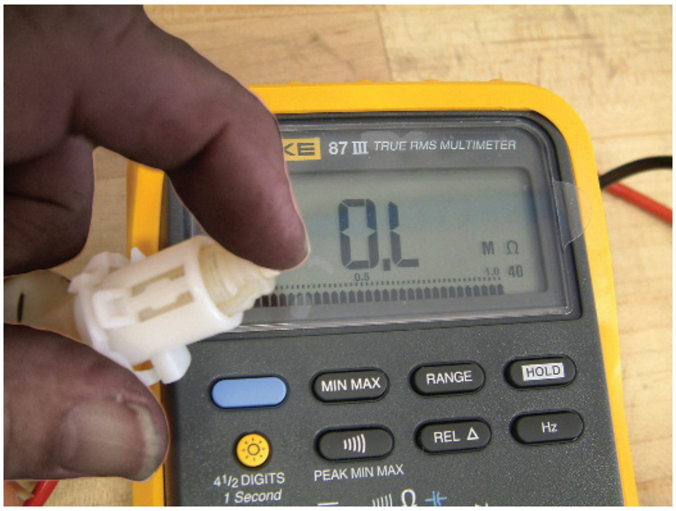

FIGURE 95–46 With the plunger pressed in (pedal up), the meter should show an open circuit (switch open).

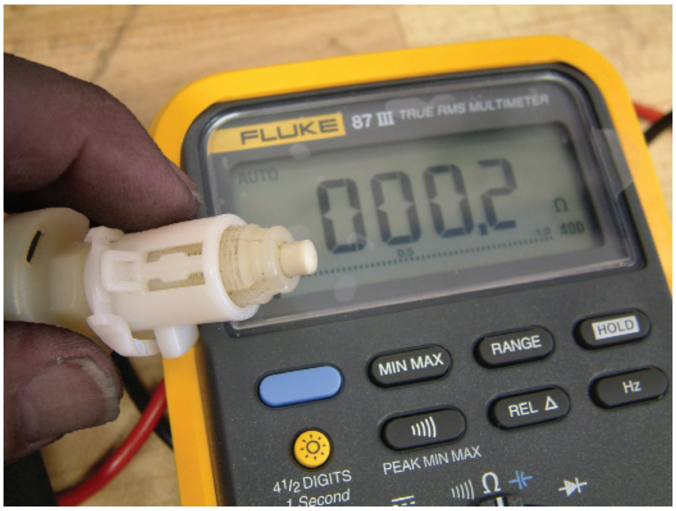

FIGURE 95–47 With the plunger released (pedal down), the switch should show very low resistance (switch closed).

TECH TIP

No Valves Can Cause a Pull to One Side

When diagnosing a pull to one side during braking, some technicians tend to blame the metering valve, the proportioning valve, the pressure-differential switch, or the master cylinder itself.

Just remember that if a vehicle pulls during braking, the problem *has* to be due to an individual wheel brake or brake line. The master cylinder and all the valves control front or rear brakes together or diagonal brakes and cannot cause a pull if not functioning correctly.

REVIEW QUESTIONS

1. What does Pascal's law state?
2. What are the symptoms of a faulty master cylinder?
3. What could cause the red brake warning lamp to come on during driving?
4. How do the metering and proportioning valves work?
5. What is the difference between a brake pedal switch and a brake pedal sensor?

CHAPTER QUIZ

1. What law of hydraulics does the brake system use?
   - **a.** Ohm's Law
   - **b.** Pascal's Law
   - **c.** Watt's Law
   - **d.** All of the above
2. The primary brake circuit fails due to a leak in the lines, leaving the secondary section of a front/rear split master cylinder. Technician A says that the driver will notice a lower-than-normal brake pedal and some reduced braking power. Technician B says that the brake pedal will "grab" higher than normal. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
3. Two technicians are discussing a problem where the brake pedal travels too far before the vehicle starts to slow. Technician A says that the brakes may be out of adjustment. Technician B says that one circuit from the master cylinder may be leaking or defective. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
4. Air in the lines causes what type of problem?
   - **a.** Vibration in the brake pedal during stops
   - **b.** Low spongy brake pedal
   - **c.** Brake noise
   - **d.** Hard brake pedal

5. Technician A says the metering valve controls the flow of brake fluid to the front brakes. Technician B says that proportioning valve is used to control the brake fluid pressure to the rear brakes. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
6. A typical brake pedal switch is ___________.
   - **a.** electrically normally open
   - **b.** electrically normally closed
   - **c.** checked using an ammeter
   - **d.** checked using a special tester
7. A combination valve could include ___________.
   - **a.** metering and proportioning valves
   - **b.** proportioning valve and pressure-differential switch
   - **c.** proportioning and metering valves and pressure-differential switch
   - **d.** Any of the above, depending on the make and model of the vehicle
8. Technician A says a pull to the right during braking could be caused by a defective metering valve. Technician B says a pull to the left could be caused by a defective proportioning valve. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
9. Brake fluid pressure is measured in what unit?
   - **a.** Square inches
   - **b.** Pounds
   - **c.** Inches

BRAKE FLUID, LINES, AND BLEEDING

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss the purpose, function, and properties of brake fluids.
- Discuss brake fluid specifications.
- Describe brake service procedures and precautions.
- Discuss the use of brake lines.
- Discuss the need for brake bleeding.
- Discuss the various methods of loosening the brake bleeder valve.
- Describe the bleeding sequence for most vehicles.
- Describe the manual bleeding procedure.
- Discuss how to vacuum bleed the hydraulic brake system.
- Discuss how to gravity bleed the hydraulic brake system.
- Discuss how to pressure bleed the hydraulic brake system.
- Describe how to bleed the ABS hydraulic unit.
- Describe brake fluid replacement or flushing.

KEY TERMS:

Armored brake line 1115 • Bleeder valve 1119 • Brake bleeding 1118 • Brake fluid 1108 • Brake pipes 1113 • Brake tubing 1113 • DOT 3 1109 • DOT 4 1109 • DOT 5 1110 • DOT 5.1 1110 • Double flare 1114 • Flexible brake hoses 1117 • Gravity bleeding 1122 • Hygroscopic 1109 • ISO 1114 • Non-hygroscopic 1110 • Polyglycol 1108 • Power bleeding 1123 • Pressure bleeding 1123 • Silicone brake fluid 1110 • Single stroke bleeding method 1120 • Vacuum bleeding 1121

BRAKE FLUID

PURPOSE AND FUNCTION **Brake fluid** is designed to function in the hydraulic brake system under all operating conditions. Brake fluid boiling point is one of the most critical aspects and ratings for brake fluid. As brake fluid ages, it absorbs moisture, which lowers its boiling point and causes increased corrosion of the brake system components. All automotive experts agree that brake fluid should be changed regularly as part of normal routine service. Even though the driver may not notice an immediate improvement, the reduced corrosion will eventually result in less money being spent for brake system component replacement in the future. Getting the old low-boiling-point brake fluid out of the system could prevent a total loss of brakes due to brake fluid boiling. All brake fluids must be able to pass tests for the following:

1. Fluidity at low temperatures
2. Controlled percentage loss due to evaporation at high temperatures (tested at 212°F [100°C])
3. Compatibility with other brake fluids
4. Resistance to oxidation
5. Specific effects on rubber, including the following:
    a. No disintegration
    b. No increase in hardness of the rubber tested
    c. Limited amount of decrease in hardness of the rubber

PHYSICAL PROPERTIES Brake fluid is made from a combination of various types of glycol, a non-petroleum-based fluid. Brake fluid is a polyalkylene-glycol-ether mixture called **polyglycol** for short. All *polyglycol brake fluid is clear to amber in color*. Brake fluid has to have the following characteristics:

- A high boiling point
- A low freezing point
- No ability to damage rubber parts in the brake system

BRAKE FLUID SPECIFICATIONS

FMVSS 116 All automotive brake fluid must meet Federal Motor Vehicle Safety Standard (FMVSS) 116. The Society of Automotive Engineers (SAE) and the Department of Transportation (DOT) have established brake fluid specification standards. ● **SEE CHART 96–1**.

The wet boiling point is often referred to as "equilibrium reflux boiling point" (ERBP). ERBP refers to the method in the specification (SAE J1703) by which the fluid is exposed to moisture and tested.

DOT 3		DOT 4	DOT 5.1	DOT 5
Dry Boiling Point				
°F	401	446	500	500
°C	205	230	260	260
Wet Boiling Point				
°F	284	311	356	356
°C	140	155	160	180

CHART 96–1

Chart showing the type of brake fluid and the wet and dry boiling temperatures for each rating.

FREQUENTLY ASKED QUESTION

What Is "Synthetic" Brake Fluid?

All glycol brake fluids are synthetic and are not petroleum-based. Brake fluid manufacturers get calls every week from people who have questions about brake fluid. For example, some are concerned because the old familiar brands have changed from "premium" to "synthetic" on the bottle. The DOT class system sets standards and testing procedures only; the ingredients used are up to the manufacturer. If it meets the standards, it will qualify as "brake fluid." Based on a combination of the properties determined by testing, glycol-based brake fluids are labeled DOT 3, 4, or 5.1 and all are synthetic.

DOT 3 **DOT 3** brake fluid is the type most often used. There are, however, certain important characteristics.

1. DOT 3 absorbs moisture. According to the SAE, DOT 3 can absorb 2% of its volume in water per year. Moisture is absorbed by the brake fluid through microscopic seams in the brake system and around seals. Over time, the water will corrode the system and thicken the brake fluid. The moisture can also cause a spongy brake pedal, due to reduced vapor-lock temperature. ● **SEE FIGURES 96–1 AND 96–2.**

DOT 3
Brake Fluid
For ABS, Disc And Drum Brakes
Conforms to DOT 3, 49CFR 571.116
and FMVSS 116, SAE-J1703
WARNING
IRRITANT

FIGURE 96–1 Brake fluid can absorb moisture from the air even through plastic, so many experts recommend that brake fluid be purchased in metal containers, if possible.

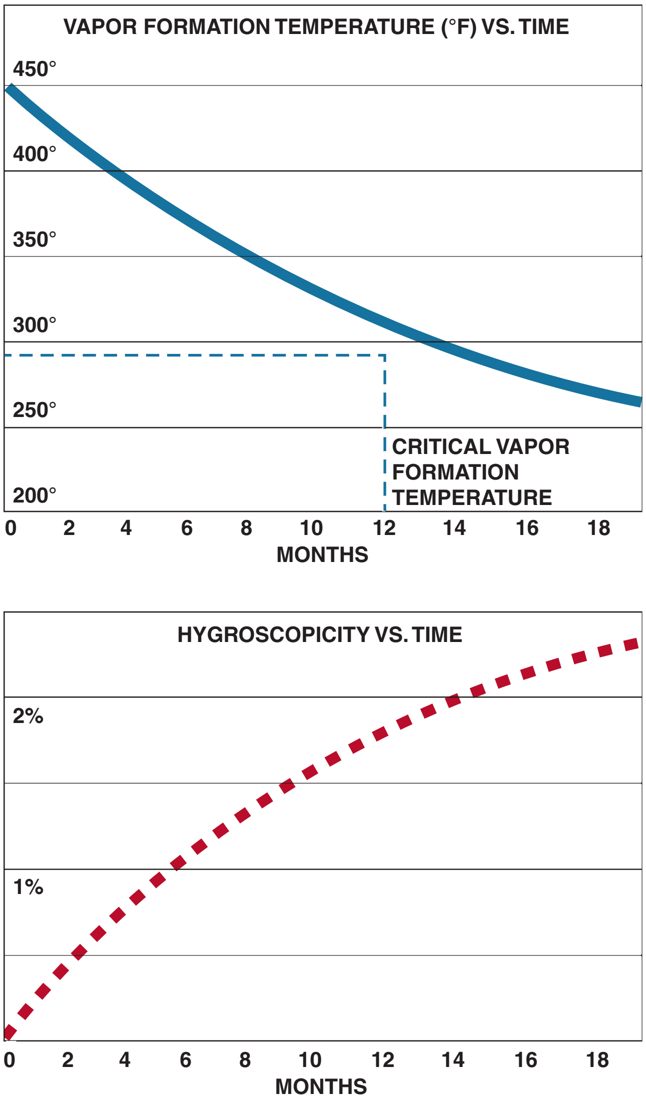

FIGURE 96–2 Brake fluid absorbs moisture from the air at the rate of about 2% per year. As the brake fluid absorbs water, its boiling temperature decreases.

2. DOT 3 must be used from a sealed (capped) container. If allowed to remain open for any length of time, DOT 3 will absorb moisture from the surrounding air, which is called **hygroscopic**.
3. Always check the brake fluid recommendations on the top of the master cylinders of imported vehicles before adding DOT 3.

CAUTION: DOT 3 brake fluid is a very strong solvent and can remove paint! Care is required when working with DOT 3 brake fluid to avoid contact with the vehicle's painted surfaces. It also takes the color out of leather shoes.

DOT 4 **DOT 4** brake fluid is the specified brake fluid for use in many European vehicles. DOT 4 is polyglycol based but has borate esters added to provide an extra buffer for the fluid against acids that can form in the moisture that has been absorbed in the fluid when it is heated. DOT 4 is approximately double the cost of DOT 3. DOT 4 can often be used where DOT 3 is used and even though the two types of brake fluid are compatible and miscible (able to be mixed), some vehicle manufacturers recommend that DOT 3 and DOT 4 not be mixed. If DOT 4 is to be used, the system should be purged of all of the old DOT 3 and replaced with DOT 4.

FREQUENTLY ASKED QUESTION

What Are the Types of DOT 4 Brake Fluid?

There are several types or specifications under the DOT 4 designation including the following:

- **DOT 4**—Specified for use in many European vehicles and some domestic vehicles. ● **SEE FIGURE 96–3**.
- **DOT 4 (long life)**
- **DOT 4+**—Specified for use in many Mercedes and Volvo vehicles.
- **DOT 4 LV (low viscosity)**—Specified for use in some newer vehicles.
- **DOT 4 racing brake fluid**—Usually blue in color to make it easy to see when all of the old fluid has been purged from the system during a brake fluid replacement procedure.

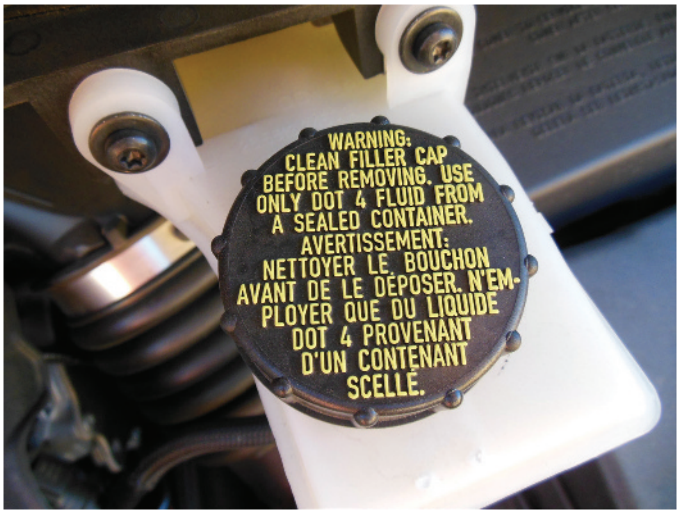

FIGURE 96–3 This Ford Escape requires DOT 4 as stated on the cap of the master cylinder.

NOTE: Because brake fluid absorbs moisture over time, many vehicle manufacturers recommend changing the brake fluid as part of the standard services to be performed routinely. The typical recommended brake fluid change interval is every two years or every 30,000 miles (48,000 km), whichever comes first. This is particularly important for vehicles equipped with an antilock brake system (ABS) because of the problem of expensive brake component wear or corrosion caused by contaminated brake fluid.

DOT 5.1 **DOT 5.1** brake fluid is a non-silicone-based polyglycol fluid and is clear to amber in color. This severe duty fluid has a boiling point of over 500°F equal to the boiling point of silicone-based DOT 5 fluid. Unlike DOT 5, DOT 5.1 can be mixed with either DOT 3 or DOT 4 according to brake fluid manufacturer's recommendations.

CAUTION: Some vehicle manufacturers such as Chrysler do not recommend the use of or the mixing of other types of polyglycol brake fluid and specify the use of DOT 3 brake fluid only. Always follow the vehicle manufacturer's recommendation.

DOT 5 **DOT 5** brake fluid is commonly called **silicone brake fluid** and is made from polydimethylsiloxanes. DOT 5 brake fluid is purple (violet) in color to distinguish it from DOT 3 or DOT 4 brake fluid. It does not absorb any water and is therefore called **non-hygroscopic**. Even though DOT 5 does not normally absorb water, it is still tested using standardized SAE procedures in a humidity chamber. After a fixed amount of time, the brake fluid is measured for boiling point. Since it has had a chance to absorb moisture, the boiling point after this sequence is called the minimum wet boiling point. Silicones have about three times the amount of dissolved air as glycol fluids (about 15% of dissolved air versus only about 5% for standard glycol brake fluid). It is this characteristic of silicone brake fluid that causes the most concern about its use.

1. Silicone brake fluid has an affinity for air; therefore, it is more difficult to bleed the hydraulic system of trapped air.
2. The trapped air expands with increasing temperature. This causes the brake pedal to feel "mushy" because the pressure exerted on the hydraulic system simply compresses the air in the system and does not transfer the force to the wheel cylinders and calipers as it should.

NOTE: The characteristic of DOT 5 silicone brake fluid to absorb air is one of the major reasons why it is not recommended for use with an antilock brake system (ABS). In an ABS, valves and pumps are used that can aerate the brake fluid. Brake fluid filled with air bubbles cannot properly lubricate the ABS components and will cause a low, soft brake pedal.

3. The air trapped in the silicone brake fluid can also "off-gas" at high altitudes, causing a mushy brake pedal and reduced braking performance. DOT 5 brake fluid has been known to create a braking problem during high-altitude (over 5,000 ft [1,500 m]) and high-temperature driving. The high altitude tends to vaporize (off-gassing) some parts of the liquid, creating bubbles in the brake system, similar to having air in the brake system.
4. DOT 5 brake fluid should not be mixed with any other type of brake fluid. Therefore, the entire braking system must be completely flushed and refilled with DOT 5.
5. DOT 5 does not affect rubber parts and will not cause corrosion.
6. DOT 5 is expensive. It is approximately four times the cost of DOT 3 brake fluid. ● **SEE FIGURE 96–4**.

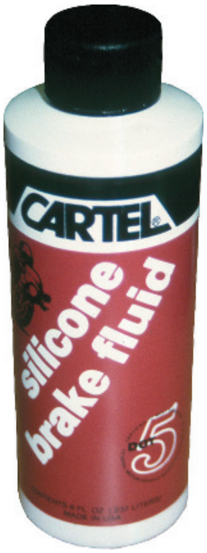

FIGURE 96–4 DOT 5 brake fluid is used mostly in motorcycles because if spilled, it will not hurt painted surfaces.

FREQUENTLY ASKED QUESTION

What Is Hydraulic Brake System Mineral Oil?

Some older French-built Citroen and British-designed Rolls-Royce vehicles used hydraulic system mineral oil (HSMO) as part of their hydraulic control systems. The systems in these vehicles use a hydraulic pump to pressurize hydraulic oil for use in the suspension leveling and braking systems.

CAUTION: Mineral hydraulic oil should never be used in a braking system that requires DOT 3 or DOT 4 polyglycol-based brake fluid.

If any mineral oil, such as engine oil, transmission oil, or automatic transmission fluid (ATF), gets into a braking system that requires glycol brake fluid, every rubber part in the entire braking system must be replaced. Mineral oil causes the rubber compounds that are used in glycol brake fluid systems to swell. ● **SEE FIGURE 96–5**.

To help prevent hydraulic system mineral oil from being mixed with glycol brake fluid, hydraulic mineral oils are *green.*

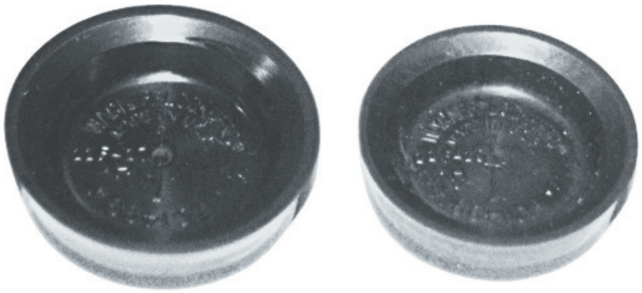

FIGURE 96–5 Both rubber sealing cups were exactly the same size. The cup on the left was exposed to mineral oil. Notice how the seal greatly expanded.

BRAKE FLUID INSPECTION AND TESTING The brake fluid should be inspected regularly by performing the following tests:

1. **Proper level.** The brake fluid level should be above the minimum level (labeled MIN) and below the maximum (labeled MAX) on the side of the master cylinder reservoir. Do not add brake fluid unless the entire brake system is carefully inspected for worn brake pads and shoes and for signs of any external leakage.
2. **Color/condition.** New brake fluid is clear or amber in color. If the brake fluid is black or discolored like black coffee or coffee with cream, the fluid should be changed. ● **SEE FIGURE 96–6**.
3. **Tested using a tester or test strips.** Often, brake fluid does not look as if it is bad but has absorbed moisture enough to reduce its effectiveness. Test strips can be used to measure copper ions that increase as the brake fluid becomes deteriorated. The copper comes from sealing washers and other brass or copper brake system components. ● **SEE FIGURE 96–7**.
4. **Boiling point tester.** An electronic tester can be used to measure the actual boiling temperature of the brake fluid. The tester probe is inserted into the brake fluid and then a

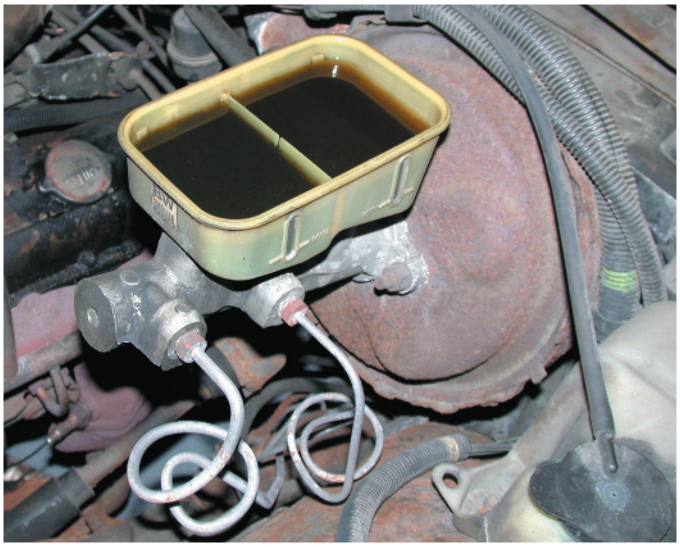

FIGURE 96–6 If the brake fluid is black in color, it should be replaced.

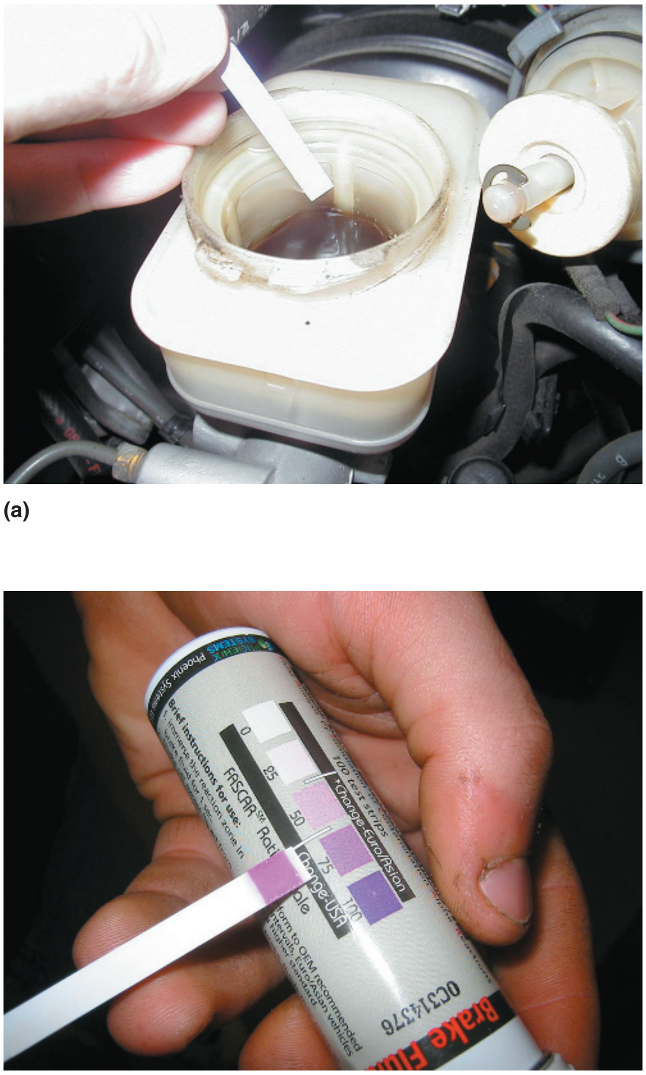

(a)

(b)

FIGURE 96–7 (a) A brake fluid test strip is being used to test the condition of the brake fluid. (b) The color of the test strip is then compared with a chart on the package, which indicates the condition and if the fluid should be replaced.

CASE STUDY

The Sinking Brake Pedal

This author has experienced what happens when brake fluid is not changed regularly. Just as many technicians will tell you, we do not always do what we know should be done to our own vehicles. While driving a four-year-old vehicle on vacation in very hot weather in a mountainous country, the brake pedal sank to the floor. When the vehicle was cold, the brakes were fine. But after several brake applications, the pedal became soft and spongy and sank slowly to the floor if pressure was maintained on the brake pedal. Because the brakes were okay when cold, I knew it had to be boiling brake fluid. Old brake fluid (four years old) often has a boiling point under 300°F (150°C). With the air temperature near 100°F (38°C), it does not take much more heat to start boiling the brake fluid. After bleeding over a quart (1 L) of new brake fluid through the system, the brakes worked normally. I'll never again forget to replace the brake fluid as recommended by the vehicle manufacturer.

Summary:

Complaint—Brake pedal would sink to the floor when driving in mountainous country.
Cause—The brake fluid was boiling causing the loss of brakes.
Correction—The brake fluid was replaced and the system bled.

button is pushed and the boiling temperature is displayed. ● **SEE FIGURE 96–8**.

5. **Brake fluid contamination test.** If brake fluid is mixed with any mineral oil, such as engine oil, power steering fluid, or automatic transmission fluid, rubber components will swell and cause brake system failure. To check for possible contamination, remove the reservoir cover from the master cylinder. If the rubber diaphragm is swelled or distorted, brake fluid contamination is likely. To check the brake fluid, use a Styrofoam cup filled with water.
   - Place a teaspoon (1 ml) of brake fluid from the master cylinder into the water.
   - Pure brake fluid will completely dissolve in the water. Petroleum or mineral oil fluids will float on the surface of the water and retain their color. Petroleum fluids will also dissolve the Styrofoam cup at the waterline.
   - If the brake fluid is contaminated, the entire braking system must be drained and flushed and all rubber components replaced.

FIGURE 96–8 An electronic tester that measures the boiling temperature of the brake fluid is useful to help determine if the brake fluid needs to be replaced. The boiling temperature of brake fluid decreases as the fluid ages.

BRAKE FLUID SERVICE PROCEDURES

STORAGE OF BRAKE FLUID

1. Store brake fluid only in its original container.
   - To help prevent possible contamination with moisture, air, or other products, purchase brake fluid in small containers.
   - Keep all brake fluid containers tightly closed to prevent air (containing moisture) from being absorbed.
2. Before opening a brake fluid container, remove any dirt, moisture, or other contamination from the top and outside of the container.
3. When a brake fluid container is empty, it should be discarded—the container should never be used for anything except brake fluid.
4. Do not transfer brake fluid to any other container that may have contained oil, kerosene, gasoline, antifreeze, water, cleaners, or any other liquids or chemicals.
5. Do not reuse brake fluid that has been siphoned from another vehicle or drawn out during a brake bleeding operation. (Brake bleeding means to open special bleeder valves in the hydraulic system to rid the system of any trapped air.)
6. Use only fresh, new brake fluid for flushing the hydraulic brake system.

CAUTION: Alcohol or flushing fluids should not be used because they cannot be totally removed and will contaminate the system. Disassembled parts, however, can and should be cleaned with denatured alcohol or spray brake cleaner where the parts can be visually inspected to be free of cleaning solutions.

BRAKE FLUID HANDLING AND DISPOSAL Polyglycol brake fluid presents little toxicity hazard, but for some individuals, brake fluid may produce moderate eye and skin irritation. For good safety practice, protective clothing and safety glasses or goggles should be worn. Brake fluid becomes a hazardous waste if spilled onto open ground, where it can seep into groundwater. The disposal requirements for brake fluid spilled onto open ground vary with the exact amount spilled and other factors. Refer to local EPA guidelines and requirements for the exact rules and regulations in your area.

CASE STUDY

The Pike's Peak Brake Inspection

All vehicles must stop about halfway down Pike's Peak Mountain in Colorado (14,110 ft [4,300 m]) for a "brake inspection." When this author stopped at the inspection station, a uniformed inspector simply looked at the right front wheel and waved us on. I pulled over and asked the inspector what he was checking. He said that when linings and drums/rotors get hot, the vehicle loses brake effectiveness. But if the brake fluid boils, the vehicle loses its brakes entirely. The inspector was listening for boiling brake fluid at the front wheel and feeling for heat about 1 ft (30 cm) from the wheel. The inspector used an infrared pyrometer to measure the front wheel brakes and if the brakes were too hot to continue, you would be instructed to pull over and wait for the brakes to cool. The inspector recommended placing the transmission into a lower gear, which uses the engine to slow the vehicle during the descent without having to rely entirely on the brakes.

Summary:

Complaint—Vehicle was stopped for an inspection.
Cause—If the brakes are too hot, the brake fluid can boil and as a result a total loss of brakes is likely.
Correction—Informed driver that this is normal procedure and a safety precaution.

BRAKE LINES

CONSTRUCTION High-pressure double-walled steel brake lines or high-strength flexible lines are used to connect the master cylinder to each wheel. The steel brake lines are also called **brake pipes** or **brake tubing**. Brake lines carry brake fluid from the master cylinder to the wheel cylinder and brake calipers. The brake lines contain and direct the pressure of the brake hydraulic system. Most of the total length of the brake line consists of rigid tubing. For maximum strength and durability, all brake systems use double-walled brake tubing made from plated steel sheet. There are two types of double-walled tubing:

- Seamless
- Multiple ply ● **SEE FIGURE 96–9**.

All double-walled brake tubing is plated with tin, zinc, or other similar substances for protection against rust and corrosion. The Society of Automotive Engineers has guidelines for brake tubing.

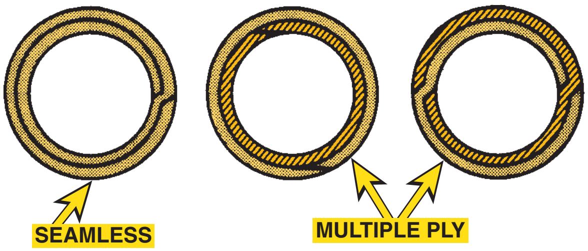

FIGURE 96–9 Steel brake tubing is double walled for strength and plated for corrosion resistance.

WARNING

Copper tubing should never be used for brake lines. Copper tends to burst at a lower pressure than steel.

SAE Standard J1047 specifies that a sample section of brake line must be able to withstand 8,000 PSI (55,000 kPa), plus other standards for resistance to fatigue, heat, rust, and corrosion.

STEEL BRAKE LINE COATINGS Because steel tube alone does not have adequate corrosion resistance, it requires a coating. The coatings in wide use include

- Aluminum-rich paint (called AlGal)
- Nylon-coated (called NyGal)
- Zinc
- Terne plate (lead and tin alloy)
- Epoxy
- PVF (Polyvinylfluoride)—olive green color

While these coatings have been effective, the liquid sodium chloride and rock salt used to de-ice winter roads break down and will eventually destroy steel tubing lines.

COPPER-NICKEL BRAKE LINES Copper-nickel brake line is commonly referred to as "90-10 copper" because it contains about 90% copper and 10% nickel. Copper-nickel brake lines have been used on several European vehicle brake systems since the 1970s, including

- Volvo
- Audi
- Porsche
- Aston Martin

Copper-nickel alloy brake tubing meets SAE Standard J1047 and ISO 4038, meeting all international and U.S. requirements for brake tubing and has the strength of steel lines, but is much more corrosion-resistant. This type is also pliable, making flaring and bending easier than when using steel brake lines.

FREQUENTLY ASKED QUESTION

Why Is the Government Asking Me to Wash My Vehicle?

If you live where salt is used to clear the roads of snow and ice, U.S. safety regulators have a message for you: "Wash the underside of your vehicle." The message came from the National Highway Traffic Safety Administration (NTHSA), which closed a five-year investigation into rusting brake fluid lines which the agency said was caused by road salt and a lack of washing. The agency urged people in 20 cold-weather states and Washington, D.C., to get their car and truck undercarriages washed several times during and after the winter, and to get their brake lines inspected for rust and replace them if necessary. ● **SEE FIGURE 96–10**.

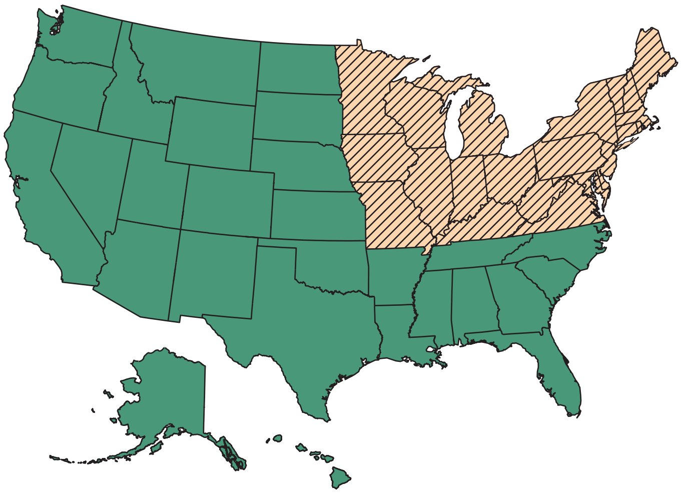

FIGURE 96–10 The rust prone states are areas where snow and the use of salt contribute to the brake line rust. Vehicles that operate outside this area also rust, but not to the extent that they do in the states known for rust problems.

TYPES OF FLARES All steel brake lines have one of two basic types of ends:

- **Double flare.** ● **SEE FIGURE 96–11**.
- **ISO**, which means International Standards Organization (also called a *ball flare* or *bubble flare*). ● **SEE FIGURE 96–12**.

BRAKE HOSE INSPECTION All brake lines, flexible hoses, and fittings should be visually inspected at least every year for the following faults:

- leaks
- dents
- kinks
- rust
- cracks

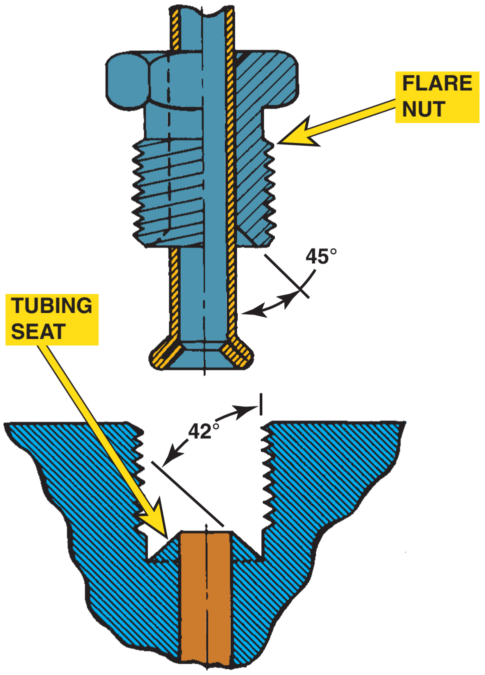

FIGURE 96–11 Because of the slight difference in flare angle, double-flare fitting seals cause a wedging action.

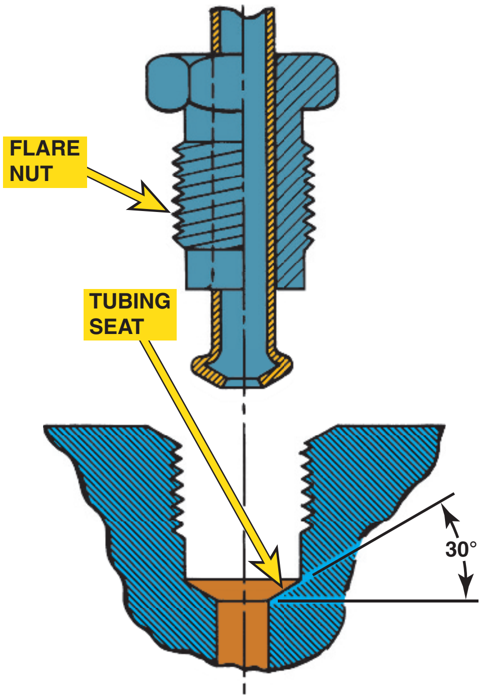

FIGURE 96–12 An ISO fitting, also called a ball or bubble flare.

- bulging
- wear
- loose fittings/supports

If any of these issues are found then the brake line/hoses should be replaced. Most experts recommend that if one flexible brake hose is replaced, then all should be replaced because they all were operating under the same conditions and if one fails, then the others may also fail soon.

BRAKE LINE REPLACEMENT If replacing a brake line, there are two options:

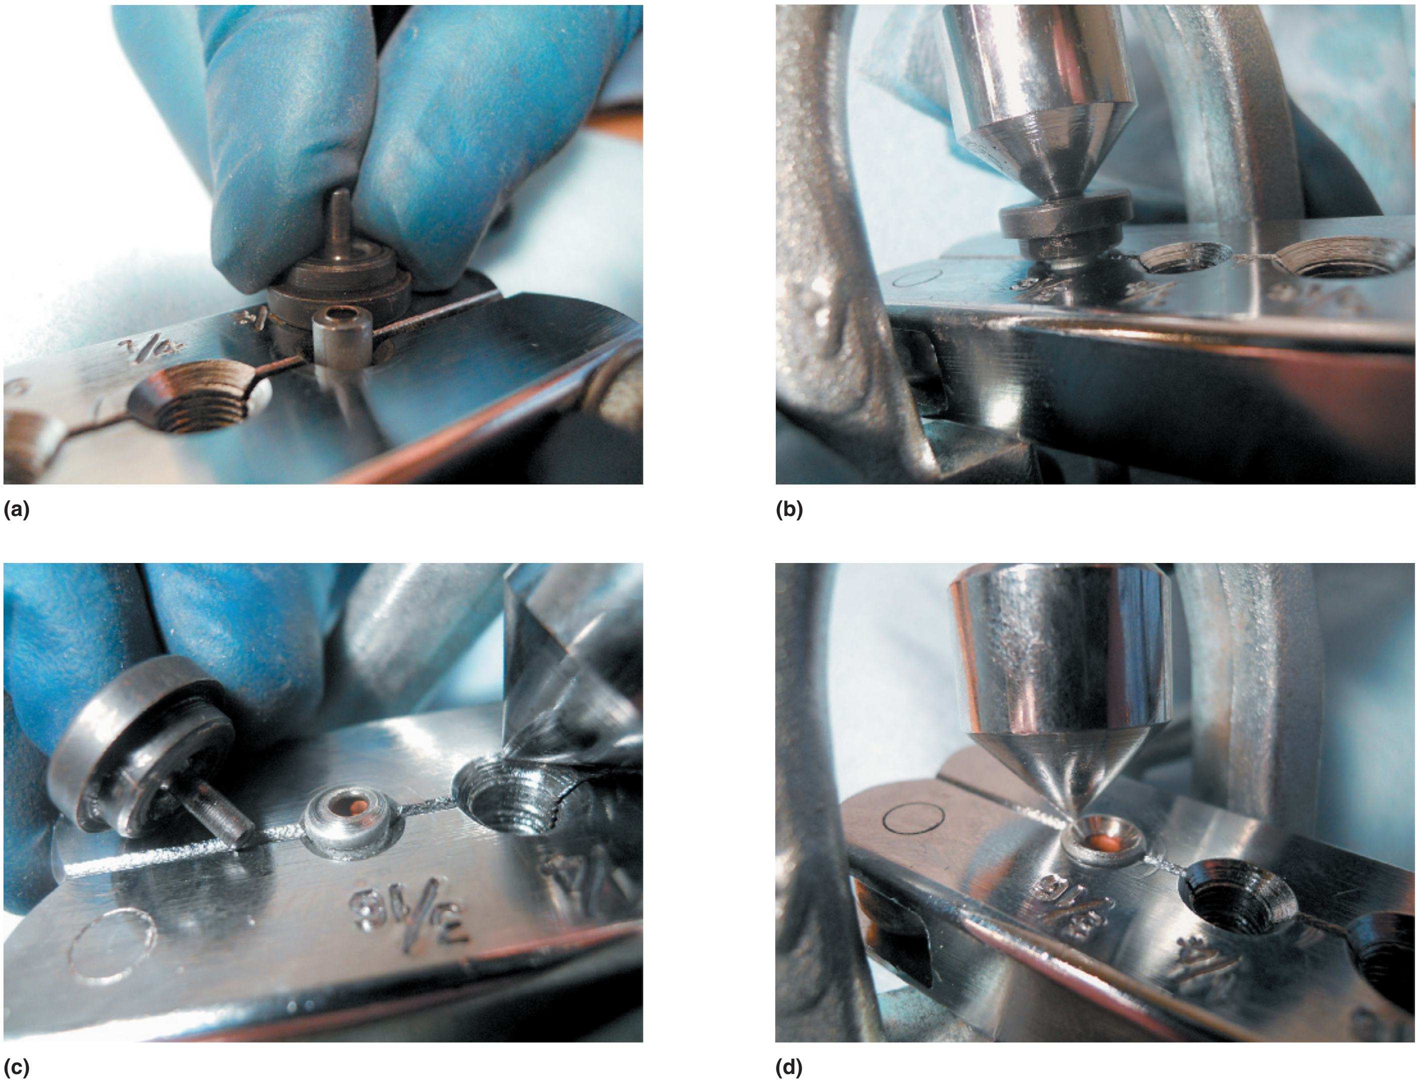
OPTION 1 Purchase pre-made lines in the diameter and length needed. Brake line can also be purchased in selected lengths already correctly flared. They are available in different diameters, the most commonly used with an outside diameter (OD) of

- 3/16 inch (4.8 mm)
- 1/4 inch (6.4 mm)
- 5/16 inch (7.9 mm)

OPTION 2 Cut and flare lines to match what is needed. When replacing steel brake lines, new steel tubing should be used and a double lap flare or an ISO flare needs to be completed at each end using a special flaring tool. Always follow the instructions that came with the flaring tool for best results. ● **SEE FIGURES 96–13 AND 96–14**.

⚠ WARNING

According to vehicle manufacturer's recommended procedures, compression fittings should never be used to join two pieces of steel brake line. Only use double-flare ends and connections, if necessary, when replacing damaged steel brake lines.



(a) (b) (c) (d)

FIGURE 96–13 Double flaring the end of a brake line. (a) Clamp the line at the correct height above the surface of the clamping tool using the shoulder of the insert as a gauge. (b) The insert is pressed into the end of the tubing. This creates the first bend. (c) Remove the insert and use the pointed tool to complete the overlap double flare. (d) The completed operation as it appears while still in the clamp.

COILED BRAKE LINE Steel brake line is often coiled to allow movement between the brake components without stress that could lead to metal fatigue and brake line breakage. The typical master cylinder attaches to the bulkhead of the vehicle and the combination valve is often attached to the frame. Because the body and frame are usually insulated from each other using rubber isolators, some movement occurs while driving. ● **SEE FIGURE 96–15**.

ARMORED BRAKE LINE In many areas of the brake system, the steel brake line is covered with a wire coil wrap. This type of brake line is called **armored brake line**. This armor is designed to prevent damage from stones and other debris that could dent or damage the brake line. If a section of armored brake line is to be replaced, armored replacement line should be installed. ● **SEE FIGURE 96–16**.

TECH TIP

Bend It Right the First Time

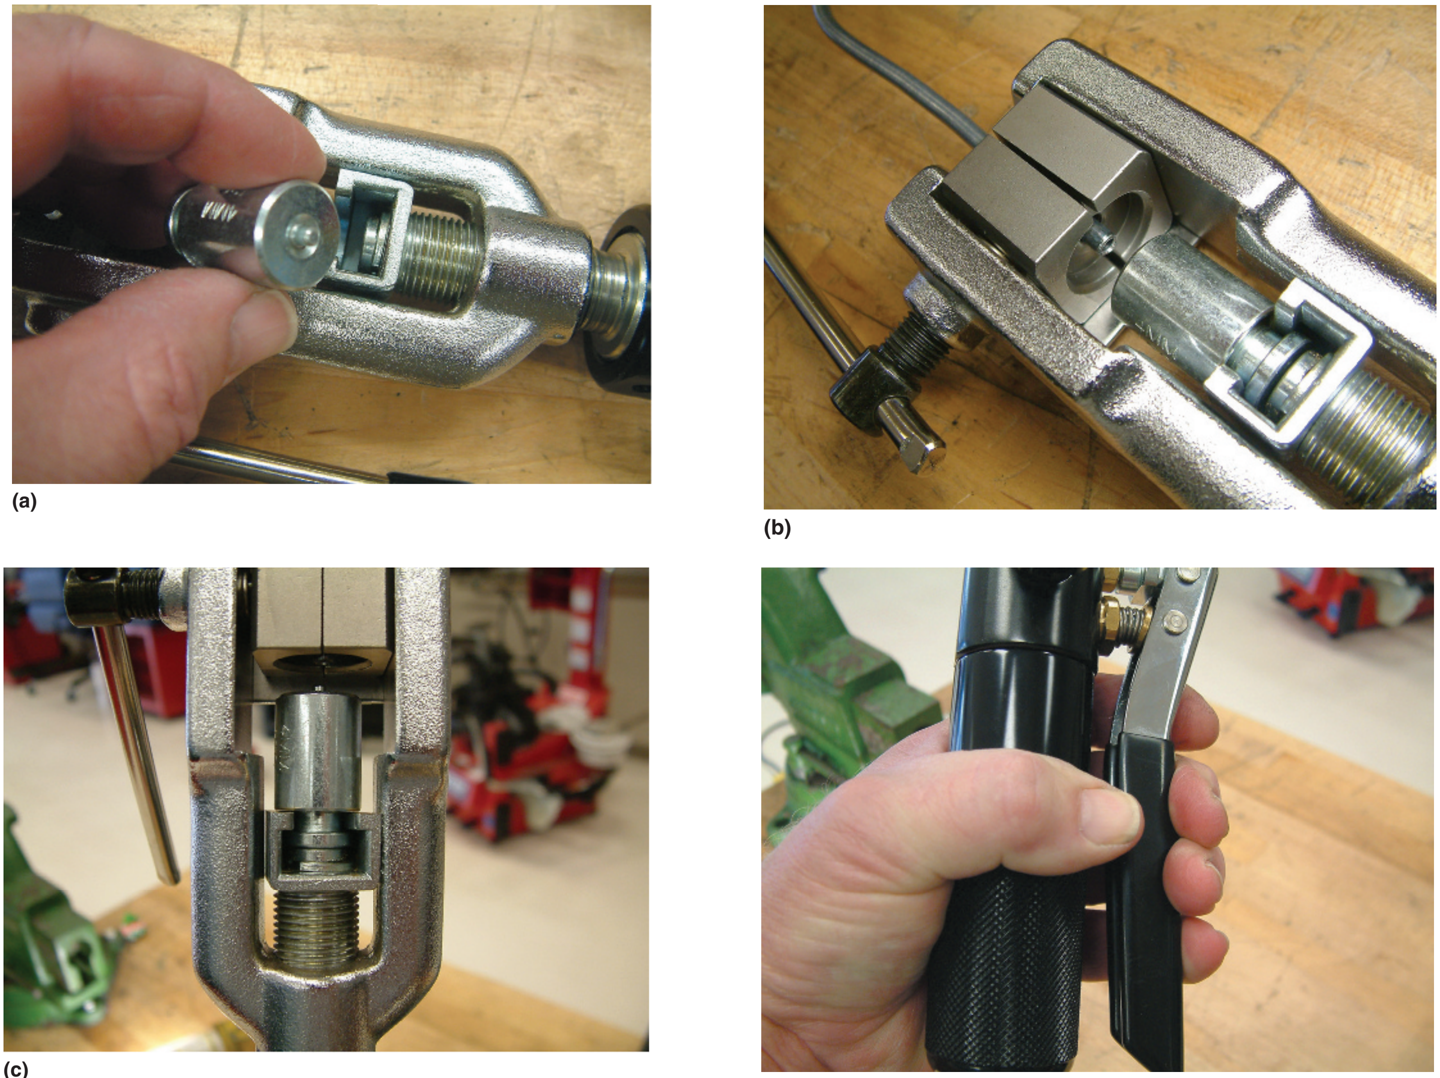
Replacing rusted or damaged brake line can be a difficult job. It is important that the replacement brake line be located in the same location as the original to prevent possible damage from road debris or heat from the exhaust. Often this means bending the brake line with many angles and turns. To make the job a lot easier, perform the following steps:

STEP 1 Use a stiff length of wire and bend the wire into the exact shape necessary.

STEP 2 Then use the wire as a pattern to bend the brake line.

STEP 3 Always use a tubing bender to avoid kinking the brake line. A kink not only restricts the flow of brake fluid, but also weakens the line. ● **SEE FIGURE 96–17**.

NOTE: Always use a tubing cutter instead of a hacksaw when cutting brake line. A hacksaw will leave a rough and uneven end that will not flare properly except when forming an ISO flare. A hacksaw is used to provide a rough surface to allow the flaring tool to grip the line during the procedure. Always check the instructions that came with the flaring tool for the exact procedure to follow. ● **SEE FIGURE 96–18.**

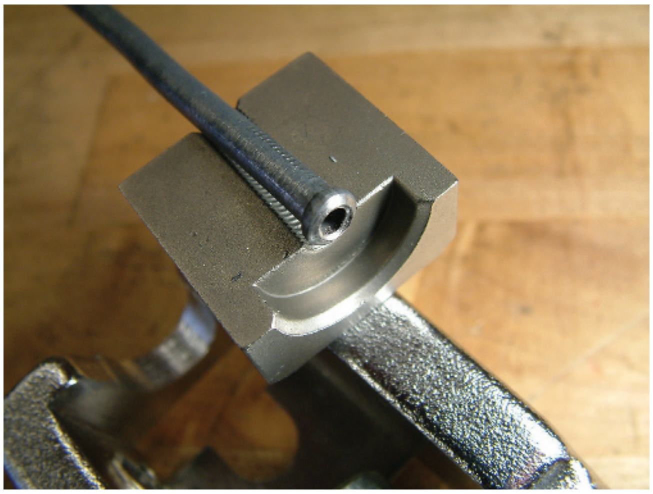


(a)

(b)

(c)

(d)



(e)

FIGURE 96–14 Making an ISO flare requires a special tool. (a) Select the proper size forming mandrel. (b) Clamp the tubing flush with the split die and place the mandrel into the tool. (c)Thread the tool handle in until the mandrel pilot seats into the tubing. (d) Close the tool valve and pump the handle until the mandrel seats in the die. (e) The strong hydraulic pressure forms the ISO flare.

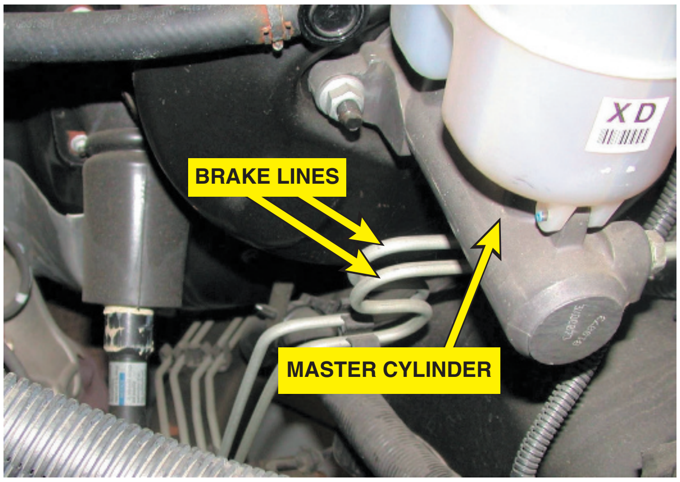


FIGURE 96–15 The coils in the brake line help prevent cracks caused by vibration.

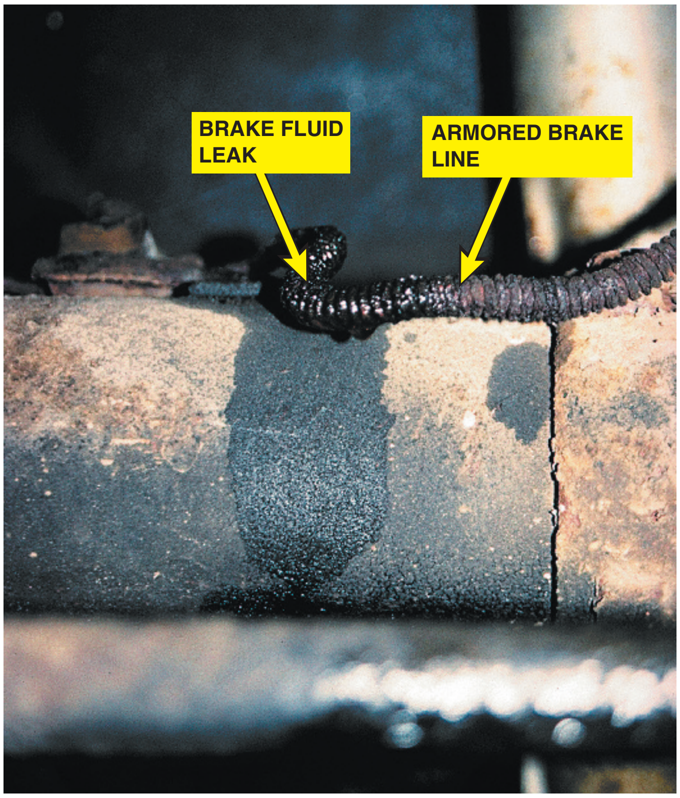

FIGURE 96–16 Armored brake line is usually used in the location where the line may be exposed to rock or road debris damage. Even armored brake line can leak and a visual inspection is an important part of any brake service.

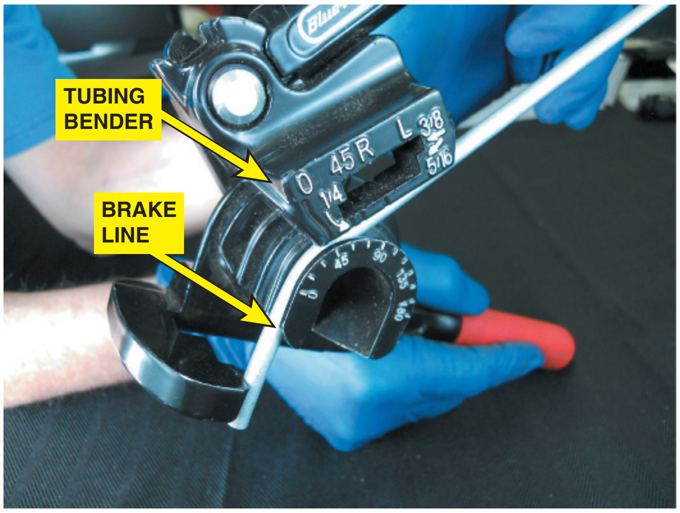

FIGURE 96–17 A tube bender being used to bend a brake line.

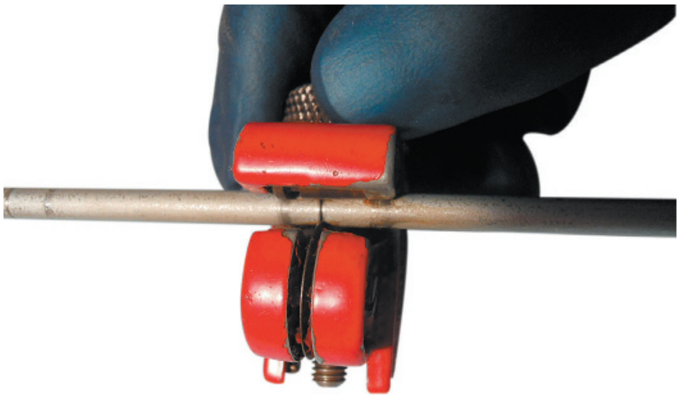

FIGURE 96–18 A tubing cutter is the preferred tool to use to cut brake line because it leaves a clean edge.

FLEXIBLE BRAKE HOSE **Flexible brake hoses** are used on each front wheel to allow for steering and suspension movement and at the rear to allow for rear suspension travel. ● **SEE FIGURE 96–19**.

Flexible brake hose is made from synthetic yarn (poly vinyl alcohol, abbreviated PVA) that is braided into position from multi-end yarn spindles. By braiding the yarn, all of the strands operate in tension and, therefore, have great strength to withstand braking system pressure over 1,000 PSI (6,900 kPa).

- A typical brake hose has an inner tube for moving the brake fluid and a cushion liner that is between the braided layers to prevent the braids from chafing. All three layers use ethylene-propylene-diene-monomer (EPDM)-type thermosetting polymers, which help prevent the hose from absorbing moisture from the outside air.
- An outside jacket is made from rubber and protects the reinforcement fabric from moisture and abrasion.
- The outside covering is also ribbed as part of the manufacturing process to hide surface blemishes. These ribs also make it easy for the technician to see if the hose is twisted. It is not unusual for flexible brake lines to become turned around and twisted when the disc brake caliper is removed and then replaced during a brake pad change. ● **SEE FIGURE 96–20**.

These rubber high-strength hoses can crack, blister, or leak and should be inspected at least every six months. ● **SEE FIGURE 96–21**.

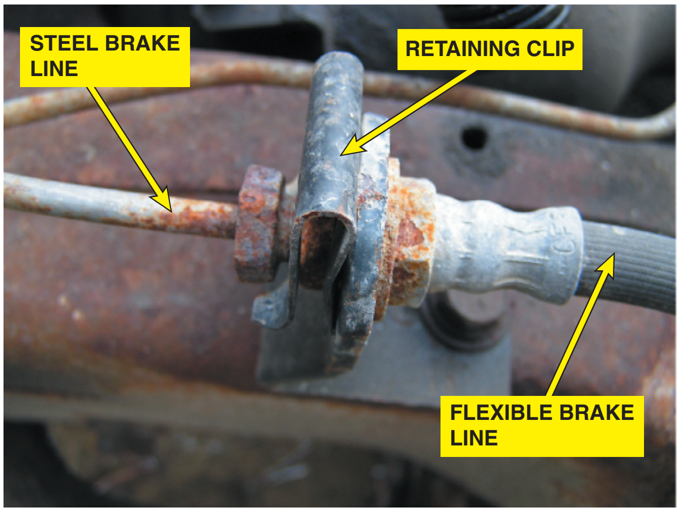

FIGURE 96–19 Flexible brake hoses are used between the frame or body of the vehicle and the wheel brakes. Because of suspension and/or steering movement, these flexible brake lines must be strong enough to handle high brake fluid pressures, yet remain flexible.

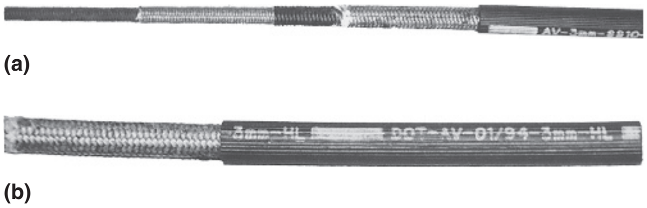

FIGURE 96–20 (a) Typical flexible brake hose showing the multiple layers of rubber and fabric. (b) The inside diameter (ID) is printed on the hose (3 mm).

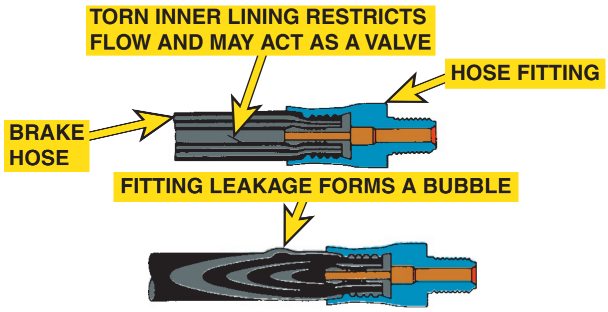

TORN INNER LINING RESTRICTS FLOW AND MAY ACT AS A VALVE
HOSE FITTING
BRAKE HOSE
FITTING LEAKAGE FORMS A BUBBLE

FIGURE 96–21 Typical flexible brake hose faults. Many faults cannot be seen, yet can cause the brakes to remain applied after the brake pedal is released.

A constricted brake hose can cause the brakes to remain applied, thereby causing excessive brake pad wear and unequal braking. A constricted flexible brake line can also cause the vehicle to pull to one side. ● **SEE FIGURE 96–22**.

CAUTION: Never allow a disc brake caliper to hang by the flexible brake line. Damage to the line can result. Always use a wire to support the weight of the caliper and always use two line wrenches when disconnecting or reattaching brake lines. ● SEE FIGURE 96–23.

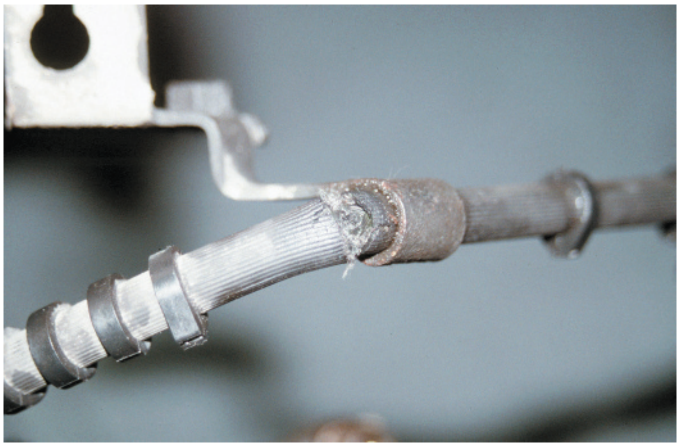

FIGURE 96–22 Flexible brake hose should be carefully inspected for cuts or other damage, especially near sections where the brake hose is attached to the vehicle. Notice the crack and cut hose next to the mounting bracket.

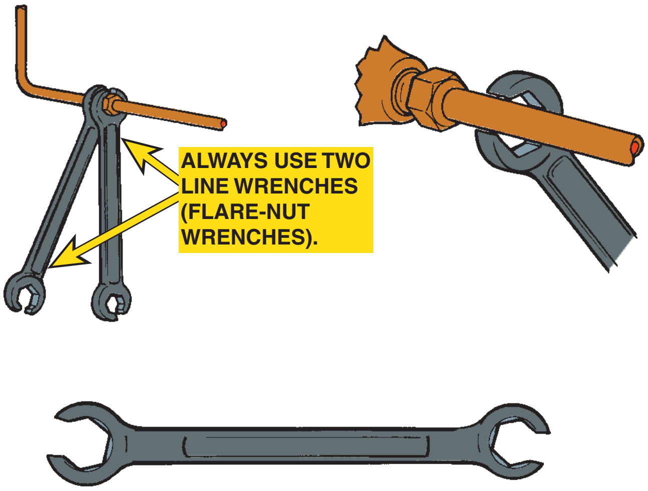

ALWAYS USE TWO LINE WRENCHES (FLARE-NUT WRENCHES).

FIGURE 96–23 Whenever disconnecting or tightening a brake line, always use the correct size flare-nut wrench. A flare-nut wrench is also called a tube-nut wrench or a line wrench.

BRAKE BLEEDING

THE NEED FOR BRAKE BLEEDING **Brake bleeding** is removing any trapped air from the hydraulic system. If air is in the brake hydraulic system, the brake pedal will often feel "spongy." The brake pedal will also travel farther (lower-than-normal brake pedal) before the brakes start to apply. Air can get into the hydraulic system whenever any hydraulic brake line or unit is opened. Air can also be drawn into the hydraulic system through small holes or loose brake line connections during the release of the brake pedal. A common source of air in the brake system of this type can occur through very small holes in rubber flexible brake lines. Another source of air in the braking system is through the absorption of moisture by the brake fluid. When moisture is absorbed, the boiling point of the brake fluid is reduced. During severe braking, the heat generated can cause the brake fluid to boil and create air bubbles in the hydraulic brake system. Air eventually travels to the highest part of the brake system, if not restricted by pressure control valves.

BLEEDING THE MASTER CYLINDER Whenever the master cylinder is replaced or the hydraulic system has been left opened for several hours, the air may have to be bled from the master cylinder. The master cylinder is located in the highest section of the hydraulic braking system. Some master cylinders are equipped with bleeder valves. If the master cylinder is not equipped with bleeder valves, it can be bled by loosening the brake line fittings at the master cylinder. Bleed the master cylinder "on the bench" before installing it on the vehicle. ● **SEE FIGURE 96–24**.

If bleeding the master cylinder after working on the hydraulic system, follow these steps:

STEP 1 Fill the master cylinder with clean brake fluid from a sealed container up to the recommended "full" level.

STEP 2 Have an assistant slowly depress the brake pedal as you "crack open" the master cylinder bleed screw starting with the section closest to the brake pedal. It is very important that the primary section of the master cylinder be bled before attempting to bleed the air out of the secondary section of the master cylinder. Before the brake pedal reaches the floor, close the bleeder valve.

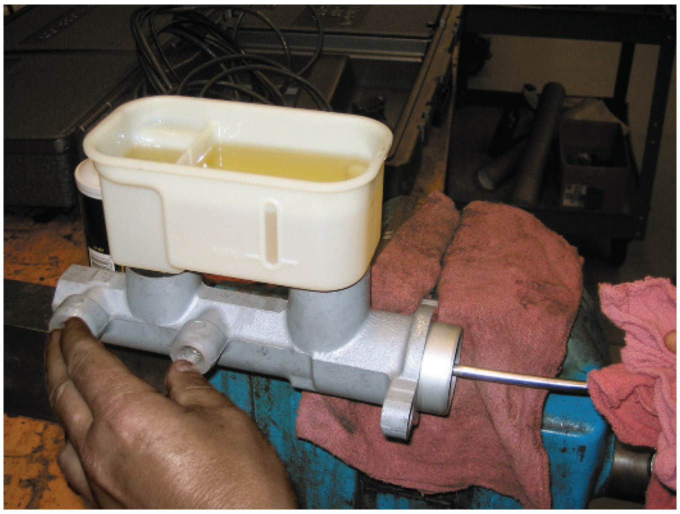

FIGURE 96–24 Bench bleeding a master cylinder. Always clamp a master cylinder in a vise by the mounting flange to prevent distortion of the cylinder bore. Bench bleeding tubes can also be used that route the fluid back into the reservoir.

TECH TIP

Check That All Bleeder Valves Are Pointing Up

Make certain all the brake components such as calipers and wheel cylinders are correctly installed with the bleeder valve located on the highest section of the part. Some wheel cylinders and calipers (such as many Ford calipers) can be installed upside down!

This usually occurs whenever both front calipers are off the vehicle and they accidentally get reversed left to right. If this occurs, the air will never be completely bled from the caliper.

NOTE: A proper manual bleeding of the hydraulic system requires that accurate communications occur between the person depressing the brake pedal and the person opening and closing the bleeder valve(s). The bleeder valve (also called a *bleed valve*) should be open only when the brake pedal is being depressed. The valve *must* be closed when the brake pedal is released to prevent air from being drawn into the system.

STEP 3 Repeat the procedure several times until a solid flow of brake fluid is observed leaving the bleeder valve. If the master cylinder is not equipped with bleeder valves, the outlet tube nuts can be loosened instead.

BRAKE BLEEDER VALVE LOOSENING METHODS

Attempting to loosen a bleeder valve often results in breaking (shearing off) the bleeder valve. Several of these service procedures can be tried that help prevent the *possibility* of breaking a bleeder valve. Bleeder valves are tapered and become wedged in the caliper on the wheel cylinder housing. ● **SEE FIGURES 96–25 AND 96–26**. All of these methods use shock to "break the taper" and to loosen the stuck valve.

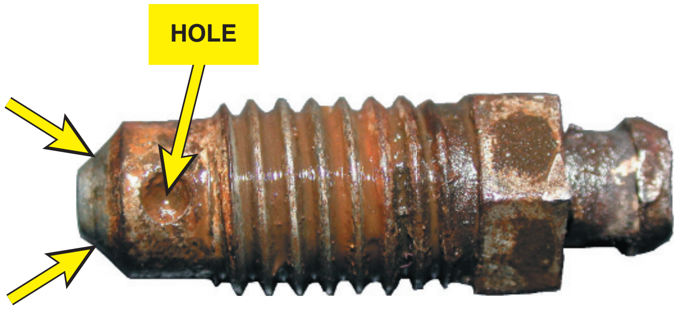

FIGURE 96–25 Typical bleeder valve from a disc brake caliper. The arrows point to the taper section that does the actual sealing. It is this taper that requires a shock to loosen. If the bleeder is simply turned with a wrench, the bleeder usually breaks off because the tapered part at the bottom remains adhered to the caliper or wheel cylinder. Once loosened, brake fluid flows around the taper and out through the hole in the side of the bleeder valve. The hole is clogged in this example and needs to be cleaned out.

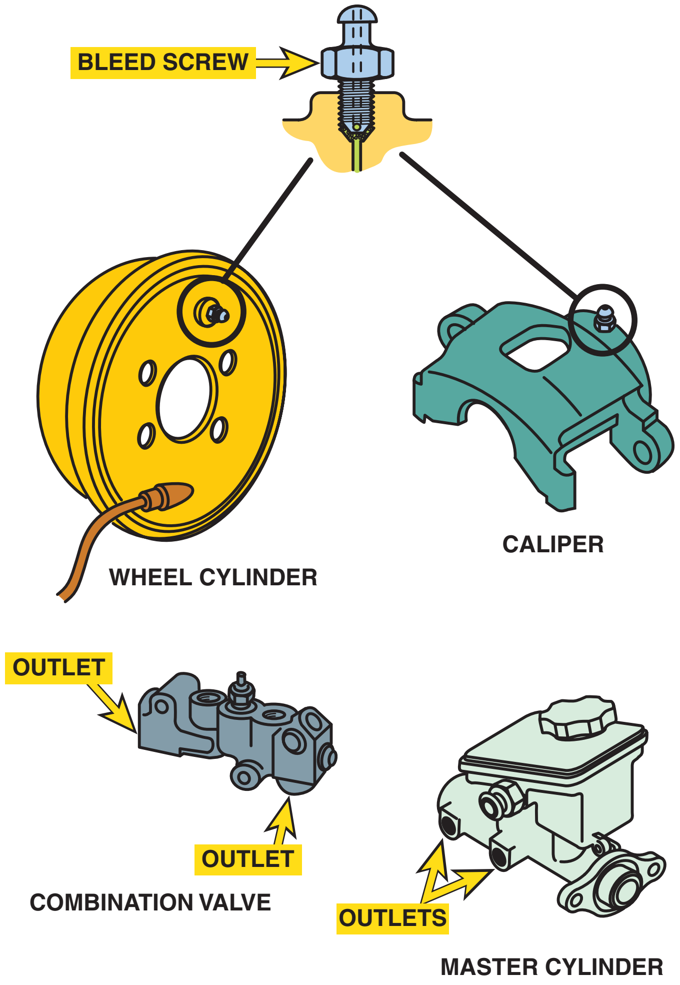

FIGURE 96–26 Typical bleeder locations. Note that the combination valve and master cylinder shown do not have bleeder valves; therefore, bleeding is accomplished by loosening the brake line at the outlet ports.

HIT AND TAP METHOD

STEP 1 Tap on the end of the bleeder valve with a steel hammer. This shock often "breaks the taper" at the base of the bleeder valve. The shock also breaks loose any rust or corrosion on the threads.

STEP 2 Using a 6-point wrench or socket, *tap* the bleeder valve in the clockwise direction (tighten).

STEP 3 Using the same 6-point socket or wrench, *tap* the bleeder valve counterclockwise to loosen and remove the bleeder valve.

NOTE: It is the *shock* of the tap on the wrench that breaks loose the bleeder valve. Simply pulling on the wrench often results in breaking off the bleeder.

STEP 4 If the valve is still stuck (frozen), repeat steps 1 through 3.

AIR PUNCH METHOD Use an air punch near the bleeder valve while attempting to loosen the bleeder valve at the same time. ● **SEE FIGURE 96–27.**

The air punch creates a shock motion that often loosens the taper and threads of the bleeder valve from the caliper or wheel cylinder. It is also helpful to first attempt to turn the bleeder valve in the clockwise (tightening) direction, then turn the bleeder in the counterclockwise direction to loosen and remove the bleeder valve.

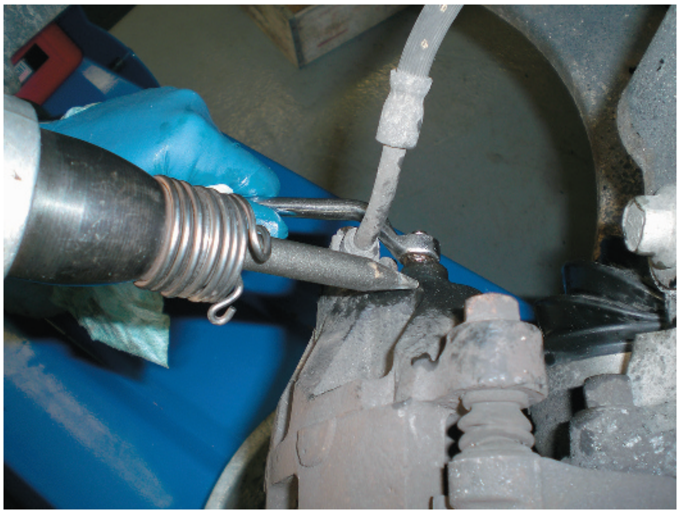

FIGURE 96–27 Using an air punch next to the bleeder valve to help "break the taper" on the bleeder valve.

HEAT AND TAP METHOD

Heat the area around the bleeder valve with a torch. The heat expands the size of the hole and usually allows the bleeder to be loosened and removed.

CAUTION: The heat from a torch will damage the rubber seals inside the caliper or wheel cylinder. Using heat to free a stuck bleeder valve will *require* that all internal rubber parts be replaced.

WAX METHOD

STEP 1 Heat the bleeder valve itself with a torch. The heat causes the valve itself to expand.

STEP 2 Remove the heat from the bleeder valve. As the valve is cooling, touch paraffin wax or candle wax to the hot valve. The wax will melt and run down around the threads of the bleeder valve.

STEP 3 Allow the bleeder valve to cool until it can be safely touched with your hand. This assures that the temperature is low enough for the wax to return to a solid and provide the lubricating properties necessary for the easy removal of the bleeder valve. Again, turn the bleeder valve clockwise before turning the valve counterclockwise to remove.

BLEEDING SEQUENCE

After bleeding the master cylinder, the combination valve should be bled if equipped. Check the level in the master cylinder frequently being careful not to allow the master cylinder to run dry and keep it filled with clean brake fluid throughout the brake bleeding procedure.

For most rear-wheel-drive vehicles equipped with a front/rear split system, start the bleeding with the wheel farthest from the master cylinder and work toward the closest. ● **SEE FIGURE 96–28**.

For most vehicles, this sequence is as follows:

1. Right rear
2. Left rear
3. Right front
4. Left front

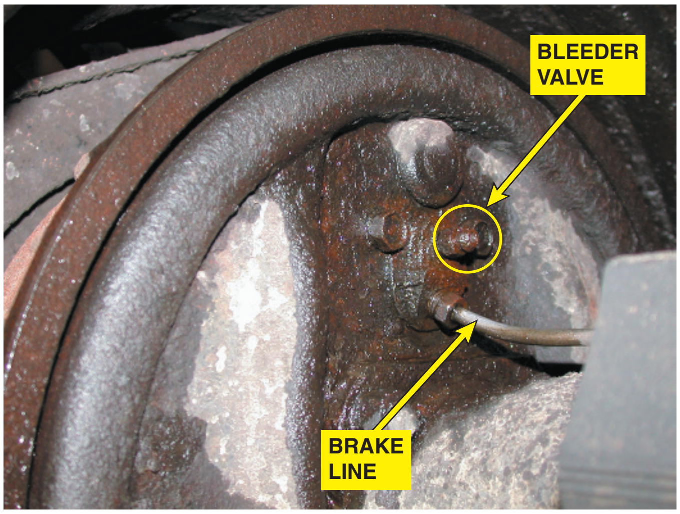

FIGURE 96–28 Most vehicle manufacturers recommend starting the brake bleeding process at the rear wheel farthest from the master cylinder.

NOTE: If the vehicle has two wheel cylinders on one brake, bleed the upper wheel cylinder first.

For vehicles equipped with a diagonal split section or equipped with ABS, follow the brake bleeding procedure recommended in the service information for the vehicle.

MANUAL BLEEDING

Manual bleeding is the most commonly used method and uses hydraulic pressure created by the master cylinder to pump fresh fluid through the brake system. This method is also called the **single stroke bleeding method**.

ADVANTAGES OF MANUAL BLEEDING

The manual method of brake bleeding is the most common. Manual bleeding requires the following:

- An assistant to apply and release the brake pedal
- A bleeder screw wrench
- Approximately 2 feet of clear, plastic hose with an inside diameter small enough to fit snugly over the bleeder screws
- A clear jar partially filled with clean brake fluid

MANUAL BLEEDING PROCEDURE

To manually bleed the brake system, follow these steps:

STEP 1 Discharge the vacuum or hydraulic power booster (if equipped) by pumping the brake pedal with the ignition OFF until the pedal feels hard.

STEP 2 Fill the master cylinder reservoir with new brake fluid and make sure it remains at least half full throughout the bleeding procedure.

STEP 3 Attach the plastic hose over the bleeder screw of the first wheel cylinder or caliper in the bleeding sequence, and submerge the end of the tube in the jar of brake fluid. ● **SEE FIGURE 96–29**.

STEP 4 Loosen the bleeder screw approximately one-half turn, and have an assistant slowly depress the brake pedal. It is extremely important when manually bleeding a brake system that the pedal be applied and released slowly

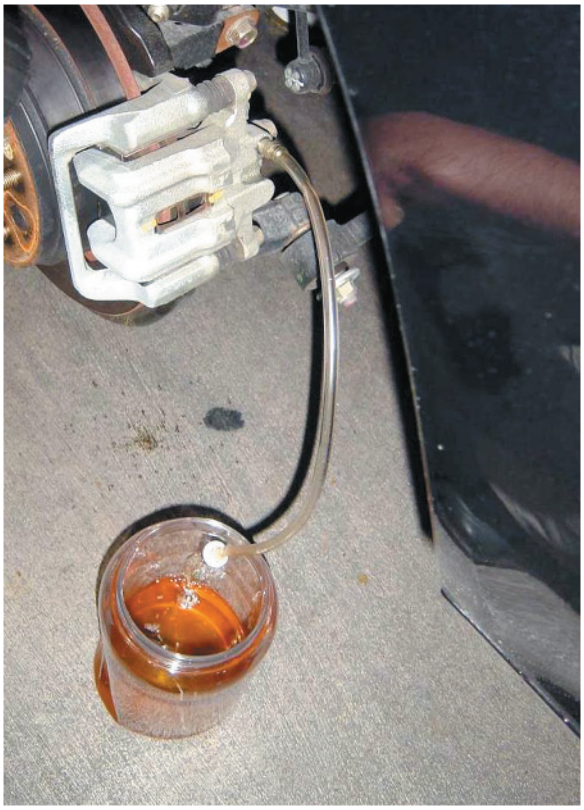

FIGURE 96–29 Bleeding brakes using clear plastic tubing makes it easy to see air bubbles. Submerging the hose in a container of clean brake fluid helps ensure that all of the air will be purged by the system.

and gently. Rapid pedal pumping can churn up the fluid and reduce the size of trapped air bubbles, making them more difficult to bleed from the system. Air bubbles leaving the bleeder screw will be visible in the hose to the jar.

STEP 5 Tighten the bleeder screw, then have your assistant slowly release the brake pedal.

STEP 6 Wait at least 15 seconds to allow time for any small bubbles to form into larger bubbles. See the Tech Tip called "Tiny Bubbles."

STEP 7 Repeat steps 4 and 5 until no more air bubbles emerge from the bleeder.

STEP 8 Transfer the plastic hose to the bleeder screw of the next wheel cylinder or caliper in the bleeding sequence, and repeat steps 4 through 7. Continue around the vehicle in the specified order until the brakes at all four wheels have been bled.

VACUUM BLEEDING

Vacuum bleeding uses a special suction pump that attaches to the bleeder screw. The pump creates a low-pressure area at the bleeder screw, which allows atmospheric pressure to force brake fluid through the system when the bleeder screw is opened.

ADVANTAGES OF VACUUM BLEEDING Vacuum bleeding requires only one technician. It is easy and the equipment needed can be low cost.

DISADVANTAGES OF VACUUM BLEEDING The disadvantage of using a vacuum bleeding method is that a vacuum tool must be used and often air can be drawn into the line between the bleeder valve and the hose creating some bubbles that can be interpreted by the technician as air in the system.

VACUUM BLEEDING PROCEDURE To vacuum bleed a brake system, use the following steps:

STEP 1 Fill the master cylinder reservoir with new brake fluid and make sure it remains at least half full throughout the bleeding procedure.

STEP 2 Attach the plastic tube from the vacuum bleeder to the bleeder screw of the first wheel cylinder or caliper in the bleeding sequence. ● **SEE FIGURES 96–30 AND 96–31**. If necessary, use one of the adapters provided with the vacuum in the catch bottle.

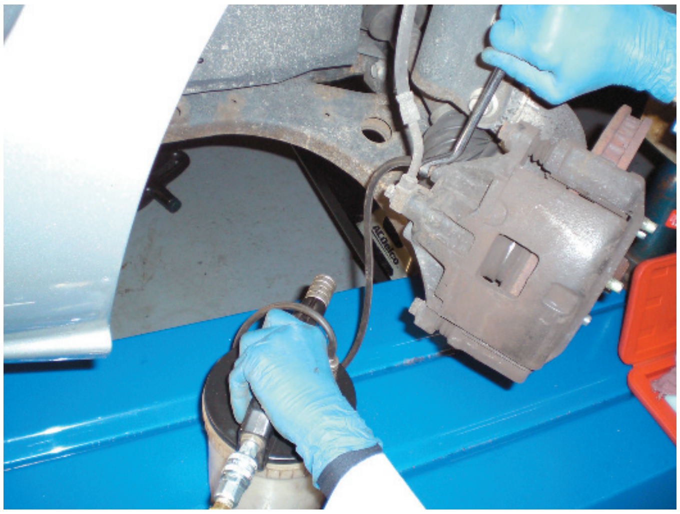

FIGURE 96–30 Using a compressed air-powered vacuum bleeder.

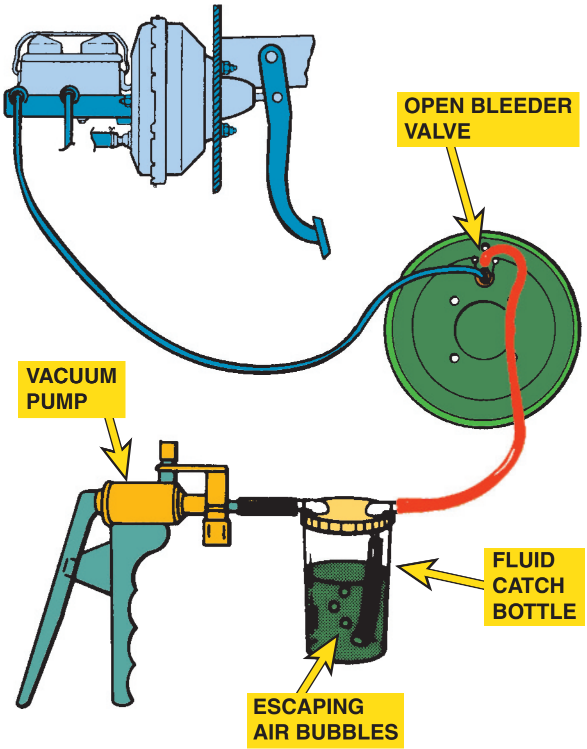

FIGURE 96–31 Vacuum bleeding uses atmospheric pressure to force brake fluid through the hydraulic system.

TECH TIP

Tiny Bubbles

Do not use excessive brake pedal force while bleeding and never bleed the brake with the engine running! The extra assist from the power brake unit greatly increases the force exerted on the brake fluid in the master cylinder. The trapped air bubbles may be dispersed into tiny bubbles that often cling to the inside surface of the brake lines. These tiny air bubbles may not be able to be bled from the hydraulic system until enough time has allowed the bubbles to re-form. To help prevent excessive force, do *not* start the engine. Without power assistance, the brake pedal force can be kept from becoming excessive. If the dispersal of the air into tiny bubbles is suspected, try tapping the calipers or wheel cylinders with a plastic hammer. After this tapping, simply waiting for a period of time will cause the bubbles to re-form into larger and easier-to-bleed air pockets. Most brake experts recommend waiting *15 seconds or longer* between attempts to bleed each wheel. This waiting period is critical and allows time for the air bubbles to form.

NOTE: To help prevent depressing the brake pedal down too far, some experts recommend placing a 2 × 4 inch board under the brake pedal. This helps prevent the seals inside the master cylinder from traveling over unused sections inside the bore that may be corroded or rusty.

STEP 3 Operate the pump handle to create a partial vacuum in the catch bottle.

STEP 4 Loosen the bleeder screw approximately one-half turn. Brake fluid and air bubbles will flow into the bottle. When the fluid flow stops, tighten the bleeder screw.

STEP 5 Repeat steps 3 and 4 until no more air bubbles emerge from the bleeder.

STEP 6 Transfer the vacuum bleeder to the bleeder screw of the next wheel cylinder or caliper in the bleeding sequence, and repeat steps 3 and 4. Continue around the vehicle in the specified order until the brakes at all four wheels have been bled.

GRAVITY BLEEDING

Gravity bleeding is a slow, but effective, method that will work on many vehicles to rid the hydraulic system of air. The procedure involves simply opening the bleeder valve and waiting until brake fluid flows from the open valve. Any air trapped in the part being bled will rise and escape from the vent port when the valve is opened. It may take several minutes before brake fluid escapes. Gravity bleeding works because any liquid tends to seek its own level. This means that the brake fluid in the master cylinder tends to flow downward toward the wheel cylinders or calipers. As long as the brake fluid level in the master cylinder is higher than the bleeder valve, the brake fluid will flow downward and out the open bleeder valve, as shown in ● **FIGURE 96–32**.

This flow of brake fluid can even get past the metering valve and proportioning valve. The proportioning valve is normally open to the rear brakes until the pressure reaches a predetermined level when it starts to limit increasing pressure to the rear brakes. The metering valve used to control or delay the operation of the front brakes is open to the front wheels until the pressure exceeds 10 to 15 PSI (70 to 100 kPa). Therefore, as long as no one is pushing on the brake pedal, the metering valve remains open to the front wheels and the brake fluid from the master cylinder can easily flow downward through the valve and out the open bleeder valve.

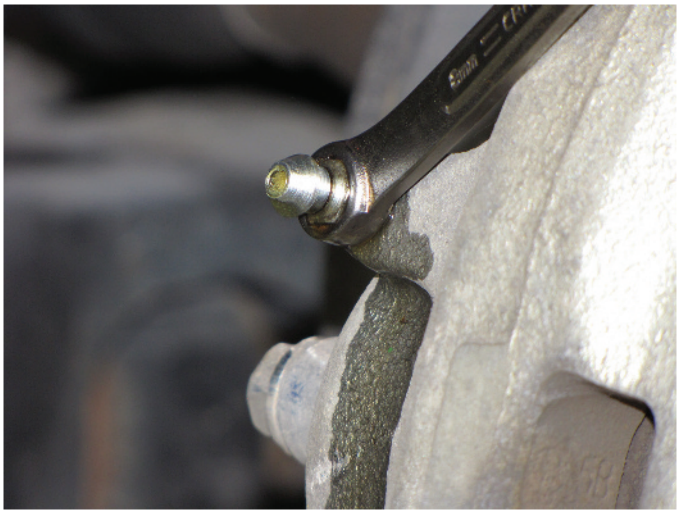

FIGURE 96–32 Gravity bleeding is simply opening the bleeder valve and allowing gravity to force the brake fluid out of the bleeder valve. Because air is lighter than brake fluid, all of the air escapes before the brake fluid runs out.

Since no pressure is exerted on the brake fluid, the large air bubbles remain large air bubbles and are not separated into smaller, harder-to-bleed air bubbles that can occur with manual bleeding.

ADVANTAGES OF GRAVITY BLEEDING All four-wheel brakes can be bled at one time using the gravity method. In this process, the bleeder screws at all four wheels are opened at the same time, and the system is allowed to drain naturally until the fluid coming out of the bleeders is free of air. Gravity bleeding can be done by a single technician, who is freed to attend to other jobs while the brakes bleed.

DISADVANTAGES OF GRAVITY BLEEDING Gravity bleeding is a slow process that can take an hour or more. When other bleeding procedures fail, gravity bleeding can sometimes be effective on brake systems that trap small pockets of air.

GRAVITY BLEEDING PROCEDURE Gravity bleeding requires the following:

- A bleeder wrench
- Four lengths of plastic hose that fit snugly over the bleeder screws
- Four jars to catch the dripping fluid—one for each wheel brake

Unless a plastic hose is used to "start a siphon" at each bleeder screw, it is possible that air may enter the system rather than be bled from it. This can occur because the total open area of the four bleeder screws is somewhat larger than that of the two compensating ports through which the fluid must enter the system. To gravity bleed the brake system, follow these steps:

STEP 1 Fill the master cylinder reservoir with new brake fluid and leave the cap off. During the bleeding process, check the fluid level periodically to ensure that the reservoir remains at least half full.

TECH TIP

The Master Cylinder One-Drip-Per-Second Test

Excessive brake wear is often caused by misadjusted brake linkage or brake light switches keeping the brake pedal from fully releasing. If the brake pedal is not fully released, the primary piston sealing cup blocks the compensating port from the brake fluid reservoir. To test if this is the problem, loosen both lines from the master cylinder. Brake fluid should drip out of both lines about one drip per second. This is why this test is also called the "Master Cylinder Drip Test." If the master cylinder does not drip, the brake pedal may not be allowing the master cylinder to fully release. Have an assistant pull up on the brake pedal. If the dripping starts, the problem is due to a misadjusted brake light or speed (cruise) control switch or pedal stop. If the master cylinder still does not drip, loosen the master cylinder from the power booster. If the master cylinder now starts to drip, the pushrod adjustment is too long.

If the master cylinder still does not drip, the problem is in the master cylinder itself. Check for brake fluid contamination. If mineral oil, such as engine oil, power steering fluid, or automatic transmission fluid (ATF), has been used in the system, the rubber sealing cups swell and can block off the compensating port. If contamination is discovered, *every* brake component that contains rubber *must* be replaced.

STEP 2 Attach a length of plastic tubing to each bleeder screw and place the ends of the tubes in jars to catch the drainage. Open each bleeder screw approximately one full turn and make sure that fluid begins to drain. Allow the system to drain until the fluid flowing from the bleeder screws is free of air bubbles. If no brake fluid comes out, remove the bleeder valve entirely—it may be clogged. Nothing but air and brake fluid will be *slowly* coming out of the wheel cylinder or caliper when the bleeder valve is removed. *Do not press on the brake pedal with the bleeder valve out while gravity bleeding.*

STEP 3 Close the bleeder screws and top up the fluid level in the master cylinder reservoir and replace the master cylinder reservoir cap.

PRESSURE BLEEDING

Pressure bleeding, sometimes called **power bleeding**, is a common method used to bleed the brake hydraulic system. In this process, a pressure bleeder attached to the master cylinder forces brake fluid through the system under pressure to purge any trapped air. Once the hydraulic system is pressurized, the technician simply opens the bleeder screws in the prescribed order and allows fluid to flow until it is free of air bubbles.

The tools required for pressure bleeding include a plastic hose and fluid catch jar as used in manual bleeding, as well as a pressure bleeder, a source of air pressure to charge the bleeder, and an adapter to attach the pressure bleeder to the master cylinder fluid reservoir. Cast-metal cylinders with integral reservoirs commonly use a flat, plate-type adapter that seals against the same surface as the reservoir cover. ● **SEE FIGURE 96–33**.

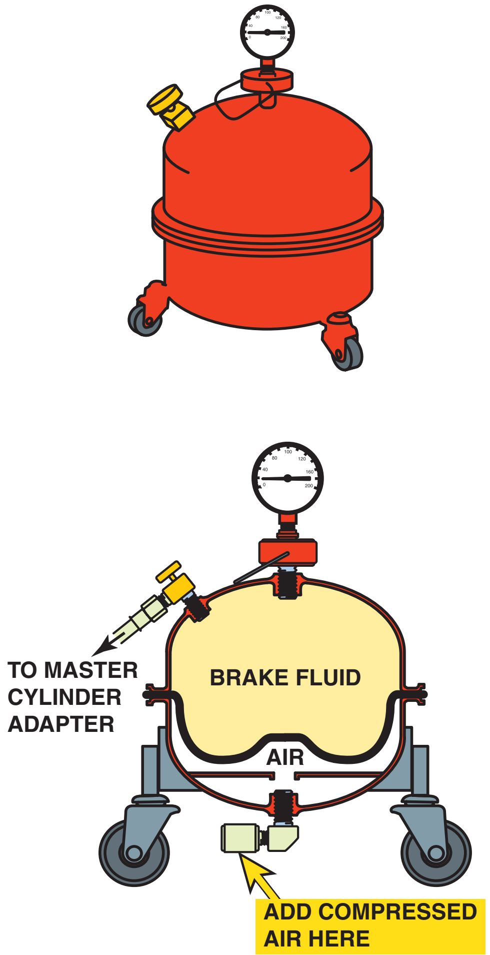

FIGURE 96–33 A typical pressure bleeder. The brake fluid inside is pressurized with air pressure in the air chamber. This air pressure is applied to the brake fluid in the upper section. A rubber diaphragm separates the air from the brake fluid.

Some plastic master cylinder reservoirs also use plate-type adapters, but others require adapters that seal against the bottom of the reservoir. ● **SEE FIGURE 96–34**. Pressure bleeder manufacturers offer many adapters to fit specific applications.

METERING VALVE OVERRIDE TOOLS In addition to the tools previously described, a metering valve override tool is required when pressure bleeding the front brakes of certain vehicles. The override tool is used to deactivate the metering valve because the operating pressure of power bleeders is within the range where the metering valve blocks fluid flow to the front brakes. Metering valves that require an override tool have a stem or button on one end that is either pushed in or pulled out to hold the valve open. The override tool performs this service.

To install the override tool used on General Motors vehicles, loosen the combination valve mounting bolt and slip the slot in the tool under the bolt head.

Push the end of the tool toward the valve body until it depresses the valve plunger, then tighten the mounting bolt to hold the tool in place.

Some full-size Ford vehicles have a metering valve with a stem that must be pushed in to bleed the front brakes, but Ford does not offer a special tool for this purpose. An assistant is needed to override the valve when the front brakes are being bled.

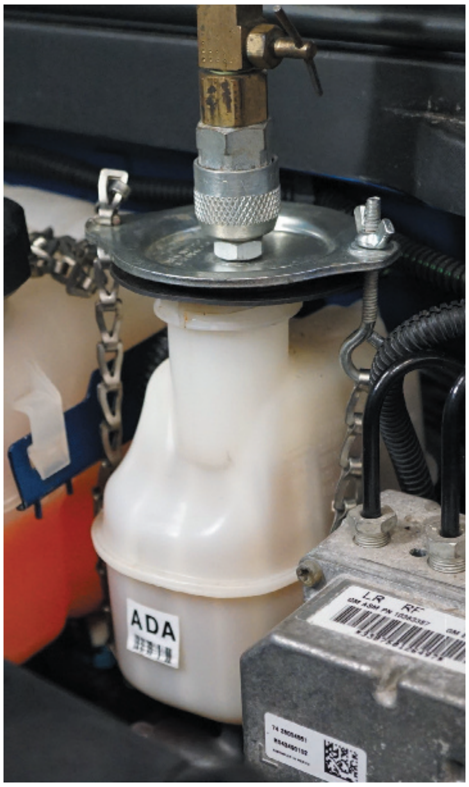

FIGURE 96–34 Brake fluid under pressure from the power bleeder is applied to the top of the master cylinder. It is very important that the proper adapter be used for the master cylinder. Failure to use the correct adapter or failure to release the pressure on the brake fluid before removing the adapter can cause fluid to escape under pressure.

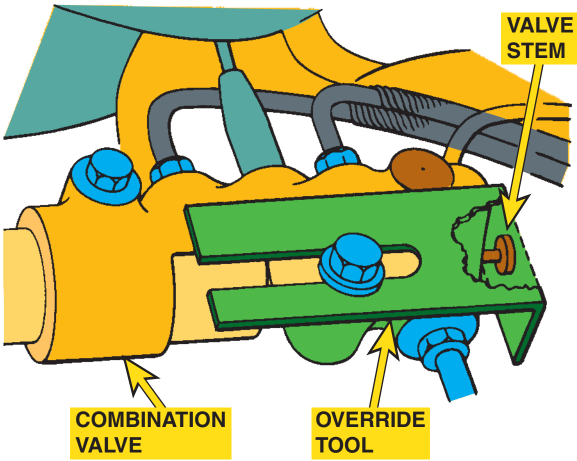

FIGURE 96–35 Metering valve override tool on a General Motors vehicle.

To install the override tool used on older Chrysler and Ford vehicles, slip one fork of the tool under the rubber boot and the other fork under the valve stem head. ● **SEE FIGURE 96–35**.

The spring tension of the tool holds the valve open, but allows the valve stem to move slightly when the system is pressurized. If the valve is held rigidly open, internal damage will result.

PRESSURE BLEEDING PROCEDURE Just as in manual bleeding, it is important to follow the proper sequence when pressure bleeding a brake system. Some manufacturers recommend one sequence for manual bleeding and another for pressure bleeding. To pressure bleed a brake system, follow these steps:

STEP 1 If it has not already been done, consult the equipment manufacturer's instructions and fill the pressure bleeder with the proper type of brake fluid.

STEP 2 Make sure the bleeder is properly sealed and the fluid supply valve is closed, then use compressed air to pressurize the bleeder until approximately 30 PSI (207 kPa) is indicated on the bleeder gauge.

STEP 3 If the vehicle is equipped with a metering valve, override it with the appropriate tool. ● **SEE FIGURE 96–36**.

STEP 4 Clean the top of the master cylinder, then remove the master cylinder cover and clean around the gasket surface. Be careful not to allow any dirt to fall into the reservoir.

STEP 5 Fill the reservoir about half full with new brake fluid, then install the proper pressure bleeder adapter on the master cylinder.

STEP 6 Connect the pressure bleeder fluid supply hose to the adapter, making sure the hose fitting is securely engaged.

STEP 7 Open the fluid supply valve on the pressure bleeder to allow pressurized brake fluid to enter the system. Check carefully for fluid leaks that can damage the vehicle finish.

STEP 8 Slip the plastic hose over the bleeder screw of the first wheel cylinder or caliper to be bled, and submerge the end of the tube in the jar of brake fluid.

STEP 9 Open the bleeder screw approximately one-half turn, and let the fluid run until air bubbles no longer emerge from the tube. Close the bleeder screw.

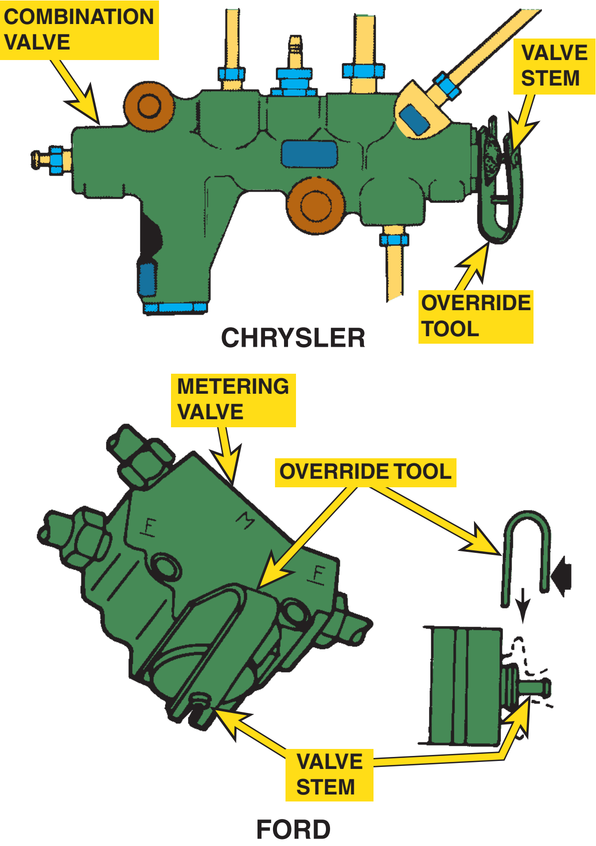

FIGURE 96–36 Pull-out-type metering valves being held out using a special override tool.

STEP 10 Transfer the plastic hose to the bleeder screw of the next wheel cylinder or caliper in the bleeding sequence, and repeat steps 8 and 9. Continue around the vehicle in the specified order until the brakes at all four wheels have been bled.

STEP 11 Remove the metering valve override tool.

STEP 12 Close the fluid supply valve on the pressure bleeder.

STEP 13 Wrap the end of the fluid supply hose in a shop towel, and disconnect it from the master cylinder adapter. Be careful to avoid spilling brake fluid.

STEP 14 Remove the master cylinder adapter, adjust the fluid level to the full point, and install the fluid reservoir cover.

HYDRAULIC ABS SERVICE

CHECK SERVICE INFORMATION Before doing any brake work on a vehicle equipped with antilock brakes, always consult the appropriate service information for the exact vehicle being serviced. For example, some manufacturers recommend discharging the hydraulic accumulator by depressing the brake pedal many times before opening bleeder valves. Many service checks require that a pressure gauge be installed in the system.

BLEEDING THE ELECTRONIC-HYDRAULIC ASSEMBLY Air can easily get trapped in the ABS electronic-hydraulic (E-H) assembly whenever the hydraulic system is opened. Even though the master cylinder and all four wheel cylinders/calipers have been bled, sometimes the brake pedal will still feel spongy. Some E-H units can be bled through the use of a scan tool where the valves are pulsed in sequence by the electronic brake controller (computer). Some units are equipped with bleeder valves while others must be bled by loosening the brake lines. Bleeding the E-H unit also purges out the older brake fluid, which can cause rust and corrosion damage. Only DOT 3 brake fluid is specified for use in an antilock brake system. Always check the label on the brake fluid reservoir and/or service manual or owner's manual.

CAUTION: Some ABS units require that the brake pedal be depressed as many as 40 times to discharge brake fluid fully from the accumulator. Failure to discharge the accumulator fully can show that the brake fluid level is too low. If additional brake fluid is added, the fluid could overflow the reservoir during an ABS stop when the accumulator discharges brake fluid back into the reservoir.

MANUALLY BLEEDING ABS WHEEL BRAKES During routine brake service, attempt to keep the air from entering the hydraulic system by doing the following:

1. Do not allow the brake system to run dry. Use a brake pedal depressor or plug any open brake line to keep brake fluid from flowing out of the brake master cylinder reservoir.
2. Do not allow the master cylinder to run dry during the bleeding operation. Check the master cylinder reservoir often and keep it filled with fresh brake fluid from a sealed container.
3. Always bench bleed a replacement master cylinder to help prevent against introducing air into the hydraulic system.

After depressing the unit as per manufacturer's recommended procedures, the brakes can be bled using the same procedure as for a vehicle without ABS. Air trapped in the ABS hydraulic unit may require that a scan tool be used to cycle the valves. ● **SEE FIGURES 96–37 AND 96–38.**

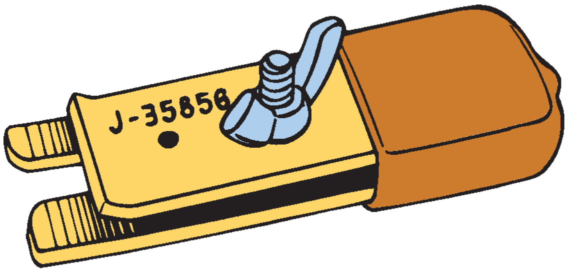

FIGURE 96–37 Special bleed valve tools are often required when bleeding some ABS units such as the Kelsey-Hayes. 4WAL system.

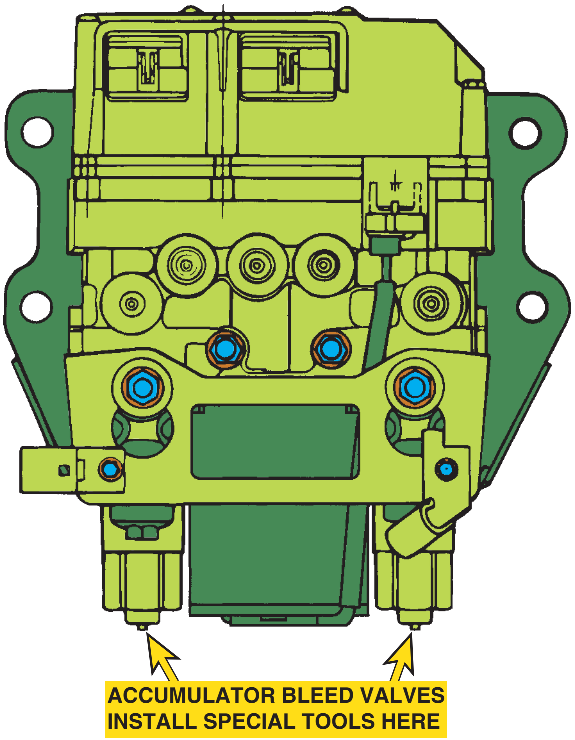

FIGURE 96–38 Two bleed valve tools are needed to bleed the Kelsey-Hayes 4WAL system, which attaches to the bleeder valves on the accumulator.

The bleeding procedure for vehicles equipped with antilock brakes is often different than vehicles without ABS. Consult the service information for the specified bleeding procedure and sequence.

SCAN TOOL BLEEDING To bleed the system using a scan tool, use the following steps:

STEP 1 Check service information and determine the specified procedure to follow. This usually involves manually bleeding the wheel brakes before using a scan tool.

STEP 2 Use a factory scan tool or one that is capable of performing an automated bleed procedure.

STEP 3 Connect the scan tool to the data link connector (DLC). This connector can be located under the dash or in the center console or even covered by a panel. Check service information for the exact location of the DLC for the vehicle being serviced. ● **SEE FIGURE 96–39.**

STEP 4 Enter vehicle information as shown on the display of the scan tool and locate the antilock brake system (ABS) function area. ● **SEE FIGURE 96–40.**

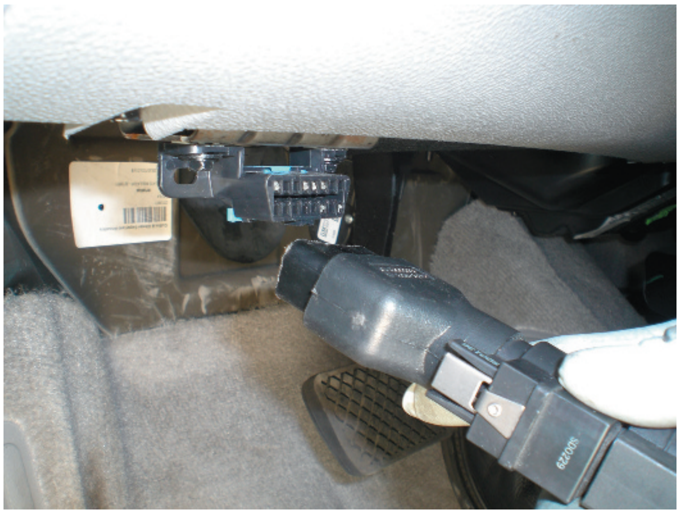

FIGURE 96–39 To perform an automated brake bleed procedure on an antilock brake system (ABS), first connect a factory or enhanced scan tool to the data link connector (DLC) located under the dash on this vehicle.

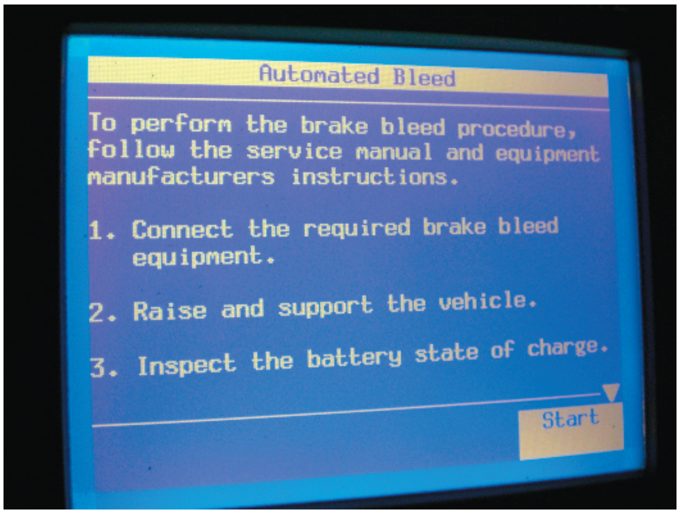
FIGURE 96–40 Access the menu that includes antilock brake system (ABS) functions.

STEP 5 Select ABS automated bleed from the ABS menu. The instructions on the scan tool could include several steps including manually bleeding the system, then allowing the scan tool to cycle the hydraulic ABS solenoid valves and then bleeding again. ● **SEE FIGURE 96–41**.

TECH TIP

ABS Bleeding Made Easy

To avoid having to bleed the hydraulic unit, use a brake pedal depressor during brake service to avoid losing brake fluid. This simple precaution keeps air from getting into the hard-to-bleed passages of the hydraulic unit.



Automated Bleed

To perform the brake bleed procedure, follow the service manual and equipment manufacturers instructions.

1. Connect the required brake bleed equipment.
2. Raise and support the vehicle.
3. Inspect the battery state of charge.

FIGURE 96–41 Scroll through the menus and select automated bleed procedure and follow the on-screen instructions.

BRAKE FLUID REPLACEMENT/FLUSHING

Brake fluid flushing is a procedure where the old brake fluid is removed and new brake fluid is added to the hydraulic system.

FLUSHING PROCEDURE The brake fluid flushing procedure usually requires the following:

- An assistant to pump the brake pedal
- A bleeder screw wrench
- Approximately 2 feet of clear, plastic hose with an inside diameter small enough to fit snugly over the bleeder screw
- A jar partially filled with clean brake fluid

To flush a brake system, use the following steps:

STEP 1 Using a turkey baster or similar tool, remove the old brake fluid from the master cylinder reservoir. ● **SEE FIGURE 96–42**.

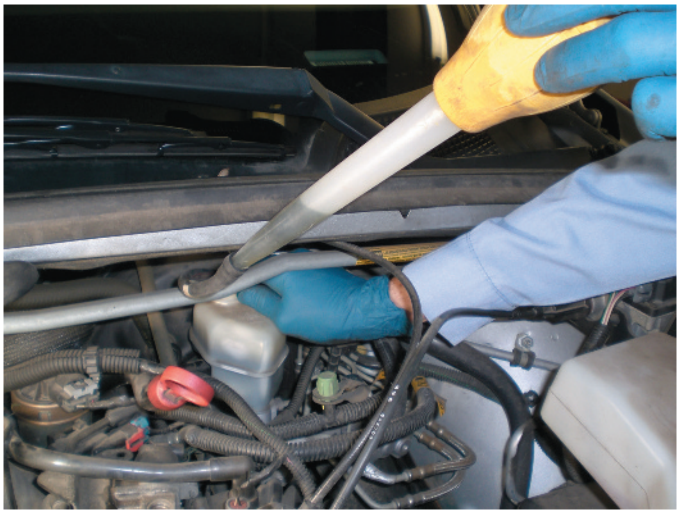


FIGURE 96–42 A turkey baster can be used to remove the old brake fluid from the master cylinder reservoir. A rubber hose was attached to the end of the turkey baster to get access to the brake fluid.

TECH TIP

Block Off the Master Cylinder

Technicians often get frustrated when trying to repair a low or spongy brake pedal. While many times, the cause is due to air trapped somewhere in the brake hydraulic system, the problem could also be due to a fault in some components such the ABS or master cylinder. One method that works is to isolate the system to see what part of the system is causing the problem. For example, if the brake line to the front brakes is blocked off using a plug and the brake pedal is now normal, then the source of the problem has been narrowed to the front brakes components.
● **SEE FIGURE 96–43**.

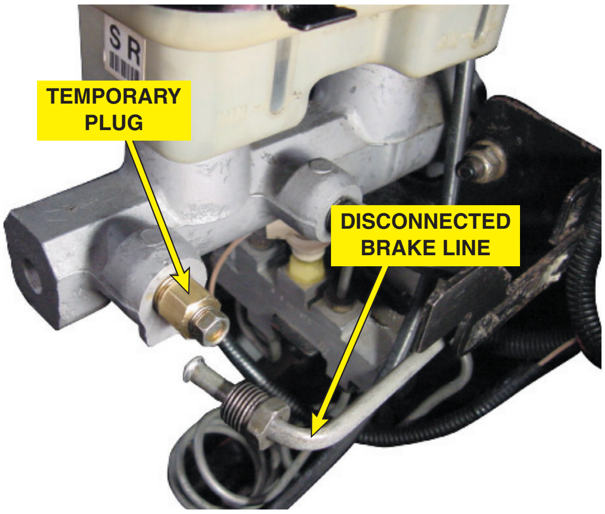

FIGURE 96–43 Using a plug at the outlet of the master cylinder is a common method when diagnosing a low brake pedal complaint.

STEP 2 Fill the master cylinder reservoir with new brake fluid from a sealed container.

STEP 3 Slip the plastic hose over the bleeder screw of the wheel cylinder or caliper to be bled and submerge the end of the tube in the jar of brake fluid.

STEP 4 Open the bleeder screw approximately one-half turn.

STEP 5 With the bleeder screw *open*, have your assistant slowly depress the brake pedal.

STEP 6 While your assistant holds the brake pedal to the floor, close the bleeder screw.

STEP 7 Continue to bleed at each wheel until the fluid that emerges from the bleeder screw is free of any discoloration and contamination.

STEP 8 Repeat steps 4 through 7 at each bleeder screw in the recommended order.

STEP 9 Check the brakes for proper operation and rebleed the system if needed.

REVIEW QUESTIONS

1. What is the difference between DOT 3, DOT 4, DOT 5.1, and DOT 5 brake fluid?
2. What four things should be done during a thorough inspection of the brake fluid?
3. Describe how to bleed the master cylinder.
4. What are the two types of flares used on brake lines?
5. Why are some brake lines coiled?

CHAPTER QUIZ

1. The type of brake fluid most often recommended by vehicle manufacturers is _____________.
   - **a.** DOT 3
   - **b.** DOT 4
   - **c.** DOT 5
   - **d.** DOT 5.1
2. Vacuum is applied where during vacuum bleeding?
   - **a.** At each wheel brake bleeder valve
   - **b.** At the master cylinder reservoir
   - **c.** At the vacuum booster check valve
   - **d.** At the metering valve end of the combination valve
3. The two types of flares used on brake lines are _____________.
   - **a.** SAE and DOT
   - **b.** double flare and ISO
   - **c.** ball flare and bubble flare
   - **d.** SAE and double flare
4. Flexible brake hose should be inspected for all of the following *except* _____________.
   - **a.** cracks
   - **b.** leakage
   - **c.** twisted
   - **d.** worn outer ribs
5. Two technicians are discussing how to loosen bleeder valves. Technician A says that a shock is usually necessary to break the taper at the base of the valve. Technician B says to apply steady, loosening torque to the bleeder valve using a 6-point wrench. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B

6. The brake bleeding procedure usually specified for a rear-wheel-drive vehicle with a front/rear split master cylinder is ______________.

a. RR, LR, RF, LF
b. LF, RF, LR, RR
c. RF, LR, LF, RR
d. LR, RR, LF, RF

7. When bleeding the brakes on a vehicle equipped with an antilock brake system, what is the function of the scan tool?

a. To open the bleeder valves
b. To maintain the fluid level in the reservoir
c. To cycle the solenoids in the ABS unit
d. To turn off the ABS light

8. Air in the brake hydraulic system can cause all of these *except* ______________.

a. a spongy brake pedal
b. a hard brake pedal
c. a lower-than-normal brake pedal
d. it may require the driver to "pump up" the brakes before they will stop the vehicle

9. The usual maximum pressure that should be used when pressure bleeding a brake system is ______________.

a. 20 PSI
b. 30 PSI
c. 50 PSI
d. 70 PSI

10. Technician A says that the brake pedal should be depressed with as much force as possible during the manual bleeding procedure. Technician B says that the brake pedal should be pumped rapidly during the manual bleeding procedure to force the air down toward the bleeder valve(s). Which technician is correct?

a. Technician A only
b. Technician B only
c. Both Technicians A and B
d. Neither Technician A nor B

WHEEL BEARINGS AND SERVICE

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Describe the types of antifriction bearings.
- Discuss bearing greases.
- Discuss types of seals.
- Explain the diagnosis of defective wheel bearings.
- Describe wheel bearing service.
- Describe sealed bearing service.
- Discuss rear drive axle classifications.
- Describe rear axle bearing and seal replacement.
- State the reasons for bearing failure.

KEY TERMS:

Antifriction bearings 1129 • Axial load 1130 • Ball bearings 1130 • Bearing race 1129 • Brinelling 1140 • Cage 1130 • Cone (inner ring) 1130 • Cup (outer ring) 1130 • Dynamic seals 1132 • Garter spring 1132 • GC-LB 1132 • Grease 1131 • Grease seal 1135 • Needle rollers 1130 • National Lubricating Grease Institute (NLGI) 1132 • Radial load 1130 • Retainer plate-type axle 1138 • Roller bearings 1130 • Spalling 1140 • Static seal 1132 • Tapered roller bearing 1136

ANTIFRICTION BEARINGS

PURPOSE AND FUNCTION Bearings allow the wheels of a vehicle to rotate and still support the weight of the entire vehicle. **Antifriction bearings** use rolling parts inside the bearing to reduce friction. Four styles of rolling contact bearings include ball, roller, needle, and tapered roller bearings, as shown in ● **FIGURE 97–1**. All four styles convert sliding friction into rolling motion. All of the weight of a vehicle or load on the bearing is transferred through the rolling part. In a ball bearing, the entire load is concentrated into small spots where the ball contacts the *inner and outer race (rings).* ● **SEE FIGURE 97–2**.

PARTS OF A WHEEL BEARING Wheel bearings are constructed using friction-reducing elements such as steel round balls or steel rollers inside of a housing. The parts involved and their names include

Inner race—The inner support that provides the rolling surface for the friction-reducing balls or rollers is called a **bearing race**, also called

- bearing cone
- bearing ring
- bearing cup

This inner race is located on the spindle or drive axle shaft.

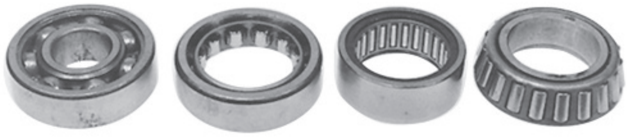

FIGURE 97–1 Rolling contact bearings include (left to right) ball, roller, needle, and tapered roller.

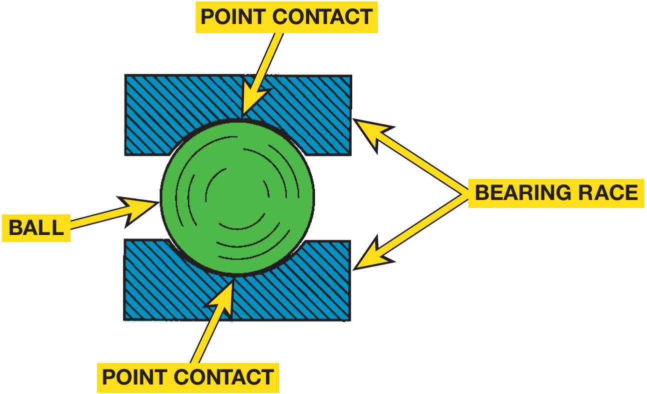

FIGURE 97–2 Ball bearing point contact.

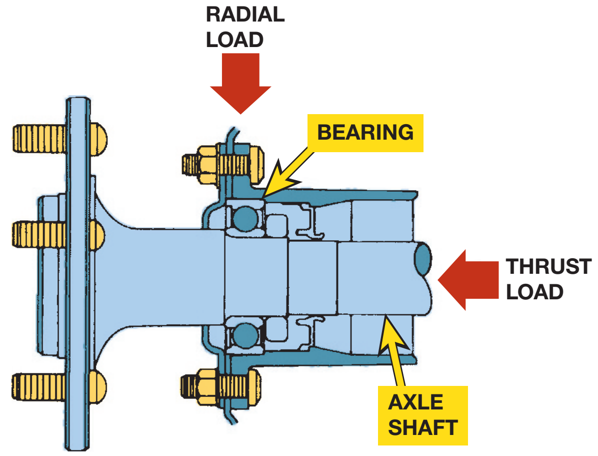

FIGURE 97–3 Radial load is the vehicle weight pressing on the wheels. The thrust load occurs as the chassis components exert a side force during cornering.

Ball bearings or roller bearings—The purpose and function of the steel balls or steel rollers is to reduce the friction of the rotating parts. Roller bearings can be either straight or tapered. These are the antifriction elements inside a bearing assembly.

Outer race—The outer race, also called the cup or cone, supports the steel balls or steel rollers. The outer race is pressed into the bearing hub or steering knuckle.

BALL BEARINGS

Ball bearings use hardened steel balls between the inner and outer race to reduce friction. While ball bearings cannot support the same weight as roller bearings, there is less friction in ball bearings and they generally operate at higher speeds. ● **SEE FIGURE 97–3**. Ball bearings can control thrust movement of an axle shaft because the balls ride in grooves on the inner and outer races. The groove walls resist lateral movement of the wheel on the spindle. Many front-wheel-drive vehicles use sealed double-row ball bearings as a complete sealed unit and are non-serviceable except as an assembly.

ROLLER BEARINGS

Roller bearings use rollers between the inner and outer race to reduce friction. A roller bearing having a greater (longer) contact area can support heavier loads than a ball bearing. ● **SEE FIGURE 97–4**.

A needle bearing is a type of roller bearing that uses smaller rollers called **needle rollers**. The clearance between the diameter of the straight roller is manufactured into the bearing to provide the proper *radial clearance* and is *not adjustable*.

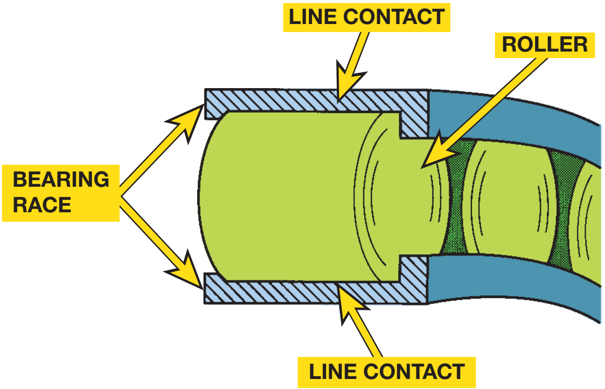

FIGURE 97–4 Roller bearing line contact.

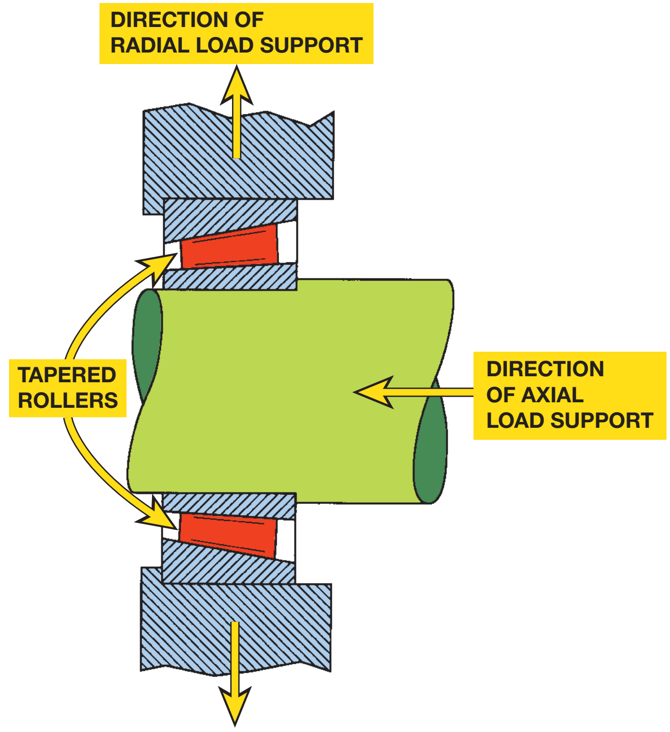

DIRECTION OF RADIAL LOAD SUPPORT
TAPERED ROLLERS
DIRECTION OF AXIAL LOAD SUPPORT

FIGURE 97–5 A tapered roller bearing will support a radial load and an axial load in only one direction.

TAPERED ROLLER BEARINGS

The most commonly used automotive wheel bearing is the **tapered roller bearing**. Not only is the bearing itself tapered, but the rollers are also tapered. By design, this type of bearing can withstand **radial loads** (up and down) as well as **axial loads** (thrust) in one direction. ● **SEE FIGURE 97–5**.

Many non-drive-wheel bearings use tapered roller bearings. The taper allows more weight to be handled by the friction-reducing bearings because the weight is directed over the entire length of each roller rather than concentrated on a small spot, as with ball bearings. The rollers are held in place by a **cage** between the inner race (also called the **inner ring or cone**) and the outer race (also called the **outer ring or cup**). Tapered roller bearings must be loose in the cage to allow for heat expansion. Tapered roller bearings should always be adjusted for a certain amount of free play to allow for heat expansion. ● **SEE FIGURE 97–6**.

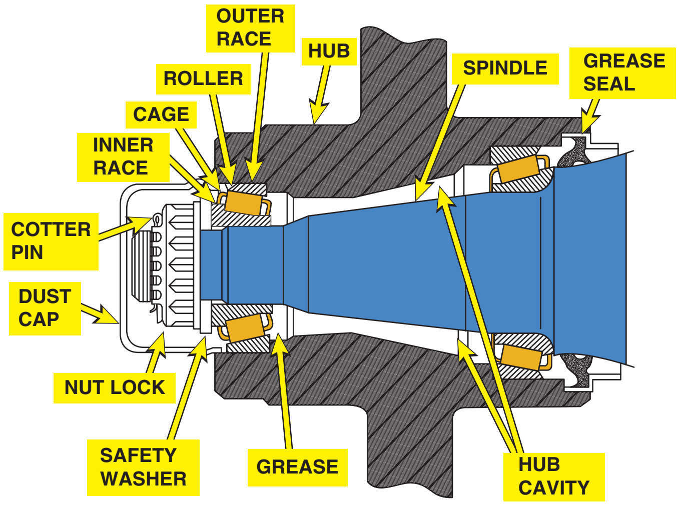

FIGURE 97–6 A cross-sectional view of a typical front wheel bearing showing the larger tapered roller bearing with grease seal on the right and the smaller outer tapered roller bearing on the left.

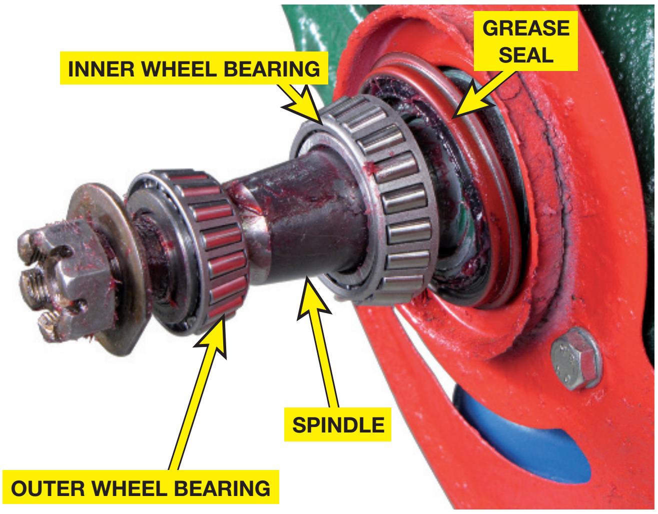

FIGURE 97–7 Non-drive-wheel hub with inner and outer tapered roller bearings. By angling the inner and outer in opposite directions, axial (thrust) loads are supported in both directions.

INNER AND OUTER WHEEL BEARINGS Many rear-wheel-drive vehicles use an inner and an outer wheel bearing on the front wheels. The inner wheel bearing is always the larger bearing because it is designed to carry most of the vehicle weight and transmit the weight to the suspension through to the spindle. Between the inner wheel bearing and the spindle, there is a grease seal, which prevents grease from getting onto the braking surface and prevents dirt and moisture from entering the bearing. ● **SEE FIGURE 97–7**.

SEALED FRONT-WHEEL-DRIVE BEARINGS Most front-wheel-drive vehicles use a sealed nonadjustable front wheel bearing. This type of bearing can include either two preloaded tapered roller bearings or a double-row ball bearing. This type of sealed bearing is also used on the rear of many front-wheel-drive vehicles.

Double-row ball bearings are often used because of their reduced friction and greater seize resistance. ● **SEE FIGURES 97–8 AND 97–9**.

BEARING GREASES

DEFINITION OF GREASE Vehicle manufacturers specify the type and consistency of grease for each application. The technician should know what these specifications mean. **Grease** is oil with a thickening agent to allow it to be installed in places where a liquid lubricant would not stay. Greases are named for their thickening agent, such as aluminum, barium, calcium, lithium, or sodium.

GREASE ADDITIVES Commonly used additives in grease include the following:

- Antioxidants
- Antiwear agents
- Rust inhibitors
- Extreme pressure (EP) additives such as sulfurized fatty oil or chlorine

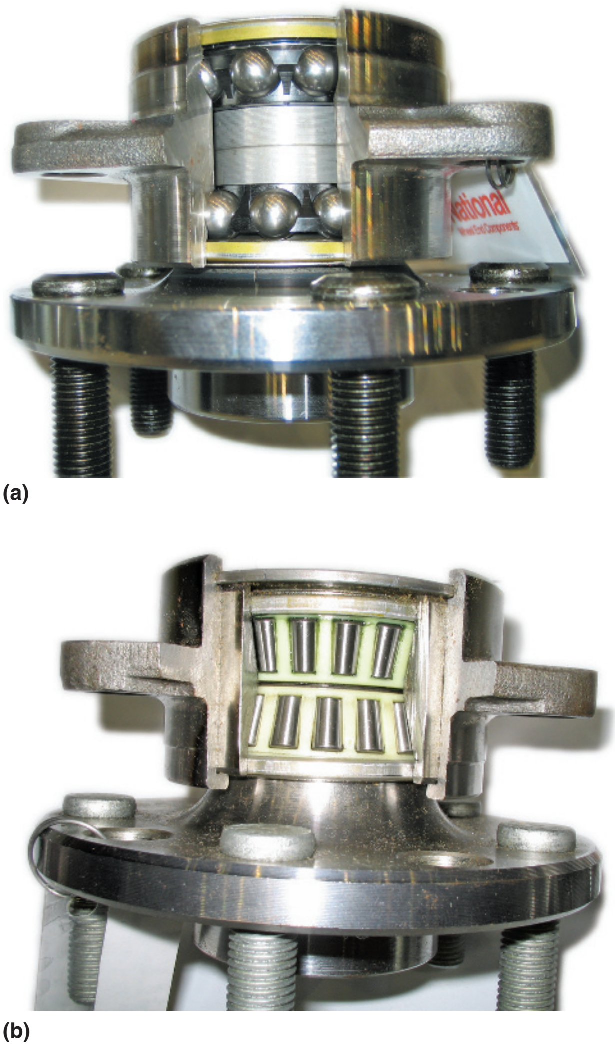

FIGURE 97–8 Sealed bearing and hub assemblies are used on the front and rear wheels of many vehicles. (a) A type using a double row of ball bearings. (b) A type using tapered roller bearings.

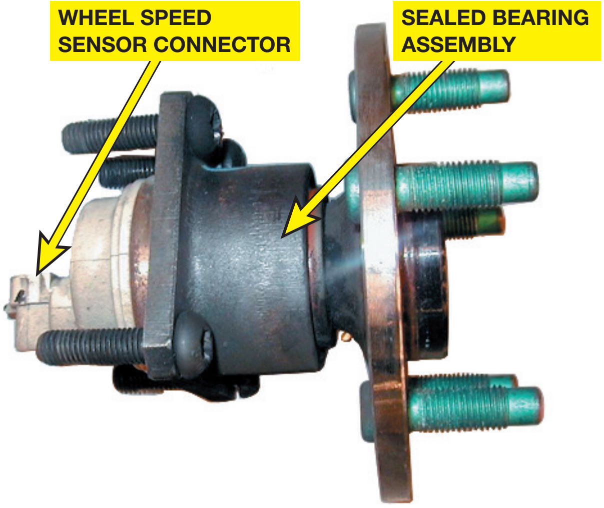

FIGURE 97–9 Sealed bearing and hub assemblies are serviced as a complete unit as shown. This hub assembly includes the wheel speed sensor.

Grease also contains a dye to not only provide product identification, but also give the grease a consistent color.

The grease contains a solid, such as graphite or molybdenum disulfide (moly), which acts as an antiseize additive.

FREQUENTLY ASKED QUESTION

What Do Different Grease Colors Mean?

Nothing. According to grease manufacturers, grease is colored for identification, marketing, and for consistency of color reasons.

- **Identification.** The color is often used to distinguish one type of grease from another within the same company. The blue grease from one company may be totally different from the blue grease produced or marketed by another company.
- **Marketing.** According to grease manufacturers, customers tend to be attracted to a particular color of grease and associate that color with quality.
- **Consistency of color.** All greases are produced in batches, and the color of the finished product often varies from one batch to another. By adding color to the grease, the color can be made consistent.

Always use the grease recommended for the service being performed.

NLGI CLASSIFICATION The **National Lubricating Grease Institute (NLGI)** uses the penetration test as a guide to assign the grease a number. Low numbers are very fluid and higher numbers are more firm or hard. Number 2 grease is the most commonly used. See the chart for other numbers.

Grease is also classified according to quality. Wheel bearing classifications include the following:

- GA—mild duty
- GB—moderate duty
- GC—severe duty, high temperature (frequent stop-and-go service)

GC indicates the highest quality. Chassis grease, such as that used to lubricate steering and suspension components, includes the following classifications:

- LA—mild duty (frequent relubrication)
- LB—high loads (infrequent relubrication)

LB indicates the highest quality. Most multipurpose greases are labeled with both wheel bearing and chassis grease classifications, such as **GC-LB**.

NATIONAL LUBRICATING GREASE INSTITUTE (NLGI) NUMBERS

NLGI NUMBER	RELATIVE CONSISTENCY
000	Very fluid
00	Fluid
0	Semi-fluid
1	Very soft
2	Soft (typically used for wheel bearings)
3	Semi-firm
4	Firm
5	Very firm
6	Hard

More rolling bearings are destroyed by overlubrication than by underlubrication because the heat generated in the bearings cannot be transferred easily to the air through the excessive grease. The cavity between the inner and out bearings should never be filled beyond one-third to one-half of their grease capacity by volume.

SEALS

PURPOSE AND FUNCTION Seals are used in all vehicles to keep lubricant, such as grease, from leaking out and to prevent dirt, dust, or water from getting into the bearing or lubricant.

TYPES OF SEALS Two general applications of seals are static and dynamic.

- **Static seals** are used between two surfaces that do not move.
- **Dynamic seals** are used to seal between two surfaces that move.

Wheel bearing seals are dynamic-type seals that must seal between rotating axle hubs and the stationary spindles or axle housing. Most dynamic seals use a synthetic rubber lip seal encased in metal. The lip is often held in contact with the moving part with the aid of a **garter spring**, as seen in ● **FIGURE 97–10**. The sealing lip should be installed toward the grease or fluid being contained. ● **SEE FIGURE 97–11**.

BEARING DIAGNOSIS

SYMPTOMS OF A DEFECTIVE BEARING Wheel bearings control the positioning and reduce the rolling resistance of vehicle wheels. Whenever a bearing fails, the wheel may not be kept in position and noise is usually heard. Symptoms of defective wheel bearings include the following:

1. A hum, rumbling, or growling noise that increases with vehicle speed
2. Roughness felt in the steering wheel that changes with the vehicle speed or cornering

SAFETY TIP

Smoking Can Kill You

Some greases contain polymers such as Teflon® that turn to a deadly gas when burned. Always wash your hands thoroughly after handling grease that contains these ingredients before smoking. If some of the grease is on the cigarette paper and is burned, these polymers turn into nitrofluoric acid—a deadly toxin.

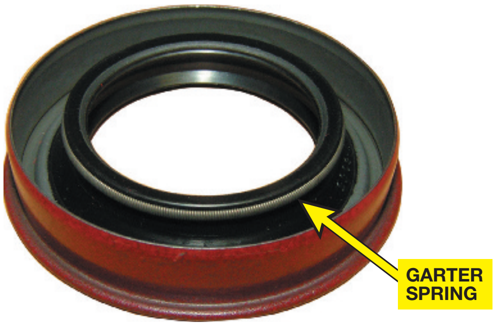

FIGURE 97–10 Typical lip seal with a garter spring.

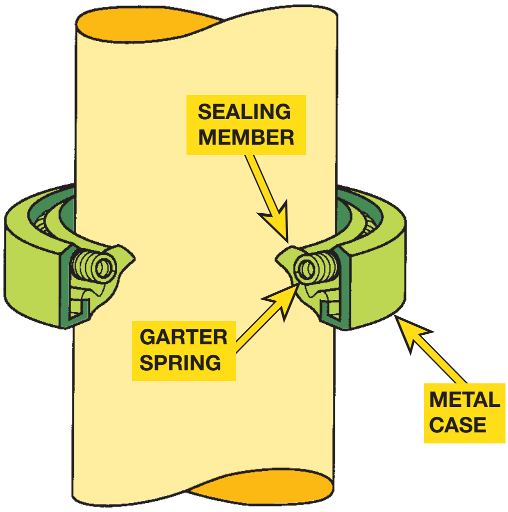

FIGURE 97–11 A garter spring helps hold the sharp lip edge of the seal tight against the shaft.

3. Looseness or excessive play in the steering wheel, especially while driving over rough road surfaces
4. A loud grinding noise in severe cases, indicating a defective front wheel bearing
5. Pulling during braking

DETERMINING BEARING NOISE FROM TIRE NOISE A defective wheel bearing is often difficult to diagnose because the noise is similar to a noisy winter tire or a severely cupped tire. Customers often request that tires be replaced as a result of the noise when the real problem is a bad wheel bearing. To help determine if the noise is caused by a wheel bearing or a tire, try the following tests:

TEST #1	Drive the vehicle over a variety of road surfaces. If the noise changes with a change in road surface, the noise is caused by a tire(s). If the noise remains the same, then the cause is a defective wheel bearing.
TEST #2	Try temporarily overinflating the tires. If the noise changes, then the tires are the cause. If the noise is the same, then defective wheel bearings are the cause.

TECH TIP

Easy Wheel Bearing Looseness Test

Looseness in a front wheel bearing can allow the rotor to move whenever the front wheel hits a bump, forcing the caliper piston in, which causes the brake pedal to kick back and creates the feeling that the brakes are locking up. Loose wheel bearings are easily diagnosed by removing the cover of the master cylinder reservoir and watching the brake fluid as the front wheels are turned left and right with the steering wheel. If the brake fluid moves while the front wheels are being turned, caliper piston(s) are moving in and out, caused by loose wheel bearing(s). If everything is OK, the brake fluid should not move. Loose wheel bearings can also cause the brake pedal to sink due to movement of the rotor, causing the caliper piston to move. This sinking brake pedal is usually caused by a defective master cylinder. Before replacing a master cylinder, check the wheel bearings.

TESTING A WHEEL BEARING With the vehicle off the ground, rotate the wheel by hand, listening and feeling carefully for bearing roughness. Grasp the wheel at the top and bottom and wiggle it back and forth, checking for bearing looseness.

WHEEL BEARING SERVICE

The steps in a non-drive-wheel bearing inspection include the following:

1. Hoist the vehicle safely.
2. Remove the wheel.
3. Remove the brake caliper assembly and support it with a coat hanger or other suitable hook to avoid allowing the caliper to hang by the brake hose.
4. Remove the grease cap (dust cap). ● **SEE FIGURE 97–12**.
5. Remove the old cotter key and discard.

NOTE: The term *cotter*, as in cotter key or cotter pin, is derived from the Old English verb meaning "to close or fasten."

6. Remove the spindle nut (castle nut).
7. Remove the washer and the outer wheel bearing.
8. Remove the bearing hub from the spindle. The inner bearing will remain in the hub and may be removed (simply lifted out) after the grease seal is pried out. ● **SEE FIGURE 97–13**.
9. Most vehicle and bearing manufacturers recommend cleaning the bearing thoroughly in solvent or acetone. ● **SEE FIGURE 97–14**. If there is no acetone, clean the solvent off the bearings with denatured alcohol or brake cleaner to make certain that the thin solvent layer is completely washed off and dry. *All solvent must be removed or allowed to dry from the bearing because the new grease will not stick to a layer of solvent.*

CAUTION: Never use compressed air to spin a bearing because the bearing can be damaged.

SMEARING
SMEARED METAL FROM SLIPPAGE CAUSED BY POOR FIT, POOR LUBRICATION, OVERLOADING, OVERHEATING, OR HANDLING DAMAGE
FRETTAGE
ETCHING OR CORROSION CAUSED BY SMALL RELATIVE MOVEMENTS BETWEEN PARTS WITH NO LUBRICATION

CHART 97–1

Wheel bearing inspection chart. Replace the bearing if it has any of the faults shown.

10. Carefully inspect the bearings and the races for the following:

a. The outer race for lines, scratches, or pits.

b. The cage should be round. If the round cage has straight sections, this is an indication of an overtightened adjustment or a dropped cage. ● **SEE CHART 97–1**.

If either of the above is observed, then the bearing, including the outer race, must be replaced. Failure to replace the outer race (which is included when purchasing a bearing) could lead to rapid failure of the new bearing. ● **SEE FIGURES 97–15 AND 97–16**.

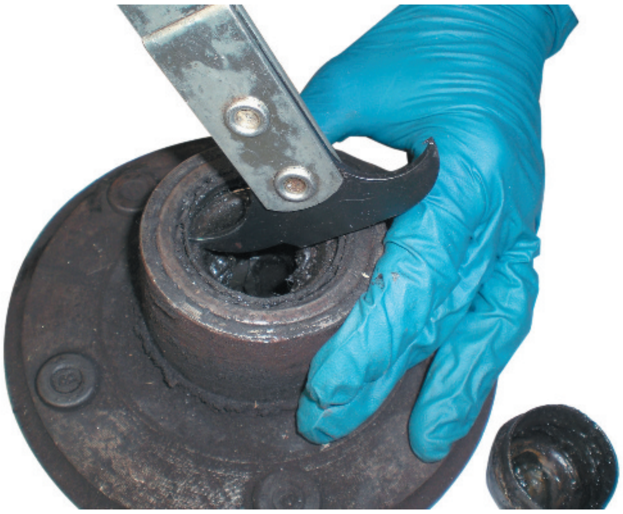

FIGURE 97–13 Using a seal puller to remove the grease seal.

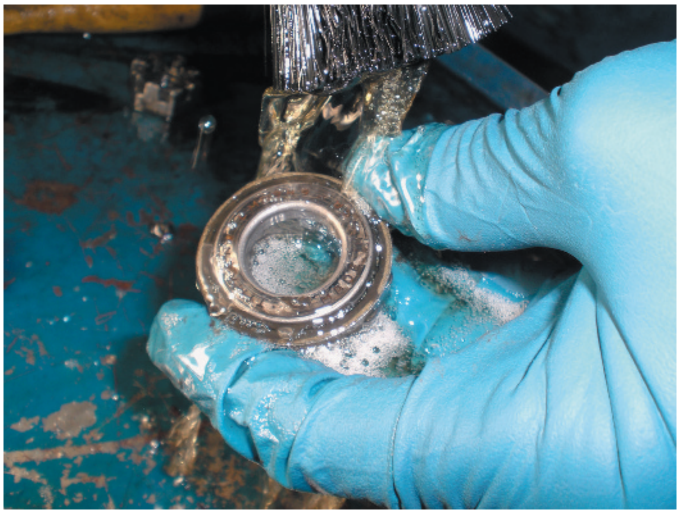

FIGURE 97–14 Cleaning a wheel bearing with a parts brush and solvent.

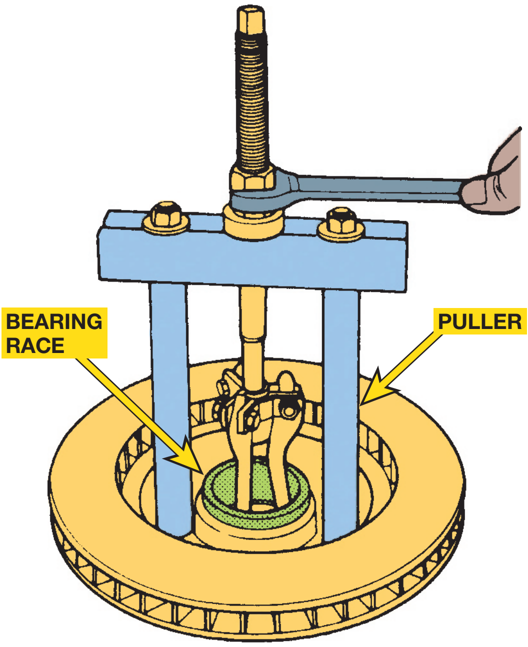

FIGURE 97–15 A wheel bearing race puller.

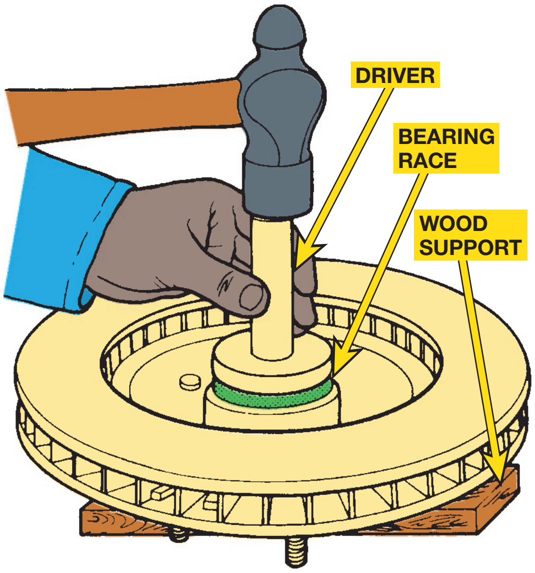

FIGURE 97–16 Installing a bearing race with a driver.

11. Pack the cleaned or new bearing thoroughly with clean, new, approved wheel bearing grease. Always clean out all of the old grease before applying the recommended type of new grease. *Because of compatibility problems, it is not recommended that greases be mixed*. There are several different ways to pack wheel bearings including
    - **By hand.** Place some grease in the palm of the hand and then force the grease through the bearing until grease can be seen out the other side. ● **SEE FIGURE 97–17**.
    - **Hand-operated bearing packer.** A hand-operated bearing packer is faster to use and produces excellent results. ● **SEE FIGURE 97–18**.
    - **Grease gun-type bearing packer.** This type of bearing packer uses a grease gun to fill the bearing with grease. The grease gun can be hand-operated or powered by electric or air. ● **SEE FIGURE 97–19**.
12. Place a thin layer of grease on the outer race.
13. Apply a thin layer of grease to the spindle, being sure to cover the outer bearing seat, inner bearing seat, and shoulder at the grease seal seat.
14. Install a new **grease seal** (also called a *grease retainer*) flush with the hub using a seal driver.

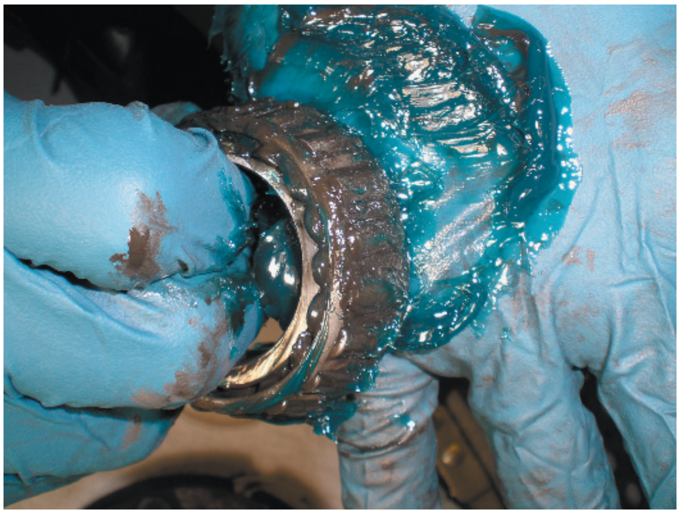

FIGURE 97–17 Notice the new blue grease has been forced through the bearing.

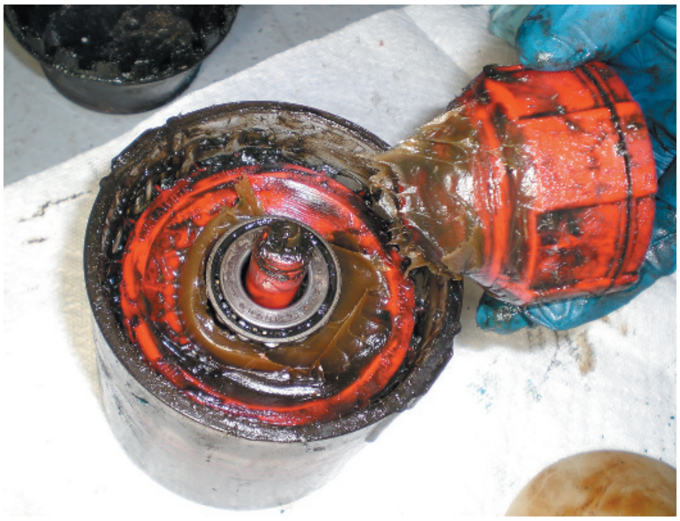

FIGURE 97–18 A commonly used hand-operated bearing packer.

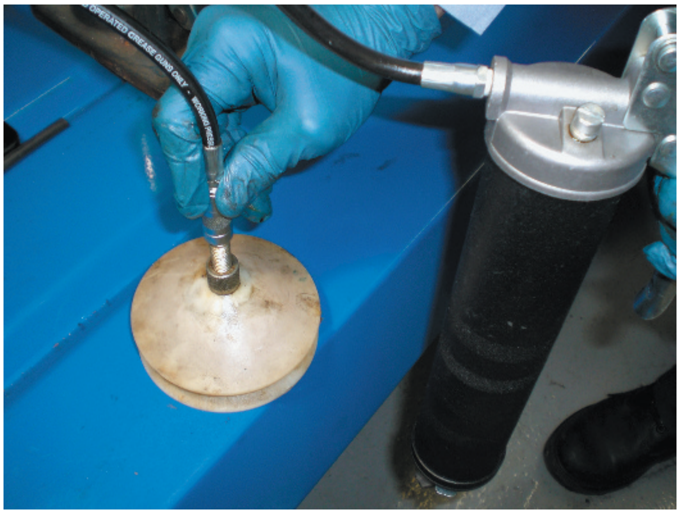

FIGURE 97–19 The wheel bearing is placed between two nylon cones and then a grease gun is used to inject grease into the center of the bearing.

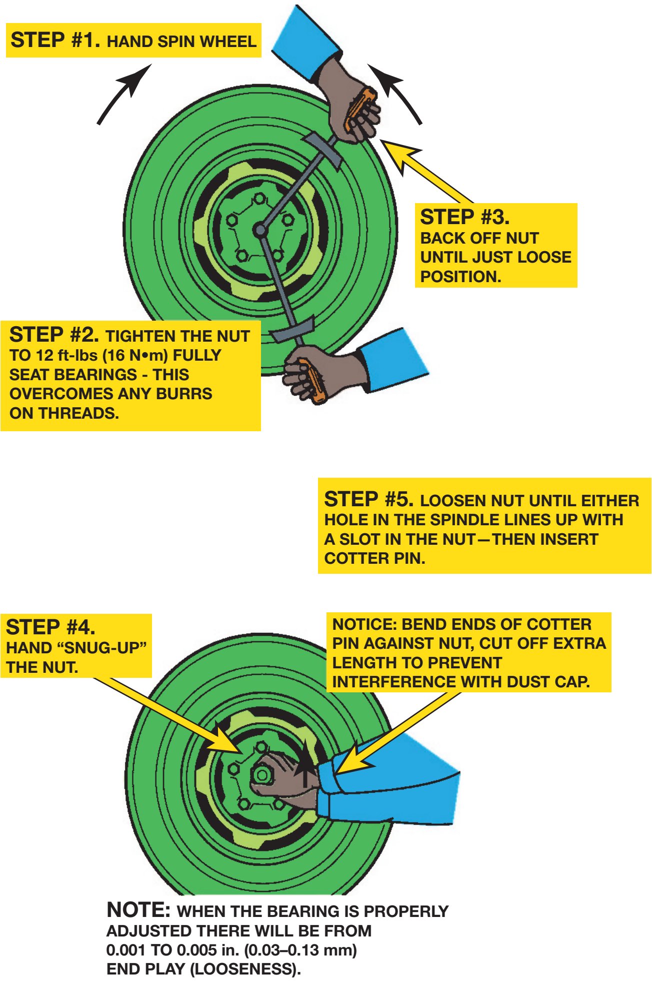
15. Place approximately three tablespoons of grease into the grease cavity of the wheel hub. Excessive grease could cause the inner grease seal to fail, with the possibility of grease getting on the brakes. Place the rotor with the inner bearing and seal in place over the spindle until the grease seal rests on the grease seal shoulder.
16. Install the outer bearing and the bearing washer.
17. Install the spindle nut and, while rotating the tire assembly, tighten to about 12 to 30 lb-ft with a wrench to “seat” the bearing correctly in the race (cup) and on the spindle. ● **SEE FIGURE 97–20**.
18. While still rotating the tire assembly, loosen the nut approximately one-half turn and then *hand tighten only* (about 5 lb-in.).

NOTE: If the wheel bearing is properly adjusted, the wheel will still have about 0.001–0.005 inch (0.03 to 0.13 mm) end play. To check for proper clearance, grasp the wheel at the top and bottom and check for a slight looseness. This looseness is necessary to allow the tapered roller bearing to expand when hot and not bind or cause the wheel to lock up.



STEP #1. HAND SPIN WHEEL
STEP #3. BACK OFF NUT UNTIL JUST LOOSE POSITION.
STEP #2. TIGHTEN THE NUT TO 12 ft-lbs (16 N•m) FULLY SEAT BEARINGS - THIS OVERCOMES ANY BURRS ON THREADS.
STEP #5. LOOSEN NUT UNTIL EITHER HOLE IN THE SPINDLE LINES UP WITH A SLOT IN THE NUT—THEN INSERT COTTER PIN.
STEP #4. HAND “SNUG-UP” THE NUT.
NOTICE: BEND ENDS OF COTTER PIN AGAINST NUT, CUT OFF EXTRA LENGTH TO PREVENT INTERFERENCE WITH DUST CAP.
NOTE: WHEN THE BEARING IS PROPERLY ADJUSTED THERE WILL BE FROM 0.001 TO 0.005 in. (0.03–0.13 mm) END PLAY (LOOSENESS).

FIGURE 97–20 The front wheel bearing adjustment procedure as specified for rear-wheel-drive vehicles. Always check service information for the specified procedure to follow.

19. Install a new cotter key. (An old cotter key could break a part off where it was bent and lodge in the bearing, causing major damage.)

NOTE: Most vehicles use a cotter key that is 1/8 inch in diameter by 1 1/2 inch long.

20. If the cotter key does not line up with the hole in the spindle, loosen slightly (no more than 1/16 in. of a turn) until the hole lines up. Never tighten more than hand tight.
21. Bending the cotter key ends up and around the nut, not over the end of the spindle where the end of the cotter key could rub on the grease cap, causing noise. ● **SEE FIGURE 97–21**.
22. Install the grease cap (dust cap) using a seal driver that applies force to the outside edge of the seal to prevent denting the grease cap. Install the wheel cover or hub cap.
23. Clean grease off the disc brake rotors or drums after servicing the wheel bearings. Use a brake cleaner and a shop cloth. Even a slight amount of grease on the friction surfaces of the brakes can harm the friction lining and/or cause brake noise.

FIGURE 97–21 A properly secured wheel bearing adjust nut.

SEALED BEARING SERVICE

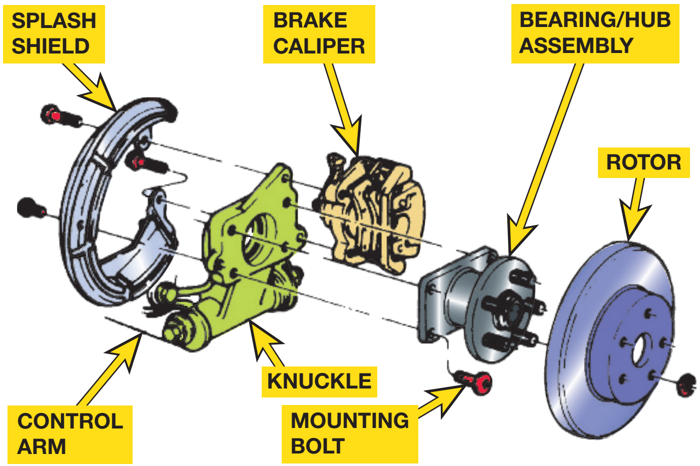
DIAGNOSIS Diagnosing a defective front bearing on a front-wheel-drive vehicle is sometimes confusing. A defective wheel bearing is usually noisy while driving straight, and the noise increases with vehicle speed (wheel speed). A drive axle shaft U-joint (CV joint) can also be the cause of noise on a front-wheel-drive vehicle, but usually makes *more noise* while turning and accelerating. Most front-wheel-drive vehicles use a sealed bearing assembly that is bolted to the steering knuckle and supports the drive axle or the rear, as shown in ● **FIGURE 97–22**.

REPLACEMENT Many front-wheel-drive vehicles use a bearing that must be pressed off the steering knuckle. Special aftermarket tools are also available to remove many of the bearings without removing the knuckle from the vehicle. Check the service information for the exact procedures to follow for the vehicle being serviced. ● **SEE FIGURES 97–23 AND 97–24**.

REAR DRIVE AXLE CLASSIFICATIONS

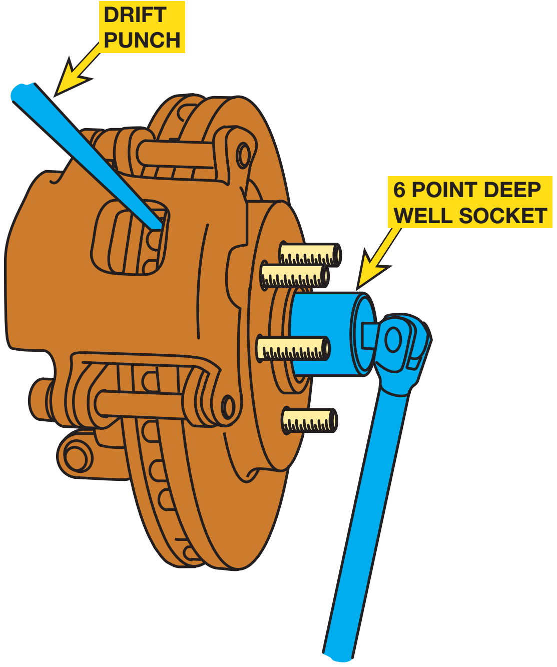
There are three rear drive axle classifications:

- Full-floating
- Three-quarter-floating
- Semi-floating



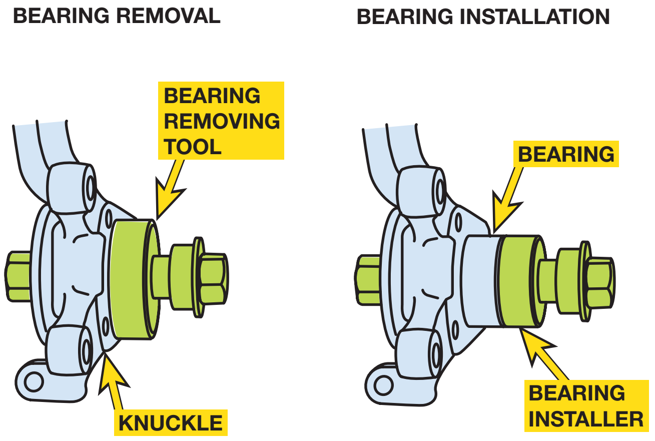
SPLASH SHIELD
BRAKE CALIPER
BEARING/HUB ASSEMBLY
ROTOR
CONTROL ARM
KNUCKLE
MOUNTING BOLT

FIGURE 97–22 A rear wheel sealed bearing hub assembly.



DRIFT PUNCH
6 POINT DEEP WELL SOCKET

FIGURE 97–23 Removing the drive axle shaft hub nut. This nut is usually very tight and the drift (tapered) punch wedged into the cooling fins of the brake rotor keeps the hub from revolving when the nut is loosened. Never use an air impact wrench to loosen or tighten the drive axle shaft nut because the hammering action will damage the bearings.



BEARING REMOVAL
BEARING INSTALLATION
BEARING REMOVING TOOL
KNUCKLE
BEARING
BEARING INSTALLER

FIGURE 97–24 A special puller makes the job of removing the hub bearing from the knuckle easy without damaging any component.

These classifications indicate whether the axle shafts or the axle housing supports the wheel. The category of a rear drive axle is determined by how the wheel and wheel bearing mount to the axle or housing.

FULL-FLOATING AXLE On a full-floating axle, the bearings are mounted and retained in the hub of the brake drum or rotor. The hub and bearing mount onto the axle housing, and are held in place by a bearing retainer or adjustment nuts and safety locks. The flanged end of the drive axle is attached to the hub by bolts or nuts. The inner end of the axle splines into the differential side gears. The wheel mounts onto the hub, and lug bolts or nuts retain it. In this design, the axle shafts "float"

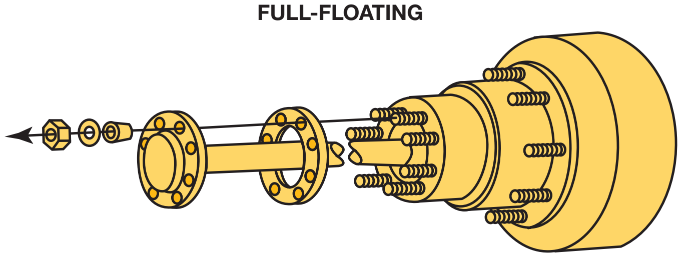


FIGURE 97–25 A typical full-floating rear axle assembly.

in the axle housing and drive the wheels without supporting their weight. Because the axle shafts do not retain the wheel, the axle shafts can usually be removed from the vehicle while it is standing on the wheels. Many three-quarter-ton pickups, all heavy-duty truck tractors, and trailers use full-floating axles. ● **SEE FIGURE 97–25**.

THREE-QUARTER-FLOATING AXLE The bearings in a three-quarter-floating axle are mounted and retained in the brake drum or rotor hub, which mounts onto the axle housing. The outer extension of the hub fits onto the end of the axle, which is usually splined and tapered, and a nut and cotter pin secure the hub to the axle. The axle shaft splines to the side gears inside the differential. The wheels are mounted on the hub and retained by lug bolts or nuts. As in the full-floating axle, the axle housing and bearings in the hub support the weight in a three-quarter-floating axle. Because of the construction of a three-quarter-floating axle, the wheel must be removed before removing the axle shaft from the vehicle. ● **SEE FIGURE 97–26**.

SEMI-FLOATING AXLE The wheel bearings in a semi-floating axle either press onto the axle shaft or are installed in the outer end of the axle housing. A retainer plate at the outer end of the axle shaft or a C-clip inside the differential at the other end keeps the axle shaft in the housing. The brake drum or rotor fits onto the end of the axle, and lug bolts or nuts fasten the wheel to the drum or rotor and to the axle. These axles are called "semi-floating" because only the inboard ends of the axle shaft "float" in the housing. The outboard end of the shaft retains the wheel and transmits the weight of the wheel to the housing. Most solid-axle rear-wheel-drive cars and light trucks use a semi-floating type of axle. ● **SEE FIGURE 97–27**.

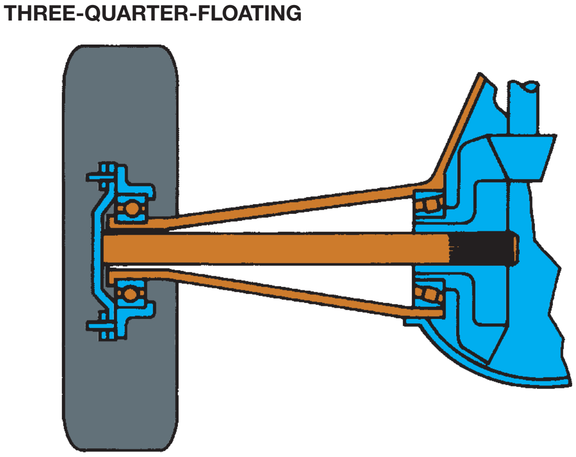

FIGURE 97–26 A three-quarter-floating rear axle.

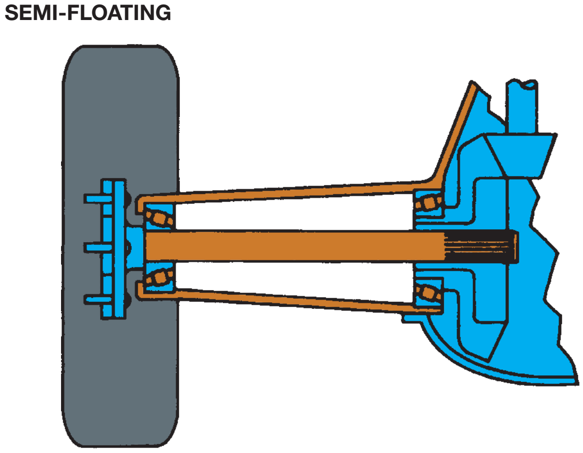

FIGURE 97–27 A semi-floating rear axle housing is the most commonly used in light rear-wheel-drive vehicles.

REAR AXLE BEARING AND SEAL REPLACEMENT

The rear bearings used on rear-wheel-drive vehicles are constructed and serviced differently from other types of wheel bearings. Rear axle bearings are either sealed or lubricated by the rear-end lubricant. The rear axle must be removed from the vehicle to replace the rear axle bearing. There are two basic types of axle retaining methods:

- **Retainer plate-type**
- **C-lock**

RETAINER PLATE-TYPE REAR AXLES The retainer plate-type rear axle uses four fasteners that retain the axle in the axle housing. To remove the axle shaft and the rear axle bearing and seal, the retainer bolts or nuts must be removed.

NOTE: If the axle flange has an access hole, then a retainer plate-type axle is used.

The hole or holes in the wheel flange permit a socket wrench access to the fasteners. After the fasteners have been removed, the axle shaft must be removed from the rear axle housing. With the retainer plate-type rear axle, the bearing and the retaining ring are press fit onto the axle and the bearing cup (outer race) is also tightly fitted into the axle housing tube. ● **SEE FIGURE 97–28**. ● **SEE FIGURE 97–29** for the method to remove the axle shaft using a rear axle puller.

C-LOCK-TYPE AXLES Vehicles that use C-locks (clips) use a straight roller bearing supporting a semi-floating axle shaft

TECH TIP

The Brake Drum Slide Hammer Trick

To remove the axle from a vehicle equipped with a retainer plate-type rear axle, simply use the brake drum as a slide hammer to remove the axle from the axle housing. ● **SEE FIGURE 97–30**. If the brake drum does not provide enough force, a slide hammer can also be used to remove the axle shaft.

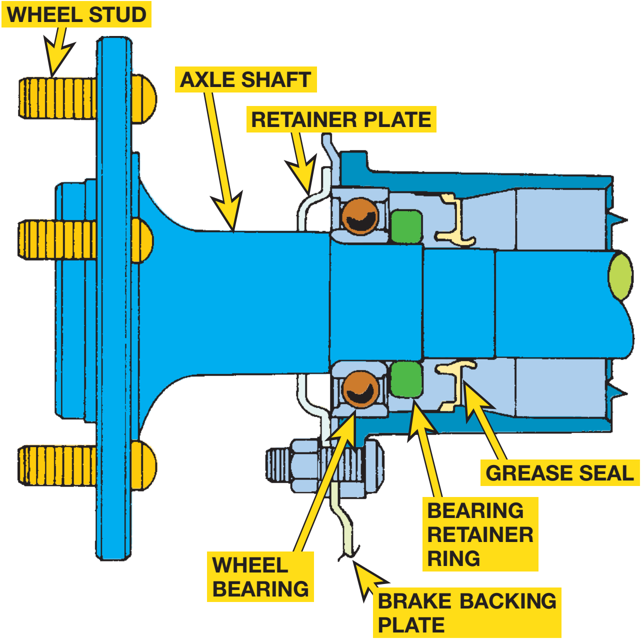

FIGURE 97–28 A retainer plate-type rear axle bearing. Access to the fasteners is through a hole in the axle flange.

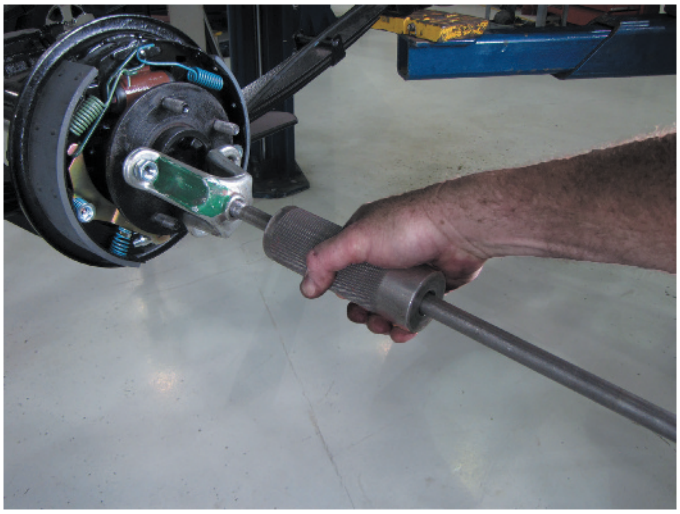

FIGURE 97–29 A slide-hammer-type axle puller can be used to remove an axle.

inside the axle housing. The straight rollers do not have an inner race. The rollers ride on the axle itself. If a bearing fails, both the axle and the bearing usually need to be replaced. The outer bearing race holding the rollers is pressed into the rear axle housing. The axle bearing is usually lubricated by the rear-end lubricant and a grease seal is located on the outside of the bearing.

NOTE: Some replacement bearings are available that are designed to ride on a fresh, unworn section of the old axle. These bearings allow the use of the original axle, saving the cost of a replacement axle.

The C-lock-type rear axle retaining method requires that the differential cover plate be removed. After removal of the cover, the differential pinion shaft has to be removed before the C-lock that retains the axle can be removed. ● **SEE FIGURES 97–31 AND 97–32**.

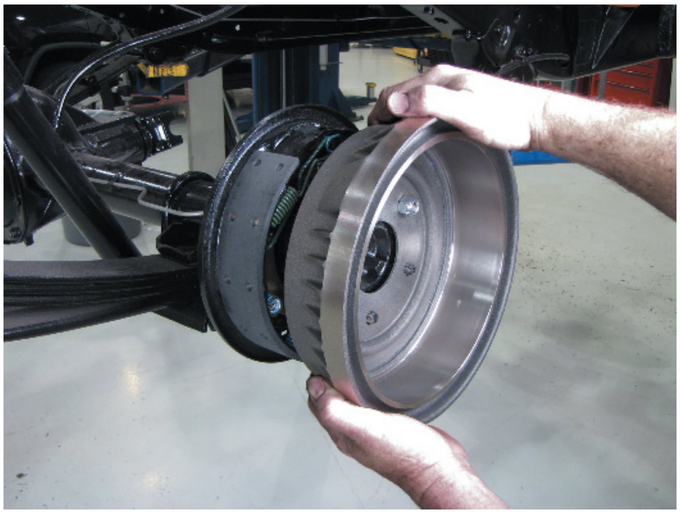

FIGURE 97–30 To remove the axle from this vehicle equipped with a retainer-plate rear axle, the brake drum was placed back onto the axle studs backward so that the drum itself can be used as a slide hammer to pull the axle out of the axle housing. After a couple of pulls, the rear axle is pulled out of the axle housing.

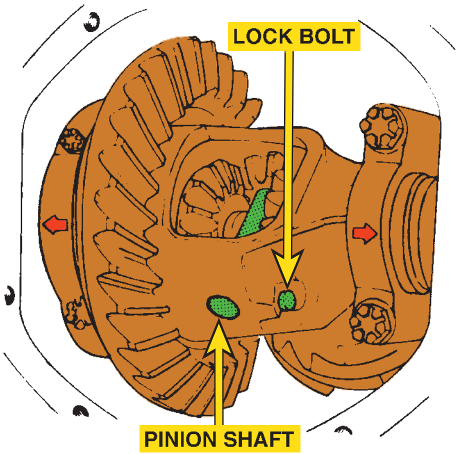

FIGURE 97–31 To remove the C-lock (clip), the lock bolt must be removed before the pinion shaft is taken out.

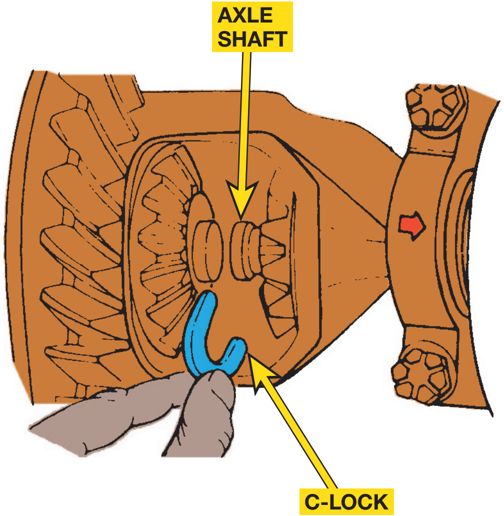

FIGURE 97–32 The axle must be pushed inward slightly to allow the C-lock to be removed. After the C-lock has been removed, the axle can be easily pulled out of the axle housing.

NOTE: When removing the differential cover, rear axle lubricant will flow from between the housing and the cover. Be sure to dispose of the old rear axle lubricant in the environmentally approved way, and refill with the proper type and viscosity (thickness) of rear-end lubricant. Check the vehicle specifications for the recommended grade.

Once the C-lock has been removed, the axle simply is pulled out of the axle tube. Axle bearings with inner races are pressed onto the axle shaft and must be pressed off using a hydraulic press. A bearing retaining collar should be chiseled or drilled into to expand the collar, allowing it to be removed. ● **SEE FIGURE 97–33**.

Always follow the manufacturer's recommended bearing removal and replacement procedures. Always replace the rear axle seal whenever replacing a rear axle bearing. ● **SEE FIGURE 97–34** for an example of seal removal.

All differentials use a vent so make sure it is clear. A clogged vent can cause excessive pressure to build up inside the differential and cause the rear axle seals to leak. If rear-end lubricant gets on the brake linings, the brakes will not have the proper friction and the linings themselves are ruined and must be replaced.

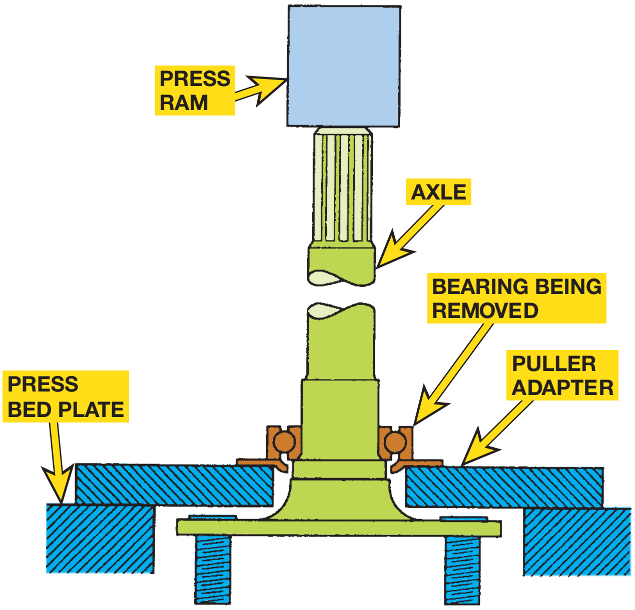

FIGURE 97–33 Using a hydraulic press to press an axle bearing from the axle. When pressing a new bearing back onto the axle, pressure should only be on the inner bearing race to prevent damaging the bearing.

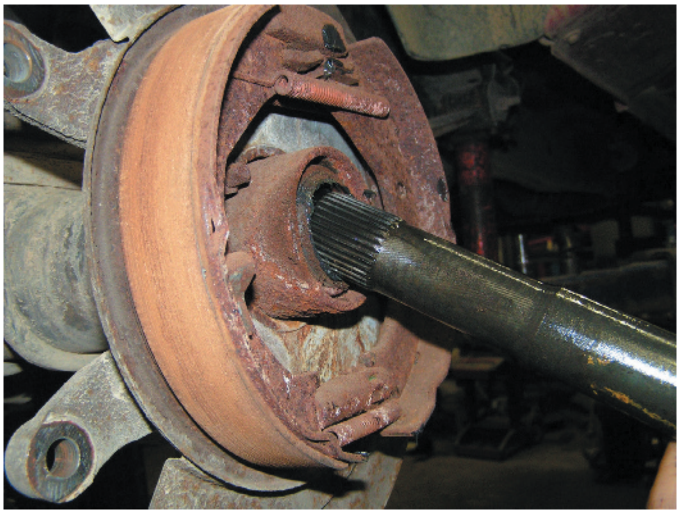

FIGURE 97–34 Removing an axle seal using the axle shaft as the tool. While this procedure is done in some shops, the preferred and specified procedure is to use a seal puller.

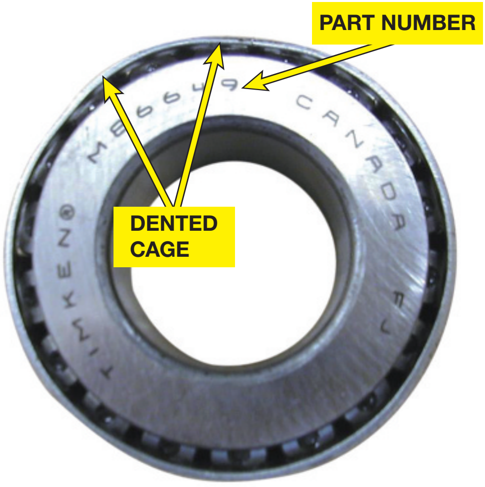

FIGURE 97–35 This bearing has a bent cage and must be replaced.

BEARING FAILURE ANALYSIS

Whenever a bearing is replaced, the old bearing must be inspected and the cause of the failure eliminated. If a bearing has a bent cage, it must be replaced. ● **SEE FIGURE 97–35**.

A wheel bearing may also fail for reasons that include the following:

METAL FATIGUE Long vehicle usage, even under normal driving conditions, causes metal to fatigue. Cracks often appear, and eventually these cracks expand downward into the metal from the surface. The metal between the cracks can break out into small chips, slabs, or scales of metal. This process of breaking up is called **spalling**.

ELECTRICAL ARCING Bearings can be damaged by poor ground wires or improper welding on the vehicle.

SHOCK LOADING Dents can be formed in the race of a bearing, which eventually leads to bearing failure. The indentations are called **brinelling** caused by the impact of loads or vibration when the bearing is not turning. It is named after Johan August Brinell, a Swedish engineer, who created the Brinell scale of hardness.

TECH TIP

Touch the Spring When Checking for Bearing Noise

Wheel bearing noises are often hard to pin down because the noise can be transmitted throughout the vehicle. Whenever diagnosing a possible defective wheel bearing, use one hand to grasp the spring while using the other hand to rotate the wheel. The roughness of a defective wheel bearing is easily detected by feeling a vibration in the coil spring. ● **SEE FIGURE 97–36**.

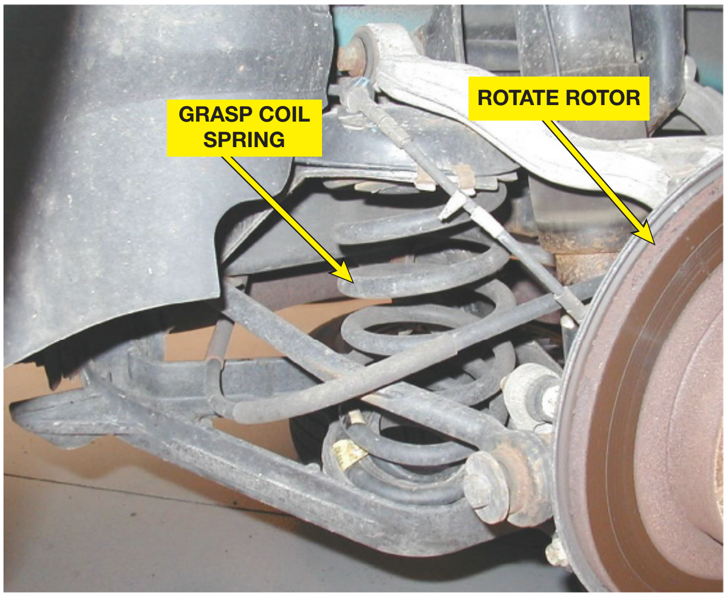

FIGURE 97–36 To detect a possible defective wheel bearing, grasp the coil spring and then rotate the wheel. If there is roughness in the bearing, a vibration will be felt in the spring.

TECH TIP

Double-Check the Bearing Part Number

Most wheel bearing/hub assemblies include the tone wheel (reluctor ring), which is used by the wheel speed sensor for use by the electronic brake control unit for electronic stability control and antilock brake operation. The number of notches or teeth on the bearing hub can and do vary. If the incorrect bearing is installed, it can cause the amber ABS warning lamp to come on and a wheel speed sensor diagnostic trouble code to be set. ● **SEE FIGURE 97–37**.

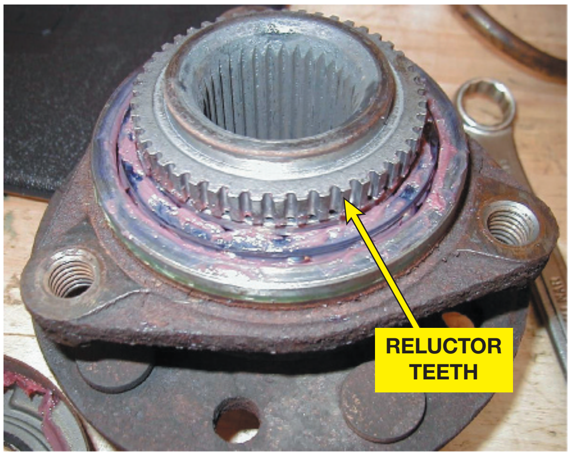

FIGURE 97–37 A bearing/hub assembly that shows the reluctor (tone wheel) teeth used by the wheel speed sensor.

CASE STUDY

The Noisy Toyota

A customer complained that a noise was heard from the rear of a Toyota Highlander SUV. During a test drive, the service technician did notice a slight noise and thought it might be due to a tire. Driving over various types of road surfaces did not change the level or the pitch (frequency) of the noise indicating that the noise was due to a bearing rather than a tire. As a double check that a tire was not the issue, the technician rotated tires placing the front tires in the rear and the rear tires on the front. Another test drive resulted in the same results.

The technician then recommended that the right rear wheel bearing (bearing hub assembly) be replaced and the customer agreed to the estimate.

When the hub bearing was removed and checked for any roughness, the technician did not feel or hear any noise from the old bearing. However, once the new bearing was replaced, the noise was gone during a test drive.

Summary:

Complaint—Customer complained of a noise from the right rear of the SUV.
Cause—Defective wheel bearing.
Correction—Replacing the right rear bearing/hub assembly fixed the noise concern.

TECH TIP

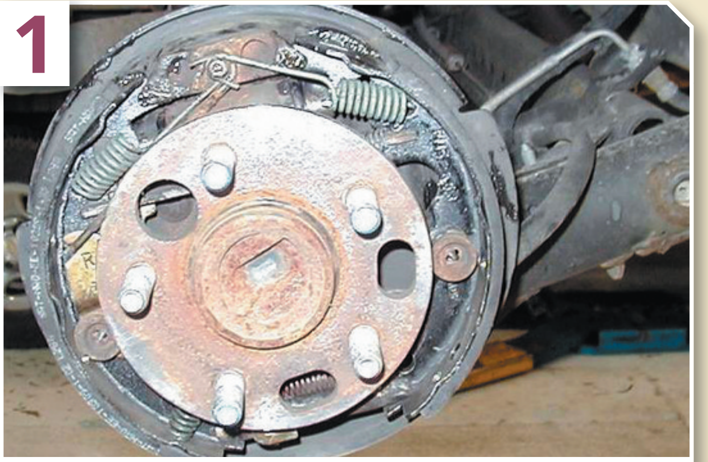
"Bearing Overload"

It is not uncommon for vehicles to be overloaded. This is particularly common with pickup trucks and vans. Whenever there is a heavy load, the axle bearings must support the entire weight of the vehicle, including its cargo. If a bump is hit while driving with a heavy load, the balls of a ball bearing or the rollers of a roller bearing can make an indent in the race of the bearing. This dent or imprint is called brinelling, named after Johann A. Brinell, a Swedish engineer who developed a process of testing for surface hardness by pressing a hard ball with a standard force into a sample material to be tested.

Once this imprint is made, the bearing will make noise whenever the roller or ball rolls over the indent. Continued use causes wear to occur on all of the balls or rollers and eventual failure. While this may take months to fail, the *cause* of the bearing failure is often overloading of the vehicle. Avoid shock loads and overloading for safety and for longer vehicle life.

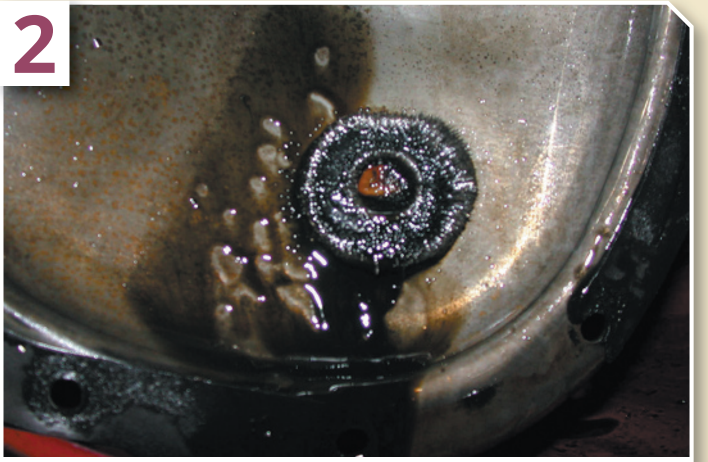
REAR AXLE BEARING SERVICE

1



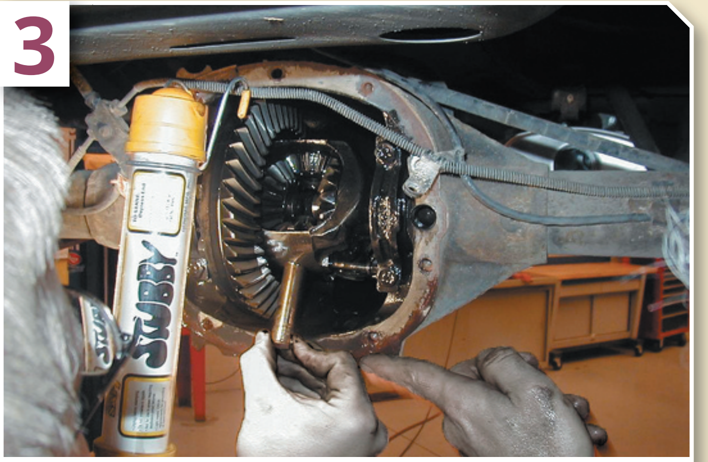
After safely hoisting the vehicle, remove the rear wheels and brake drums.

2



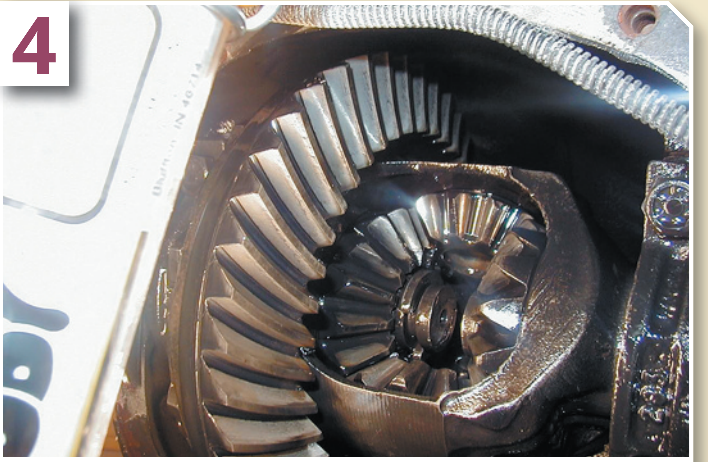
Remove the rear differential cover and inspect the magnet for metal particles that would indicate serious wear or damage.

3



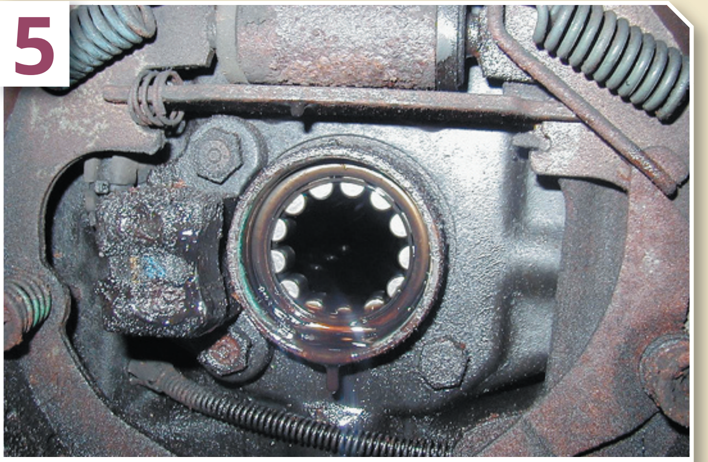
Remove the retaining bolt and allow the pinion shaft to be removed.

4



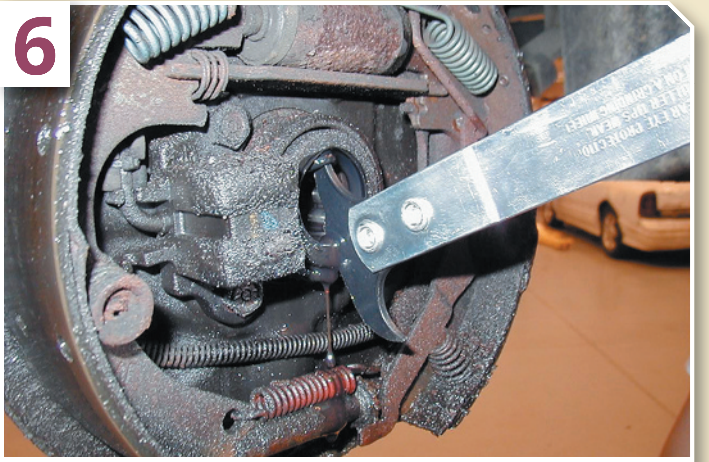
Push the axle inward toward the center of the vehicle to free the axle clip.

5



After removing the clip, the axle can then be removed. Note that the backing plate is wet, indicating that the axle seal has been leaking.

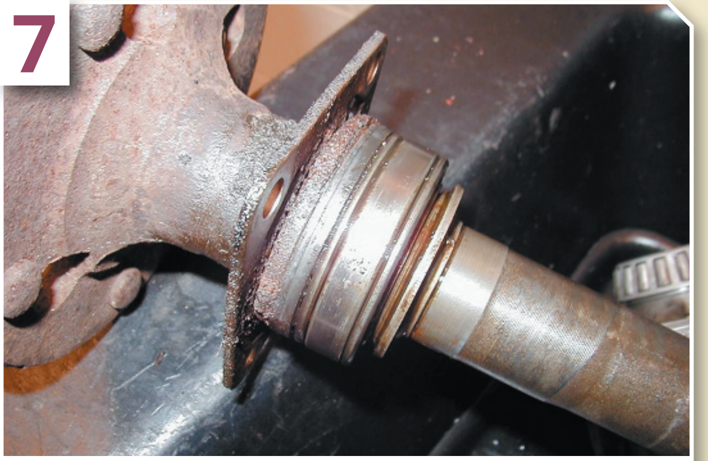
6



A seal removal tool being used to remove the axle seal.

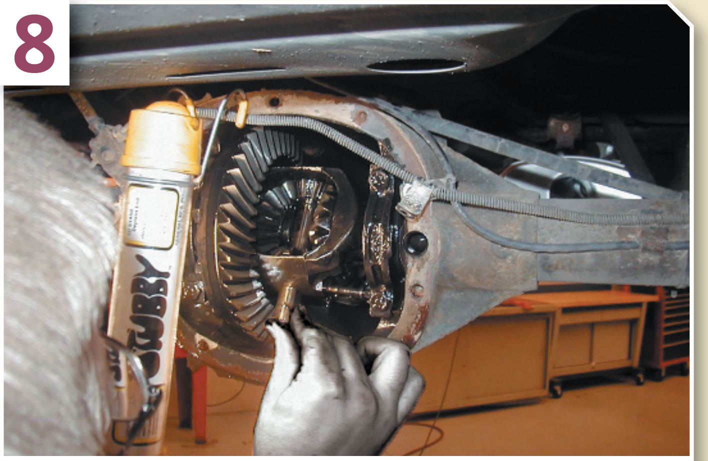
STEP BY STEP

7



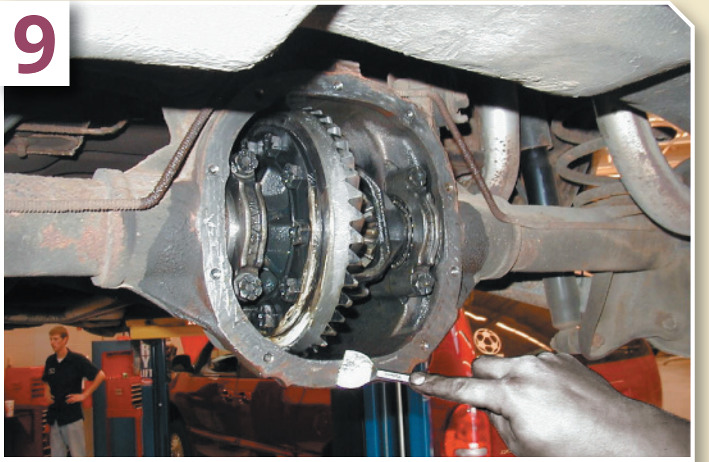
If a retainer-type axle is being serviced, the bearing and seal need to be pressed off of the axle.

8



After installing a new bearing and seal, insert the axle and install the clip, then the pinion shaft.

9



Clean the differential housing before installing the cover gasket and cover. Refill the differential with the specified fluid.

REVIEW QUESTIONS

1. List three common types of automotive antifriction bearings.
2. Explain the adjustment procedure for a typical tapered roller wheel bearing.
3. List four symptoms of a defective wheel bearing.
4. Describe how the rear axle is removed from a C-lock-type axle.
5. What is the meaning of the different colors of grease?

CHAPTER QUIZ

1. Which type of automotive bearing can withstand radial and thrust loads, yet must be adjusted for proper clearance?
   - **a.** Roller bearing
   - **b.** Tapered roller bearing
   - **c.** Ball bearings
   - **d.** Needle roller bearing
2. Which type of sealed bearings are mostly used on the front wheels of front-wheel-drive vehicles?
   - **a.** Roller bearing
   - **b.** Single tapered roller bearing
   - **c.** Double-row ball bearing
   - **d.** Needle roller bearing
3. The bearing grease most often specified is rated NLGI ___________.
   - **a.** #00
   - **b.** #0
   - **c.** #1
   - **d.** #2
4. Technician A says that a defective wheel or axle bearing often makes a growling or rumbling noise. Technician B says that a defective wheel or axle bearing often makes a noise similar to a tire with an aggressive mud or snow design. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
5. After a non-drive-wheel bearing has been properly adjusted, how much end play should the wheel have?
   - **a.** Zero
   - **b.** 0.001 to 0.005 inch
   - **c.** 0.10 to 0.30 inch
   - **d.** 1/16 to 3/32 inch
6. What part(s) should be replaced when servicing a wheel bearing on a non-drive wheel?
   - **a.** The bearing cup
   - **b.** The grease seal
   - **c.** The cotter key
   - **d.** Both the grease seal and the cotter key
7. Two technicians are discussing differentials. Technician A says all differentials are vented. Technician B says that a clogged vent can cause the rear axle seal to leak. Which technician is correct?
   - **a.** Technician A only
   - **b.** Technician B only
   - **c.** Both Technicians A and B
   - **d.** Neither Technician A nor B
8. Which type of drive axle would a heavy-duty truck tractor have?
   - **a.** Full-floating
   - **b.** Semi-floating
   - **c.** Three-quarter floating
   - **d.** Any of these
9. The differential cover must be removed before removing the rear axle on which type of axle?
   - **a.** Retainer plate
   - **b.** C-lock
   - **c.** Press fit
   - **d.** Welded tube
10. On a bearing that has been shock loaded, the race (cup) of the bearing can be dented. This type of bearing failure is called ___________.
    - **a.** spalling
    - **b.** arcing
    - **c.** brinelling
    - **d.** fluting

DRUM BRAKES

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Identify drum brake component parts.
- Discuss the advantages of drum brakes.
- Discuss the disadvantages of drum brakes.
- Explain the function of the backing plate and wheel cylinders.
- Explain the function of drum brake shoes.
- Describe the operation of non-servo brakes.
- Explain the operation of dual-servo brakes.
- Discuss automatic brake adjusters.

KEY TERMS:

Anchor eyes 1149 • Beehive hold-down 1151 • Bonded linings 1150 • Brake fade 1145 • Brake shoe hold-downs 1151 • Brake shoe return springs 1150 • Brake shoes 1148 • Core charge 1149 • Double-trailing brake 1152 • Dual-servo brake 1153 • Duo-Servo 1153 • Gas fade 1146 • Labyrinth seal 1147 • Leading shoe 1152 • Leading-trailing brake 1152 • Ledges 1148 • Lining fade 1146 • Lining table 1149 • Mechanical fade 1146 • Nibs 1149 • Non-servo brake 1151 • Over-travel spring 1155 • Pawl 1154 • Piston stops 1147 • Platform 1149 • Primary shoe 1153 • Riveted linings 1150 • Secondary shoe 1153 • Self-energizing action 1151 • Shoe anchors 1147 • Shoe contact areas 1148 • Shoe rim 1149 • Shoe support pads 1148 • Shoe web 1149 • Trailing shoe 1152 • Water fade 1147

DRUM BRAKES

BACKGROUND Drum brakes were the first type of brakes used on motor vehicles. Even today, over 100 years after the first "horseless carriages," drum brakes are still used on the rear of many vehicles, as shown in ● **FIGURE 98–1**. The drum brake has been more widely used than any other automotive brake design. ● **SEE FIGURE 98–2**.

Although the disc brake has proven its superiority in extreme braking conditions, and has replaced the drum brake on the front axle of vehicles, the drum brake continues to have a number of advantages that contribute to its use on the rear axle of many trucks, vans, SUVs, and cars.

DRUM BRAKE ADVANTAGES

SELF-ENERGIZING AND SERVO ACTION The primary advantage of drum brakes is that they can apply more stopping power for a given amount of force applied to the brake pedal than can disc brakes. This is possible because the drum brake design offers a self-energizing action that helps force the brake linings tightly against the drum. In addition, some drum brake designs use an effect called servo action that enables one brake shoe to help apply the other for increased stopping power. Both self-energizing and servo action are explained in detail later in the chapter.

PARKING BRAKE SERVICE One advantage of drum brakes is that they make excellent parking brakes. A simple linkage fitted to the brake assembly allows relatively low effort from the driver to hold a heavy vehicle in place when parked. Disc brakes, which do not benefit from self-energizing or servo action, require a complex set of extra parts to provide enough force to work well as parking brakes.

DRUM BRAKE DISADVANTAGES

BRAKE FADE Drum brakes are not very efficient at dissipating heat. The brake drum covers the linings, and most of the heat produced during braking must pass through the drum, from the inside out into the air.

The greatest drawback of drum brakes is that they are susceptible to fade. **Brake fade** is the loss of stopping power that occurs when excessive heat reduces the friction between the

brake shoe linings and the drum. The four types of brake fade include the following:

1. **Mechanical fade. Mechanical fade** occurs when the brake drum gets so hot that it expands away from the brake linings. The brake shoes then move outward to maintain contact with the drum, causing the brake pedal to drop toward the floor as additional brake fluid moves into the hydraulic system.
2. **Lining fade. Lining fade** occurs when the friction coefficient of the brake lining material drops off sharply because intense heat makes it "slippery." Unlike mechanical fade, brake pedal travel does not increase when lining fade occurs. Instead, the pedal becomes hard and there is a noticeable loss of braking power.
3. **Gas fade. Gas fade** occurs under extended hard braking from high speeds. A thin layer of hot gases and dust particles

TECH TIP

Quick-and-Easy Drum Brake Adjustment Check

Tap the brake drum lightly with a hammer or wrench. If the brake shoes are not contacting the drum, the drum will ring like a bell. If the shoes are contacting the drum, the sound will be muffled.

can build up between the brake shoe linings and drum. The gas layer acts as a lubricant and reduces friction. As with the lining fade, the brake pedal becomes hard, and greater application force is required to maintain a constant level of stopping power.

4. **Water fade. Water fade** occurs when moisture is trapped between the shoes and drum, where it acts as a lubricant. This lowers braking efficiency until friction creates enough heat to evaporate the water.

BRAKE ADJUSTMENT Another disadvantage of the drum brake design is its need for an adjusting mechanism. As the brake shoe lining material wears, the clearance between the linings and drum increases, resulting in longer brake pedal travel. To maintain a high brake pedal, a mechanism must be included in the brake assembly for adjustment of the clearance between the brake shoe and drum. Most vehicles have automatic adjusters that maintain the proper clearance between the brake linings and the drum.

BRAKE PULL Brake pull occurs when the friction assemblies on opposite sides of the vehicle have different amounts of stopping power. These differences can be caused by brake fade or misadjustment of the clearance between the brake linings and drum.

BACKING PLATE AND WHEEL CYLINDERS

BACKING PLATE The foundation of every drum brake is the backing plate that mounts to the steering knuckle on the front brakes, or to the suspension or axle housing on the rear brakes. ● **SEE FIGURE 98–3.**

The backing plate serves as the mounting surface for all the other friction assembly parts. The backing plate also functions as a dust and water shield to keep contaminants out of the brake assembly. The edge of the backing plate curves outward to form a lip that strengthens the backing plate and fits inside the brake drum to help prevent water entry. The lip fits into a machined groove in the open edge of the brake drum to provide an even better water barrier or seal. This type of seal is called a **labyrinth seal**. ● **SEE FIGURE 98–4.**

In addition to mounting holes for the various brake parts, the backing plate may also have openings that are used to inspect the wear of the brake linings, or adjust the lining-to-drum clearance. These openings are sometimes sealed with metal plugs that must be punched out the first time inspection or adjustment is needed. Rubber plugs are available to seal the holes and prevent water entry once the metal plugs have been removed.

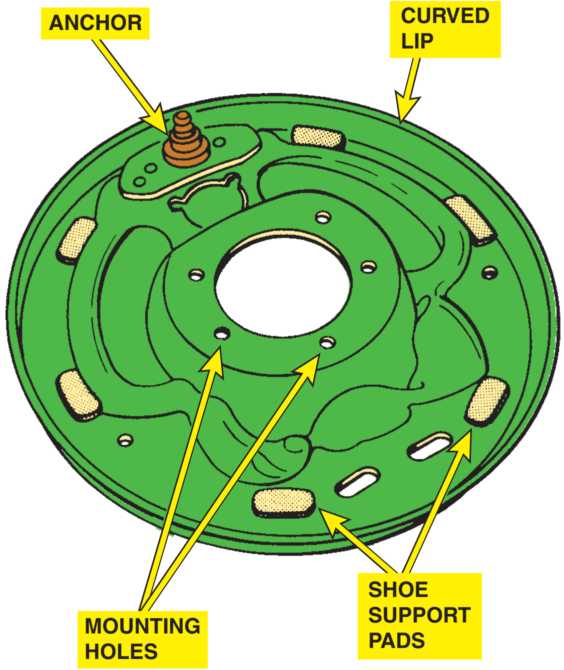

FIGURE 98–3 The backing plate is the foundation of every drum brake. There are normally six pads where the brake shoes contact the backing plate.

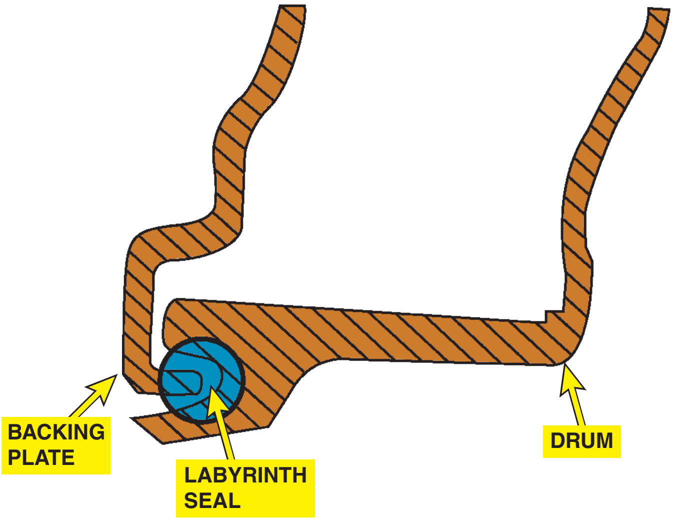

FIGURE 98–4 A labyrinth seal is created between the lip of the backing plate and the groove in the brake drum.

SHOE ANCHORS **Shoe anchors** prevent the brake shoes from rotating with the drum when the brakes are applied. The majority of drum brakes have a single anchor, but some drum brake designs use two or more.

Many anchors are a simple round post that is permanently mounted on the backing plate. The brake shoes have semicircular cutouts where they contact the anchor, and the anchor positively locates the shoe on the backing plate. Another type of anchor is the self-centering or keystone anchor. ● **SEE FIGURE 98–5.** It is called a keystone anchor because of the angled shape similar to a keystone used on the top center of a stone arch.

PISTON STOPS Some backing plates incorporate **piston stops** that prevent the wheel cylinder pistons from coming out of their bores when the friction assembly is disassembled for servicing. The stops may be part of a reinforcing plate positioned under the anchor or they can be stamped directly into the shape of the backing plate itself. ● **SEE FIGURE 98–6.**

REINFORCING PLATE
PISTON STOPS
WHEEL CYLINDER

FIGURE 98–6 Piston stops prevent the wheel cylinder from coming apart.

When piston stops are used, the wheel cylinder must be removed from the backing plate before it can be taken apart for servicing.

SHOE SUPPORT PADS The **shoe support pads** are stamped into the backing plate and contact the edges of the brake shoes to keep the linings properly aligned with the center of the friction surface inside the brake drum. These pads are also called **ledges** or **shoe contact areas**. The support pads are slightly coated with special high-temperature silicone brake grease to minimize wear, prevent rust, and eliminate squeaking that can occur when the shoes move slightly on the pads during a stop.

WHEEL CYLINDERS Hydraulic pressure is transferred from the master cylinder to each wheel cylinder through brake fluid. The force exerted on the brake fluid by the driver forces the piston inside the wheel cylinder to move outward. ● **SEE FIGURE 98–7.** Through pushrods or links, this movement acts on the brake shoes, forcing them outward against the brake drum. ● **SEE FIGURE 98–8.**

DRUM BRAKE SHOES

TERMINOLOGY The linings of drum brakes are attached to curved metal assemblies called **brake shoes**. Most shoes are made of two pieces of sheet steel welded together in a T-shaped cross section. ● **SEE FIGURE 98–9.**

LINING TABLE
WEB
BRAKE LINING
NIB

FIGURE 98–9 Steel brake shoes are made from two stampings welded together—the web and the lining table.

The outer edge is lined with a friction material that contacts the brake drum to generate the actual stopping power. The ends of the linings on most brake shoes are tapered to prevent vibration and brake noise as shown in ● **FIGURE 98–10.**

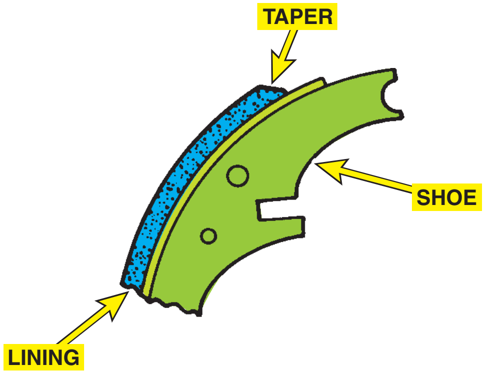

FIGURE 98–10 Tapered ends on the linings help to reduce brake noise.

The curved metal piece on the outer portion of the shoe is called the **lining table**, the **shoe rim**, or **platform**. The lining table supports the block of friction material that makes up the brake lining. On some shoes, the edge of the lining table contains small V- or U-shaped notches called **nibs**. The nibs rest against the shoe support pads on the backing plate when the shoe is installed.

The metal piece of the shoe positioned under the lining table and welded to it is called the **shoe web**. All of the application force that actuates the shoe is transferred through the web to the lining table. The web usually contains a number of holes in various shapes and sizes for the shoe return springs, hold-down hardware, parking brake linkage, and self-adjusting mechanism.

One end of the web usually has a notch where the wheel cylinder touches the shoe, while the other end commonly has a flat or curved surface where the shoe meets an anchor or adjusting link. The upper ends of the webs on dual-servo brake shoes have semicircular cutouts called **anchor eyes**. ● **SEE FIGURE 98–11**.

Brake shoes are parts that can be relined and reused many times if the web and lining table are not damaged. Brake shoes for any given application are usually available in both "new" and "relined" versions from suppliers. Relined brake shoes are usually sold on an exchange basis. At the time of purchase, a **core charge** is added to the cost of the relined parts. This charge is refunded when the old shoes are returned in rebuildable condition.

PRIMARY AND SECONDARY BRAKE SHOES In a dual-servo drum brake system, the shoes in a dual-servo brake perform different jobs. The primary shoe (forward-facing shoe) is self-energized by drum rotation to create a servo action that forces the secondary shoe more firmly against the drum. Because of this, the two shoes have physical differences and cannot be interchanged.

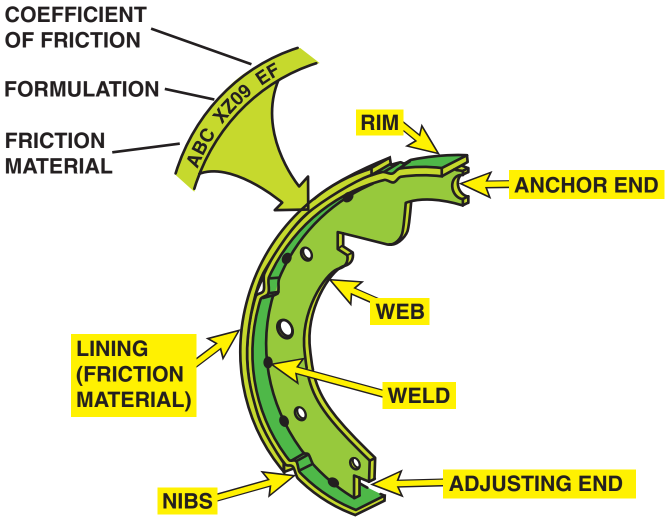

FIGURE 98–11 Typical drum brake shoe and the names of the parts.

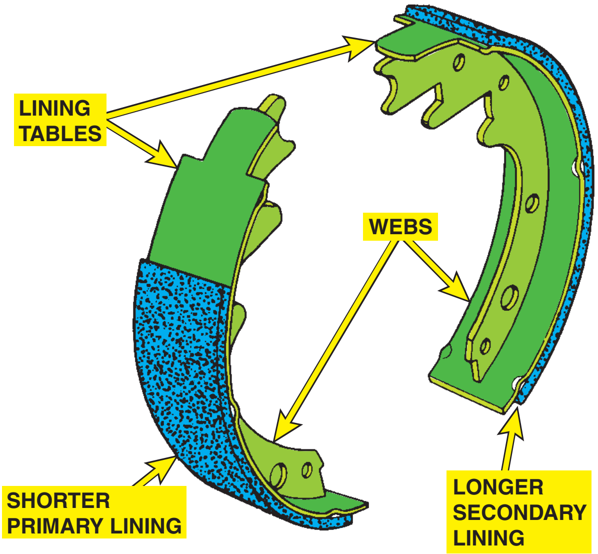

FIGURE 98–12 The primary (forward facing) brake shoe often has a shorter lining than the secondary shoe (rearward facing).

To help deal with the added friction, heat, and wear it undergoes, the lining of the secondary shoe extends nearly the full length of the shoe lining table. ● **SEE FIGURE 98–12**. The secondary shoe lining material also has a high coefficient of friction to provide good stopping power. The primary shoe undergoes far less stress than the secondary shoe, and its lining is often shorter—sometimes less than half the length of the lining table. In addition, the lining material usually has a lower coefficient of friction. This prevents the shoe from engaging the drum too quickly or harshly, which could cause the brakes to grab or lock.

On most dual-servo brake primary shoes, the lining is positioned near the center of the lining table. However, in some cases, the lining may be positioned above or below the lining table centerline. Higher or lower lining positions provide better braking action, or prevent noise, in some vehicles. ● **SEE FIGURE 98–13**.

LINING ASSEMBLY METHODS There are two main methods used to mount brake linings to the brake shoe.

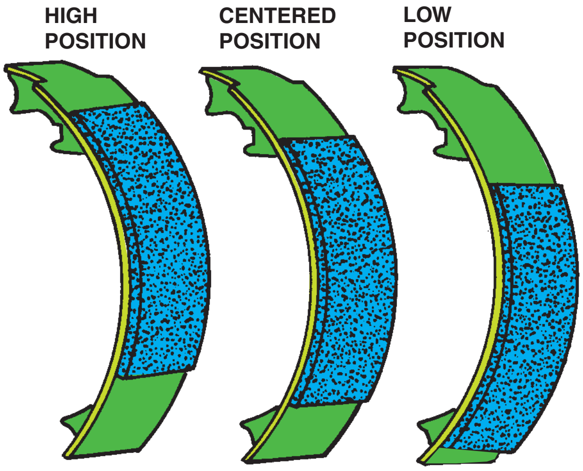

FIGURE 98–13 Primary shoe lining may vary depending on the application.

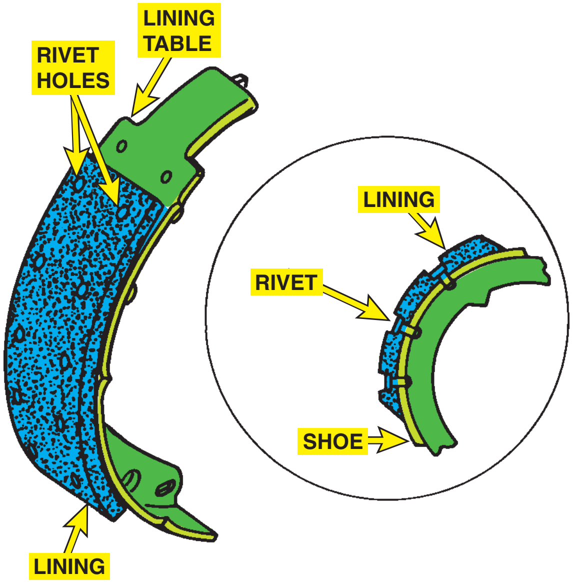


RIVET HOLES
LINING TABLE
LINING
RIVET
SHOE
LINING

FIGURE 98–14 Riveted brake linings are quiet and reliable at high temperatures.

RIVETING The brake block is attached to the lining table or backing plate with copper or aluminum rivets. ● **SEE FIGURE 98–14.** Riveting has the following advantages:

- The major advantage of riveting is that it allows a small amount of flex between the brake block and lining table or backing plate. This play enables the assembly to absorb vibration, and the result is that **riveted linings** operate more quietly than bonded linings.
- Rivets are also very reliable and will not loosen at high temperatures.

Riveting has the following disadvantages:

- Rivet holes, however, do create stress points in the lining where cracks are likely to occur.
- Riveted lining has a reduced service life because the linings must be replaced before the rivet head contacts the brake drum.
- The rivet can cause deep grooves to be cut into the drum, often requiring replacement if the worn brakes are not detected early enough to prevent damage.

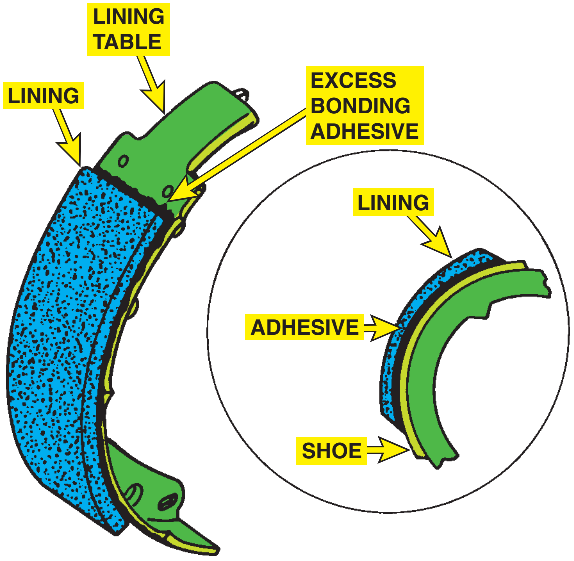
BONDING **Bonded linings** use high-temperature adhesive to glue the brake block directly to the shoe lining table or pad backing plate as shown in ● **FIGURE 98–15**. Heat and pressure are then applied to cure the assembly. Bonding is a common form of shoe and pad assembly and is most often used to mount organic friction materials.

Bonding has several advantages including the following:

- Without rivets, bonded linings can wear closer to the lining table or backing plate and provide a longer service life. If the linings wear too far, bonding adhesive is not as destructive to drums or rotors as rivets.
- Bonded linings also have fewer problems with cracking because they have no rivet holes to weaken the brake block.

Bonded linings have the following disadvantages:

- If a bonded lining gets too hot, the bonding adhesive will fail and allow the brake block to separate from the lining table or backing plate.



LINING TABLE
LINING
EXCESS BONDING ADHESIVE
LINING
ADHESIVE
SHOE

FIGURE 98–15 Many brake linings are bonded.

- Bonded linings are also more prone to be noisy because they do not allow any vibration absorbing flex between the brake block and lining table or backing plate.

RETURN SPRINGS

The **brake shoe return springs** retract the shoes to their unapplied positions when the brake pedal is released. This helps prevent brake drag and aids the return of brake fluid to the master cylinder reservoir. Most brakes use closed-coil return springs to retract the brake shoes. ● **SEE FIGURE 98–16.**

FIGURE 98–16 A typical drum brake assembly showing the support plate (backing plate), anchor pin, and springs.

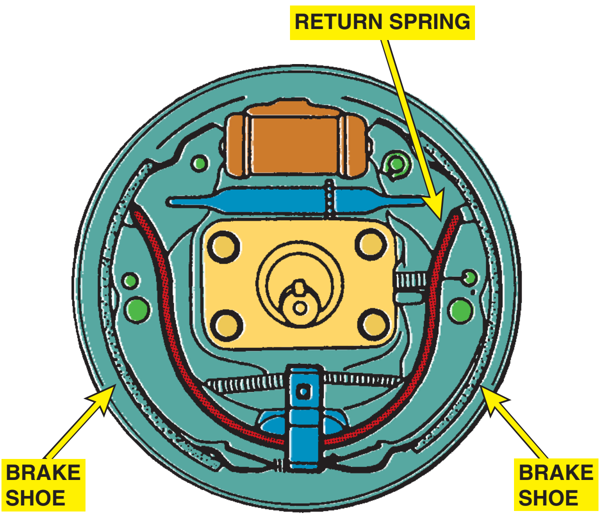

FIGURE 98–17 A single spring-steel spring is used on some drum brakes. The spring also takes the place of the shoe hold-down springs.

The coils on these springs are very tightly wound and contact one another when the spring is relaxed. Some vehicles have a single, large, horseshoe-shaped return spring. ● **SEE FIGURE 98–17.**

The type, location, and number of return springs vary from one brake design to the next. All springs are installed in one of two ways. Some connect directly from shoe to shoe, while others connect from one shoe to the anchor post.

BRAKE SHOE HOLD-DOWNS While the return springs retract the brake shoes to their unapplied positions, the **brake shoe hold-downs** keep the shoes securely against the support pads on the backing plate. The hold-downs prevent noise, vibration, and wear, but still allow the shoes to move out and back as the brakes are applied and released. The hold-downs also provide enough freedom of movement to allow adjustments of the shoes outward as the linings wear. Shoe hold-downs take many forms, as shown in ● **FIGURE 98–18.**

The most common design is a steel pin installed through a hole in the backing plate and a corresponding hole in the brake shoe web. A spring fits over the end of the pin against the shoe web, and a special washer compresses the spring and locks onto the flattened end of the pin.

Another type of hold-down is a taper-wound coil spring with a hook formed on its end. Because of its shape, this part is sometimes called a **beehive hold-down**. The hook end of the spring is installed through a hole in the brake shoe web and attached into a retaining clip that fits into a corresponding hole in the backing plate.

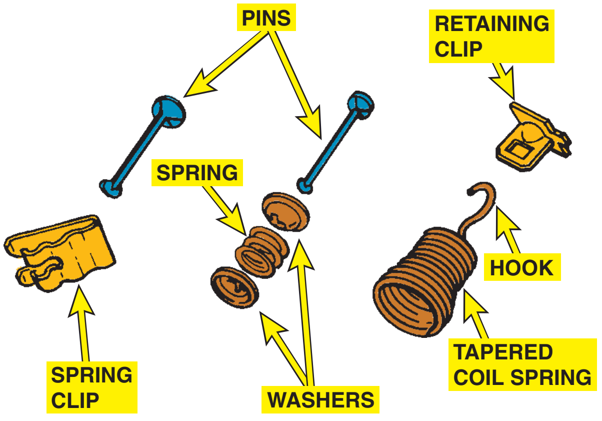

FIGURE 98–18 Various types and styles of hold-down springs.

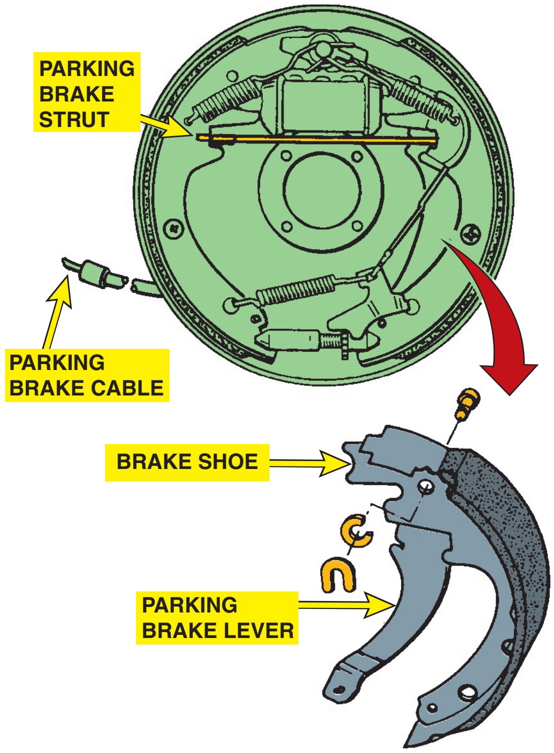

FIGURE 98–19 A mechanical brake linkage is part of most drum brake assemblies.

TECH TIP

Purchase Quality Brake Linings for Best Performance

While many brands of replacement brake lining provide acceptable stopping power and long life, purchasing factory brake lining from a dealer is usually the best opportunity to get lining material that meets all vehicle requirements. Aftermarket linings are not required by federal law to meet performance or wear standards that are required of original factory brake linings.

PARKING BRAKE LINKAGE Most rear drum brake friction assemblies include a parking brake linkage. The linkage commonly consists of a cable, lever, and strut system that spreads the brake shoes apart to apply the brake mechanically. The parking brake strut plays a large part in many of the automatic brake adjusters. ● **SEE FIGURE 98–19.**

BRAKE DRUMS The brake drum is not connected to the backing plate, but turns with the wheel. The drum mounts on the hub or axle, and covers the rest of the brake assembly. Brake drums are made of cast iron or cast aluminum with a cast-iron liner. Many of these drum types may have ribs or fins on their outer edge to help dissipate heat. ● **SEE FIGURE 98–20.**

NON-SERVO BRAKE DESIGN

PURPOSE AND FUNCTION A **non-servo brake** feature is that each brake shoe is applied individually. The action of one shoe has no effect on the action of the other. Many non-servo drum brakes use **self-energizing action** to improve their braking performance.

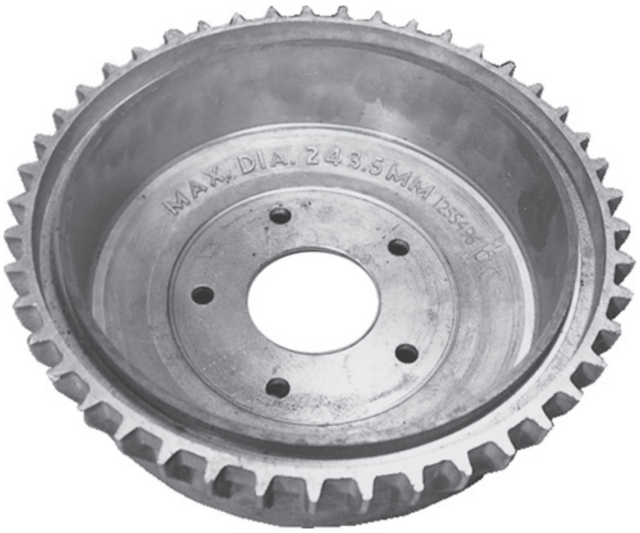

FIGURE 98–20 An aluminum brake drum with a cast-iron friction surface. The cooling fins around the outside help dissipate the heat from the friction surface to the outside air.

PARTS AND OPERATION

Self-energizing action occurs when the forward or **leading shoe** contacts the drum and the drum attempts to rotate the shoe along with it. However, the shoe cannot rotate because its far end (relative to drum rotation) is fixed in place by an anchor. As a result, drum rotation *energizes* the shoe by forcing it outward and wedging it tightly against the brake drum.

The drum also attempts to rotate the reverse or **trailing shoe** as it contacts the drum. However, in this case, the far end of the shoe (relative to drum rotation) is not solidly anchored. As a result, drum rotation *de-energizes* the shoe by forcing it inward away from the brake drum.

When this type of brake is applied with the vehicle backing up, the roles of the forward and reverse shoes are switched. The reverse shoe becomes the leading shoe, which is self-energized by drum rotation, while the forward shoe becomes the trailing shoe, which is de-energized. *A leading shoe is always energized by drum rotation. A trailing shoe is always de-energized by drum rotation.* The simple drum brake assembly in ● **FIGURE 98–21** shows how the self-energizing process works.

The first shoe from the wheel cylinder in the direction of drum rotation is the leading shoe. If the piston of a wheel cylinder moves in the same direction as drum rotation when the brakes are applied, the shoe it actuates is a leading shoe. If the piston moves opposite the direction of drum rotation, the shoe actuated is the trailing shoe.

Leading shoes generally wear at a faster rate than trailing shoes because they are applied with greater force. Where a brake uses one leading and one trailing shoe, the leading shoe will sometimes have a thicker lining or one with a larger surface area than that of the trailing shoe. The thicker or larger lining balances the wear between the two shoes so that they will both need replacement at about the same time.

DOUBLE-TRAILING BRAKE

The least powerful non-servo drum brake is the **double-trailing brake**. ● **SEE FIGURE 98–22.** This design has two trailing shoes and does not use any self-energization. Both shoes have the same size and shaped linings that are applied with equal force by a pair of single-piston wheel cylinders. Each shoe is anchored at the end opposite the wheel cylinder that applies it. In many double-trailing brakes, the backside of one-wheel cylinder serves as the anchor for the brake shoe actuated by the other wheel cylinder.

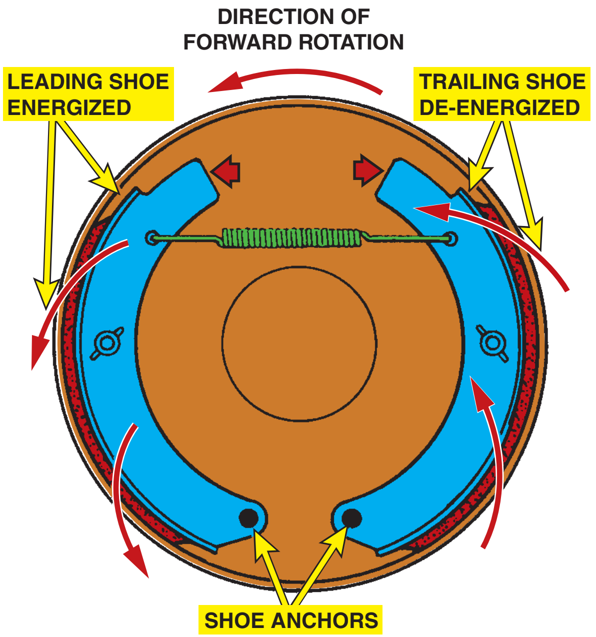

FIGURE 98–21 Self-energizing action can increase or decrease the stopping power of a brake shoe.

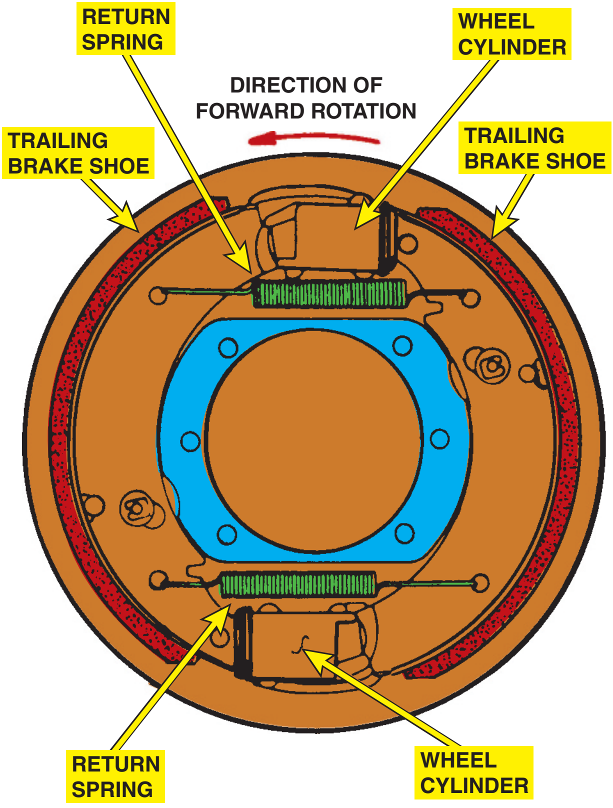

FIGURE 98–22 A double-trailing non-servo drum brake.

LEADING-TRAILING BRAKE DESIGN

The non-servo **leading-trailing brake** has one leading shoe and one trailing shoe. ● **SEE FIGURE 98–23.** Typically, a single, two-piston wheel cylinder is mounted at the top of the backing plate and the two brake shoes are anchored at the bottom of the backing plate.

The brake design has one energized and one de-energized shoe regardless of whether it is applied while the vehicle is

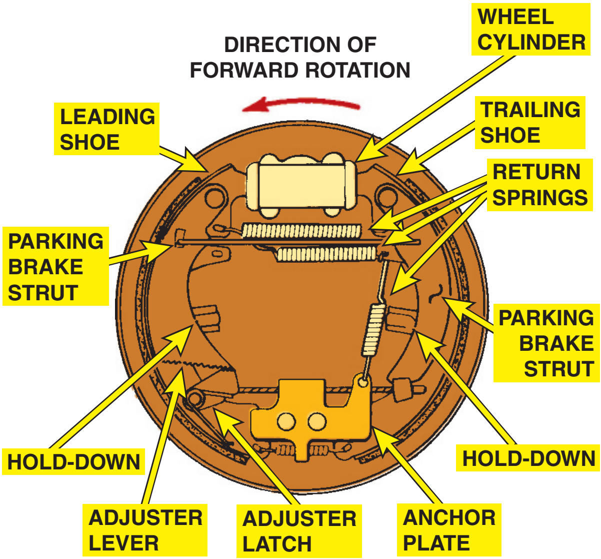

FIGURE 98–23 A leading-trailing non-servo brake.

traveling forward or in reverse. This allows the leading-trailing brake to work equally well in either direction. The leading shoe usually wears more than the trailing shoe.

Leading-trailing brakes are popular on the rear wheels of many small and front-wheel-drive vehicles because, although they are not as powerful as a servo brake, they are less prone to lockup. They have the further benefit of making a good parking brake in both directions.

DUAL-SERVO BRAKE DESIGN

PURPOSE AND FUNCTION The **dual-servo brake** is the most common drum brake design. The name "servo" comes from the fact that one shoe "serves" the other to increase application force. All servo brakes used on automobiles are of the dual-servo design that works with equal force in both directions.

The primary advantage of the dual-servo brake is that it is more powerful than any of the non-servo designs. Another advantage of the dual-servo brake is that it makes a good parking brake. Dual-servo action not only makes the brake very powerful, it allows the brake to hold equally well in both directions.

Dual-servo brakes are more susceptible to pull than other brake designs, and their greater application force can lead to faster fade under extreme braking conditions.

NOTE: Dual-servo brakes are also called Duo-Servo, which is a brand name of the Bendix Corporation.

DUAL-SERVO BRAKE CONSTRUCTION The basic dual-servo brake uses one anchor and a single two-piston wheel cylinder. ● **SEE FIGURE 98–24**. The anchor is usually mounted at the top of the backing plate with the wheel cylinder directly beneath it. The tops of the brake shoes are held against the anchor by individual return springs. The bottoms of the shoes are spaced apart by an adjusting link held in position by a third return spring that connects the two shoes.

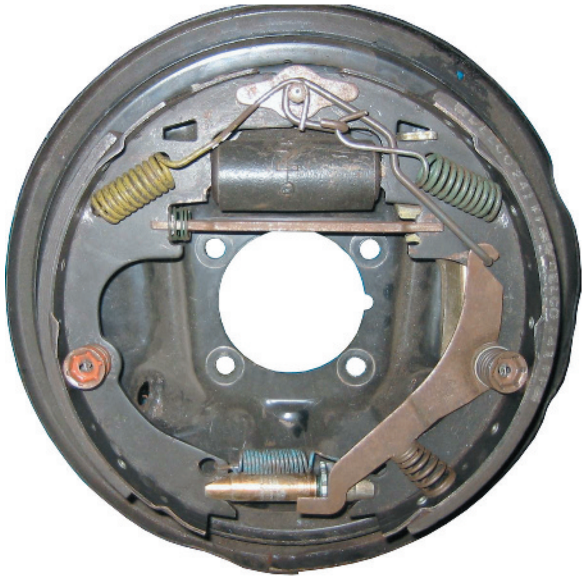

FIGURE 98–24 A typical dual-servo drum brake.

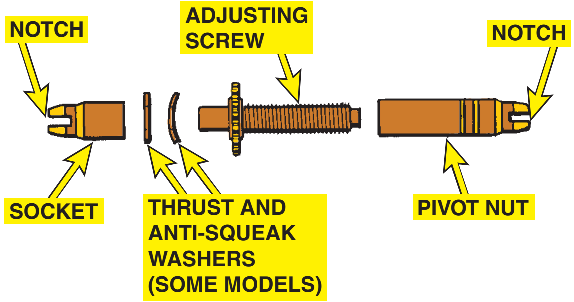

FIGURE 98–25 A typical dual-servo brake adjusting link assembly.

ADJUSTING LINK The adjusting link consists of a starwheel that is part of an adjusting screw, a pivot nut that one end of the adjusting screw threads into, and a socket that rotates freely on the opposite end of the adjusting screw. ● **SEE FIGURE 98–25**. The outer ends of the pivot nut and socket are notched to fit over the brake shoe webs. Some adjusting links have a steel thrust washer and/or spring washer installed between the socket and the starwheel. These washers allow easier rotation of the starwheel and help reduce brake squeal.

NOTE: Adjusting links generally have specific left- or right-hand threads and must be installed on the correct side of the vehicle.

PRIMARY AND SECONDARY BRAKE SHOES Although dual-servo brakes make use of self-energizing action to help provide servo action, the two brake shoes are not called leading and trailing parts as in non-servo brakes. Instead, they are identified as the **primary shoe** and the **secondary shoe**. To identify the primary shoe on a dual-servo brake with a single two-piston wheel cylinder, point to the wheel cylinder, and then move your finger in the direction of drum rotation. The first shoe reached is the primary shoe and the other shoe is the secondary shoe.

The secondary brake shoe provides approximately 70% of the total braking power in a dual-servo brake. For this reason, the lining is usually somewhat larger than that of the primary shoe. In addition, some manufacturers use different types of friction materials on the primary and secondary shoes to help equalize wear.

DUAL-SERVO BRAKE OPERATION When a dual-servo brake is applied, the wheel cylinder attempts to force the tops of both brake shoes outward against the drum. ● **SEE FIGURE 98–26**.

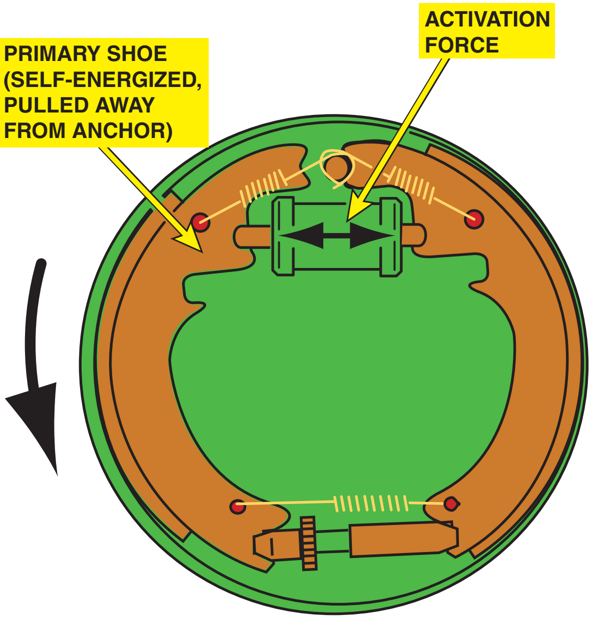

FIGURE 98–26 Dual-servo brake operation. The primary shoe on the left exerts a force on the secondary shoe on the right.

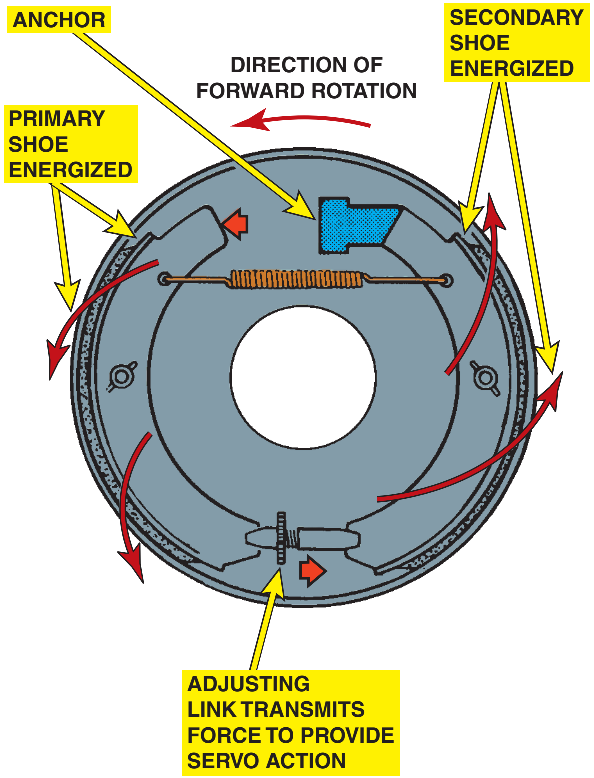
As the primary shoe makes contact, it rotates with the drum because its far end (relative to the direction of drum rotation) is not directly anchored to the backing plate. As the primary shoe rotates, it forces the adjusting link and the secondary shoe to also rotate until the secondary shoe seats firmly against the anchor.

Although the wheel cylinder attempts to push the top of the secondary shoe outward, the rotational force developed by friction between the brake shoes and drum is much greater than the force developed by hydraulic pressure in the wheel cylinder. As a result, the secondary shoe is held against the anchor. In effect, only one-half of the wheel cylinder is used to apply the brakes.



ANCHOR
DIRECTION OF FORWARD ROTATION
SECONDARY SHOE ENERGIZED
PRIMARY SHOE ENERGIZED
ADJUSTING LINK TRANSMITS FORCE TO PROVIDE SERVO ACTION

FIGURE 98–27 Dual-servo action greatly increases the application force on the secondary shoe.

SERVO ACTION Once all clearance is taken up between the brake shoes, adjusting link, and anchor, both brake shoes become self-energized like the leading shoes in a non-servo brake. The anchor pin prevents the secondary shoe from rotating, and the adjusting link (held in position by the secondary shoe) serves as the anchor for the primary shoe. Servo action then occurs as a part of the braking force generated by the primary shoe is transferred through the adjusting link to help apply the secondary shoe. ● **SEE FIGURE 98–27**.

When a dual-servo brake is applied with the vehicle moving in reverse, the primary and secondary shoes switch roles. The primary shoe is forced against the anchor while the secondary shoe moves outward and rotates with the drum to apply the primary shoe with a greater force.

TECH TIP

Rear-Wheel Lockup? Check the Adjustment

Servo action enables a drum brake to provide increased stopping power, but it can also cause the brakes to grab and lock if they get too far out of adjustment. As clearance between the shoes and drum increases, the primary brake shoe is allowed a greater range of movement. The farther the shoe moves, the more speed it picks up from the rotating brake drum. At the moment the slack is taken up between the brake shoes, adjusting link, and anchor, the speed of the primary shoe is converted into application force by servo action. If the primary shoe is moving too quickly, it will apply the secondary shoe very hard and fast, causing the brakes to grab and possibly lock the wheels.

AUTOMATIC BRAKE ADJUSTERS

SERVO BRAKE STARWHEEL AUTOMATIC ADJUSTERS Servo brakes use three styles of starwheel adjusters:

- **Cable.** ● **SEE FIGURE 98–28.**
- **Lever.** ● **SEE FIGURE 98–29.**
- **Link.** ● **SEE FIGURE 98–30.**

All three adjusters mount on the secondary brake shoe and adjust only when the brakes are applied while the vehicle is moving in reverse.

As the brakes are applied on a vehicle with a cable or link automatic adjuster, the wheel cylinder and drum rotation combine to move the secondary shoe away from the anchor. Movement of the shoe causes the cable or linkage to pull up on the adjuster **pawl**. ● **SEE FIGURE 98–31**. If the brake lining has worn far enough, the pawl engages the next tooth on the starwheel. When the brakes are released, the pawl return spring pulls the pawl down, rotating the starwheel and moving the brake shoes apart to reduce the lining-to-drum clearance.

FIGURE 98–31 The operation of a typical self-adjuster. Notice that the adjuster actually moves the starwheel. The starwheel adjuster use left-hand and right-hand threads and must be installed on the correct side of the vehicle to function as designed.

Some servo brakes with cable-actuated starwheel automatic adjusters have an **over-travel spring** assembly on the end of the cable. ● **SEE FIGURE 98–32**. In this design, the adjuster pawl is mounted *under* the starwheel, and adjustment is made as the brakes are applied rather than released. The over-travel spring dampens the movements of the adjuster mechanism and prevents overadjustment if the brakes are applied very hard and fast. It also prevents damage to the adjusting mechanism if the starwheel seizes or is otherwise unable to rotate.

The lever starwheel adjuster makes the adjustment as the brakes are applied rather than released. The operation includes the following actions:

- As the secondary shoe moves away from the anchor, the solid link between the anchor and the top of the adjuster lever forces the lever to rotate around the pivot point where it attaches to the brake shoe.
- This moves the bottom half of the lever downward, which causes the pawl to rotate the starwheel and make the adjustment.
- The separate pawl piece is free to pivot on the lever to prevent damage if the starwheel will not rotate.
- When the brakes are released, the return springs lift the lever. If the brakes have worn enough, the end of the lever engages the next tooth on the starwheel and additional adjustment will be made the next time the brakes are applied.

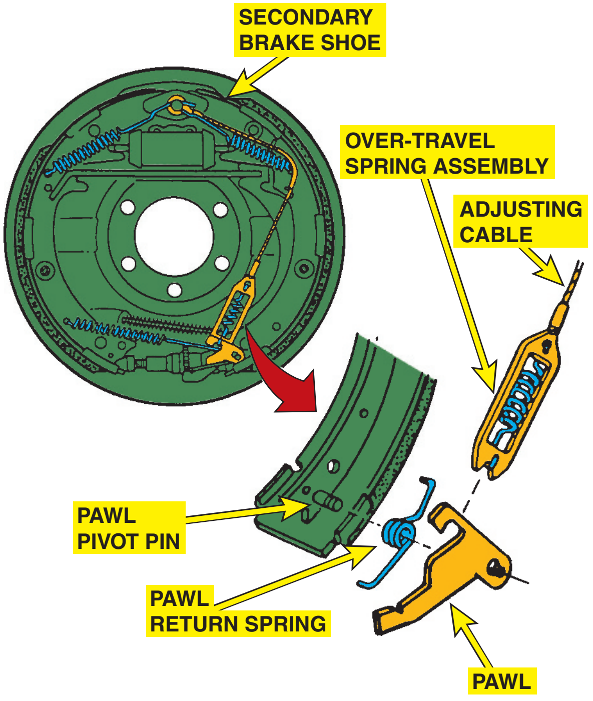

FIGURE 98–32 A cable-actuated starwheel adjuster with an over-travel spring.

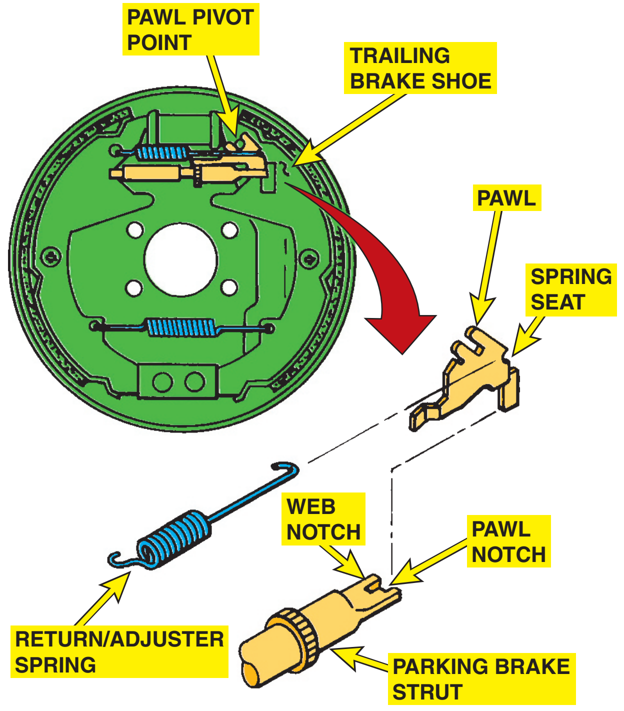

FIGURE 98–34 A non-servo brake with a lever-actuated starwheel automatic adjuster on the trailing shoe. This type of adjuster makes the adjustment as the brakes are released.

NON-SERVO STARWHEEL AUTOMATIC ADJUSTERS

OPERATION The starwheel automatic adjusters used on non-servo brakes may be mounted on either the leading or trailing shoe. These types of adjusters work whenever the brakes are applied—in either the forward or reverse direction. A leading-shoe design is shown in ● **FIGURE 98–33**.

When the brakes are not applied, the adjuster pawl is held in position by the parking brake strut. When the brakes are applied and the primary shoe moves out toward the brake drum (away from the parking brake strut), the pawl spring pivots the pawl downward where it mounts on the brake shoe and rotates the starwheel to adjust the brake. When the brakes are released, the return springs retract the shoes and the pawl is levered back into its resting position by the parking brake strut. If the linings have worn far enough, the lever engages the next tooth on the starwheel and further adjustment will occur the next time the brakes are applied.

The trailing-shoe non-servo starwheel adjuster shown in ● **FIGURE 98–34** works somewhat like the leading-shoe design, but it makes the adjustment as the brakes are released rather than applied. The upper shoe return spring in this design returns the brake shoes and operates the automatic adjuster, as follows:

- When the brakes are not applied, spring tension holds the trailing shoe and the adjuster pawl tightly against the parking brake strut.

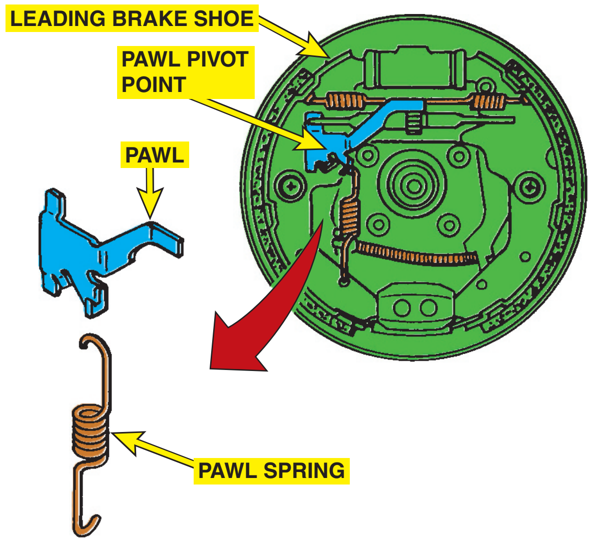

FIGURE 98–33 A non-servo brake with a lever-actuated starwheel automatic adjuster on a leading shoe. This type of adjuster makes an adjustment as the brakes are applied.

TECH TIP

Cool the Brakes before Backing

Self-adjusters can overadjust the rear drum brakes if the brake drums are hot and have increased in diameter due to the heat. For example, if a pickup truck towing a boat had to brake while backing down a long, steep grade to the boat ramp, the rear brake drums could become larger in diameter due to the heat created during braking. The brakes could over-adjust if the driver repeatedly depresses and releases the brake pedal while backing the trailer down the boat ramp. Then, after the boat has been removed from the trailer and the rear brakes have cooled, the drums will shrink and keep the rear brakes from releasing, preventing the truck from moving up the ramp.

NOTE: Some drum brakes are equipped with a bimetallic heat sensor that prevents the self-adjusters from working if the brakes are hot.

- When the brakes are applied, the trailing shoe moves out toward the drum and away from the parking brake strut. This allows the adjuster pawl, which is restrained by the return spring, to pivot where it attaches to the brake shoe, causing the adjuster arm to move upward.
- If the brakes have worn far enough, the arm will engage the next tooth of the starwheel.
- When the brakes are released, the return spring pulls the brake shoes back together and the parking brake strut levers the adjuster pawl downward to rotate the starwheel and adjust the brakes.

REVIEW QUESTIONS

1. Describe the difference between a dual-servo and a leading-trailing drum brake system.
2. List all the parts of a typical drum brake.
3. Explain how a self-adjusting brake mechanism works.
4. Why should a driver allow the brakes to cool before backing a long distance?
5. What is a labyrinth seal?

CHAPTER QUIZ

1. A vehicle with drum brakes on the rear wheels will usually have ________ brakes on the front wheels.
   a. expanding shoe
   b. disc
   c. banded
   d. internal shoe
2. Technician A says that drum brakes can fail to slow the vehicle if driven through deep water. Technician B says that when drum brakes get hot, the brake pedal will drop because the drum expands away from the shoes. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
3. Two technicians are discussing drum brake shoes. Technician A says that forward and rearward facing shoes are the same and can be installed in either position on any drum brake system. Technician B says that the longer lining should always be placed toward the front of the vehicle. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
4. Which part of the drum brake shoe contacts the ledges on the backing plate?
   a. Anchor eye
   b. Nib
   c. Web
   d. Lining table
5. A typical drum brake backing plate has how many shoe support pads (also called ledges)?
   a. 3
   b. 4
   c. 6
   d. 8
6. Which lining does most of the braking on a dual-servo brake?
   a. Front (forward facing)
   b. Rear (rearward facing)
   c. Both contribute equally
   d. Depends on the speed of the vehicle
7. Which lining wears the most on a leading-trailing brake?
   a. Leading (forward facing)
   b. Trailing (rearward facing)
   c. Both contribute equally
   d. Depends on the speed of the vehicle
8. Technician A says that starwheel adjusters use different threads (left- and right-handed) for the left and right sides of the vehicle. Technician B says that a pawl contacts the teeth of the starwheel adjuster. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
9. Technician A says that self-adjusters used on most drum brakes work when the brakes are applied, then release while traveling in reverse. Technician B says that some adjusters can over-adjust if the brake drums are hot. Which technician is correct?
   a. Technician A only
   b. Technician B only
   c. Both Technicians A and B
   d. Neither Technician A nor B
10. Two technicians are discussing drum brake self-adjusters. Technician A says that a frozen starwheel adjuster can cause the brakes to lock up due to the adjusting lever being unable to move the adjuster causing the linkage to bind. Technician B says that some brakes self-adjust when the brakes are applied rather than when released. Which technician is correct?
    a. Technician A only
    b. Technician B only
    c. Both Technicians A and B
    d. Neither Technician A nor B

DRUM BRAKE DIAGNOSIS AND SERVICE

LEARNING OBJECTIVES:

After studying this chapter, the reader should be able to:

- Discuss drum brake diagnosis and brake drum removal.
- Discuss brake drum removal.
- Explain the procedure for drum brake disassembly and inspection of parts.
- Describe how to reassemble the drum brake.
- Describe how to adjust drum brakes.
- Describe the symptoms of a faulty drum brake.

KEY TERMS:

Bearingized 1162 • Brake hardware kits 1163 • Speed nuts 1159 • Tinnerman nuts 1159

DRUM BRAKE DIAGNOSIS

DIAGNOSTIC STEPS Diagnosing brake concerns includes the following steps:

STEP 1 Verify the customer complaint (concern). For example, common drum brake concerns include the following:

- Low brake pedal
- Parking brake does not hold the vehicle on a hill
- Noise while braking
- Noise when the vehicle is moving, but the brakes are not applied

STEP 2 Perform a visual inspection of the brakes and related parts, such as the wheels, tires, and suspension system.

STEP 3 Determine the root cause. For example, this could include determining that the parking brake is corroded causing the brake shoes to wear. Replacing just the brake shoes will not correct the root cause.

STEP 4 Restore the brake system to like-new operation, which is the purpose of any repair.

STEP 5 Test-drive the vehicle to verify that the service has corrected the customer's complaint.

Drum brake service usually involves the following steps:

STEP 1 Remove the brake drums.

STEP 2 Inspect the brake drums for damage and measure the inside diameter and compare to specifications.

STEP 3 Inspect brake linings and hardware for wear or damage.

STEP 4 Inspect the wheel cylinder and brake lines for leakage.

STEP 5 Check the backing plate for excessive rust or wear.

BRAKE DRUM REMOVAL

MARK DRUMS The drum has to be removed before inspection or repair of a drum brake can begin. There are two basic types of drums, and the removal procedure depends on which type is

WARNING

Removal of the brake drum should occur inside a sealed vacuum enclosure equipped with a HEPA filter or washed with a brake washer. ● **SEE FIGURE 99–1**.

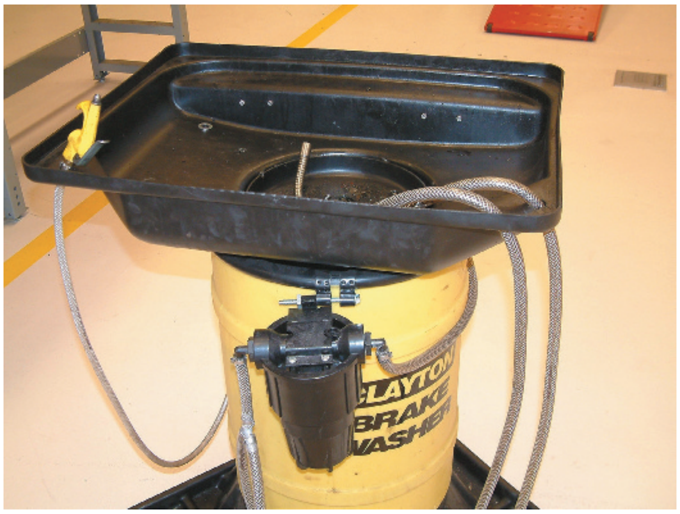

FIGURE 99–1 An aqueous-based (water-based) brake washer can be used to wet down the outside of the brake assembly before removing the drum. After the drum is removed, wash down the shoes and other parts to capture the dust into the washer.

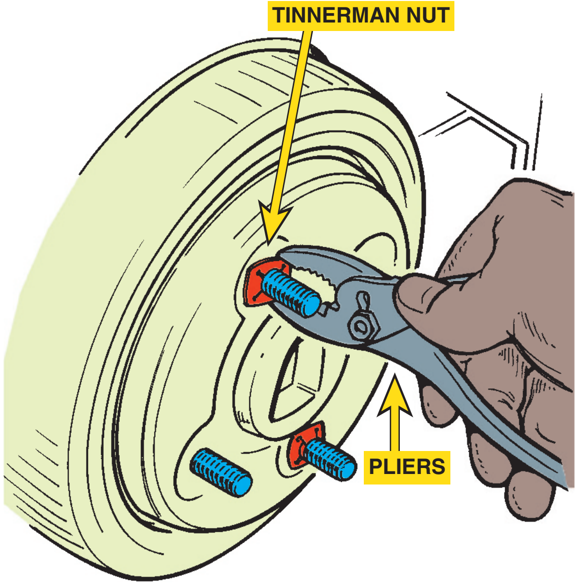

FIGURE 99–2 Tinnerman nuts are used at the assembly plant to prevent the brake drum from falling off until the wheels are installed.

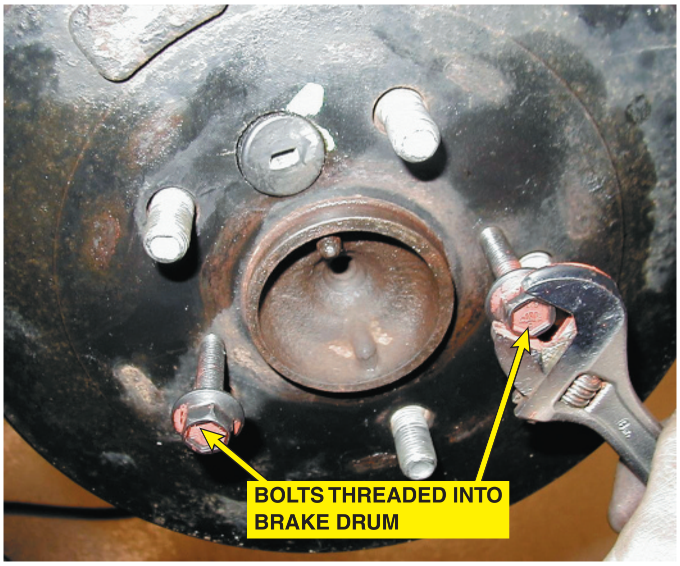

FIGURE 99–3 Turning the bolts that are threaded into the brake drum forces the drum off the hub.

being serviced. With either type, it is usually recommended that the drums be marked with an “L” for left or an “R” for right so that they can be replaced in the same location.

HUB OR FIXED DRUMS

A fixed or hub-mounted drum is often used on the rear of front-wheel-drive vehicles. The drum has a hub for inner and outer bearings and is retained by a spindle nut. To remove the brake drum, remove the dust cap and cotter key that is used to retain the spindle nut. Remove the spindle nut and washer and then the brake drum can be carefully pulled off the spindle.

HUBLESS OR FLOATING DRUMS

Floating or hubless drums are usually used on the rear of a rear-wheel-drive vehicle. The drums are secured to the axle flange by the wheel and lug nuts. New vehicles have **tinnerman nuts** (clips), also called **speed nuts,** on the stud when the vehicle is being assembled. These thin sheet-metal nuts keep the brake drum from falling off during shipping and handling prior to installation of the rear wheels. ● **SEE FIGURE 99–2**.

The tinnerman nuts can be discarded because they are not needed after the vehicle leaves the assembly plant. After removing the wheels, the drum *should* move freely on the hub and slip off over the brake shoes. Some drum brakes have two threaded holes in the drum that allow bolts to be installed. ● **SEE FIGURE 99–3**.

By tightening the bolts, the drum is forced off of the hub. Two situations that can prevent the drum from being removed include the following:

1. **The drum is rusted to the hub.** The fit between the drum and the hub is very close because it is this center pilot hole in the drum that centers the drum on the axle. Rust and corrosion often causes the drum to seize to the hub. Striking the area inside the wheel studs will usually break the drum loose from the hub. Sometimes a torch has to be used to expand the pilot hole.

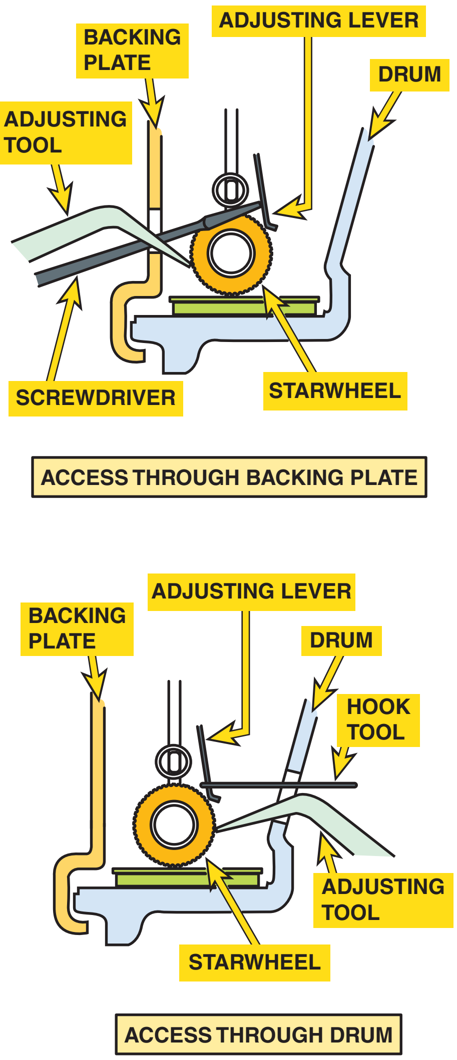
NOTE: Use of an air hammer with a flat-headed driver against the hub also works well to break the drum loose from the hub.

CAUTION: Overheating or not allowing the drum to cool slowly can cause the brake drum to distort. Using a puller can also damage a drum.

2. **The brake shoes are worn into the drum.** Even if the pilot hole is loose, many brake drums cannot be removed because the inner edge of the brake drum catches on the lining. Pulling outward on the drum often bends the backing plate or breaks some of the mounting hardware. To prevent damage, remove the adjuster plug from the backing plate or drum and back off the adjuster. ● **SEE FIGURE 99–4**.

NOTE: Be sure to reinstall the adjuster opening plugs. These plugs help keep water and debris out of the brakes.

After removing the brake drums, they should be cleaned, inspected, measured, and possibly machined before being returned to service.



ADJUSTING LEVER

ACCESS THROUGH DRUM

FIGURE 99–4 If the brake shoes have worn into the drum, the adjuster can be backed in after removing the access plug. After removing the plug, use a wire or a screwdriver to move the adjusting lever away from the starwheel, then turn the starwheel with a brake adjusting tool, often called a "brake spoon."

DRUM BRAKE DISASSEMBLY AND INSPECTION

DISASSEMBLY PROCEDURE After removal of the brake drum, the brake shoes and other brake hardware should be wetted down with a solvent or enclosed in an approved evacuation system to prevent possible asbestos release into the air. Precautions should be taken to prevent any asbestos that may be present in the brake system from becoming airborne. Removal of the brake drum should occur inside a sealed vacuum enclosure equipped with a HEPA filter or washed with water or solvent. ● **SEE FIGURE 99–5**.

Usually, the first step in the disassembly of a drum brake system is removal of the return (retracting) springs. ● **SEE FIGURE 99–6**.

After the return springs have been removed, the hold-down springs and other brake hardware can be removed. ● **SEE FIGURE 99–7**.

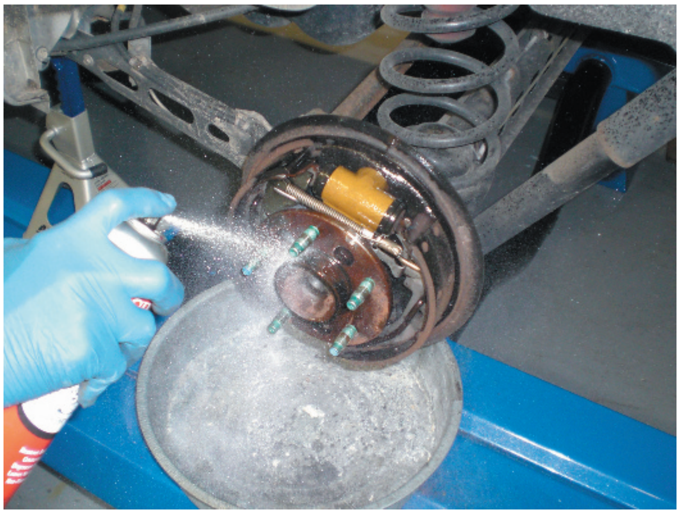

FIGURE 99–5 A liquid soaking solvent, such as brake cleaner, should be used to wet the linings. The purpose of wetting the lining material while the drum is still on the vehicle is to prevent the possibility of asbestos from the lining becoming airborne. Asbestos is only hazardous when asbestos dust is airborne and is breathed in during brake system service.

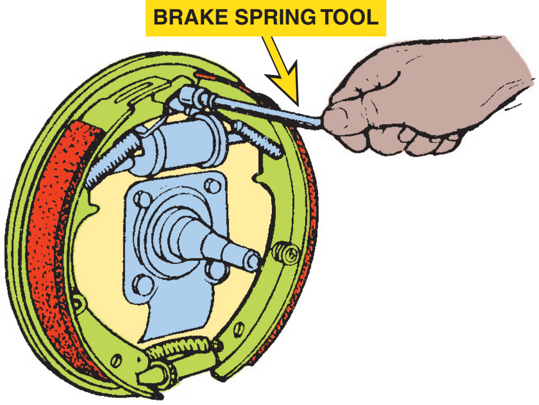

BRAKE SPRING TOOL

FIGURE 99–6 Using a brake spring tool to release a return (retracting) spring from the anchor pin.

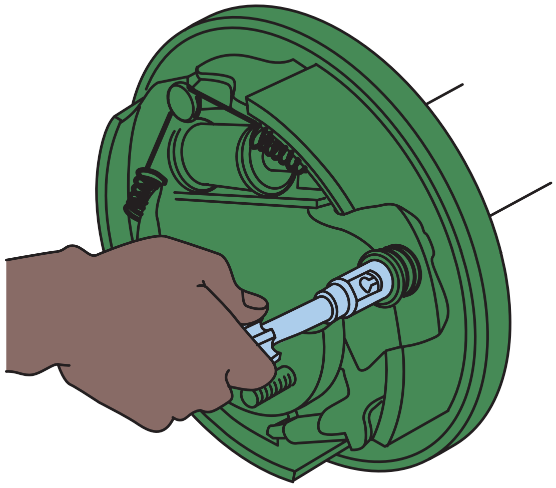

FIGURE 99–7 A special tool, called a hold-down spring tool, being used to depress and rotate the retainer.

NOTE: There are generally no "exact" disassembly or reassembly procedures specified by the manufacturer. The order in which the parts are disassembled or reinstalled is based on experience and the personal preference of the technician.

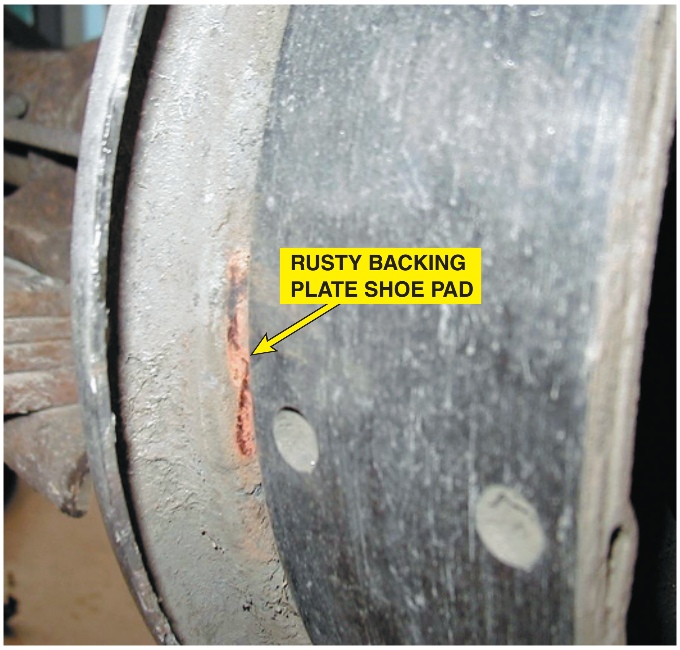

FIGURE 99–8 A typical rusting backing plate shoe pad. This can cause the brakes to squeak when the shoes move outward during a brake application and again when the brake pedal is released.

INSPECTING THE BACKING PLATE The backing plate supports the parts of the drum brake and helps to keep water from getting onto the brake shoes. The backing plate bolts to the rear axle or spindle and is made from stamped steel. Backing plates are plated (usually with cadmium) or painted to prevent rusting. To inspect the backing plate, follow these steps:

STEP 1 When brakes are serviced, the six raised contact surfaces, called pads, ledges, or shoe contact areas, of the backing plate should be inspected because they rub against the sides of the shoes. If the pads are worn more than 1/16 inch (1.5 mm), the backing plate should be replaced. ● **SEE FIGURE 99–8**.

STEP 2 The backing plate must be inspected for looseness or bending.

STEP 3 Backing plates should also be inspected to ensure that they are parallel with the axle flange.

STEP 4 The raised pads should be cleaned and lubricated. Lithium high-temperature brake grease, synthetic brake grease, silicone grease, or antiseize should be used to lubricate drum brake parts. ● **SEE FIGURE 99–9**.

DRUM BRAKE LINING INSPECTION Both primary (front facing) and secondary (rear facing) lining material must be thicker than 0.060 inch (1.5 mm). To inspect the drum brake lining, follow these steps:

STEP 1 Some vehicles are equipped with holes in the backing plate that allow for a visual inspection of the thickness of the lining. Most vehicle and brake lining manufacturers recommend replacing worn brake lining when the thickness of the riveted lining reaches 0.060 inch or less. An American nickel is about 0.060 inch thick, so simply remember that you must always have at least “a nickel’s worth of lining.” ● **SEE FIGURES 99–10 AND 99–11**.

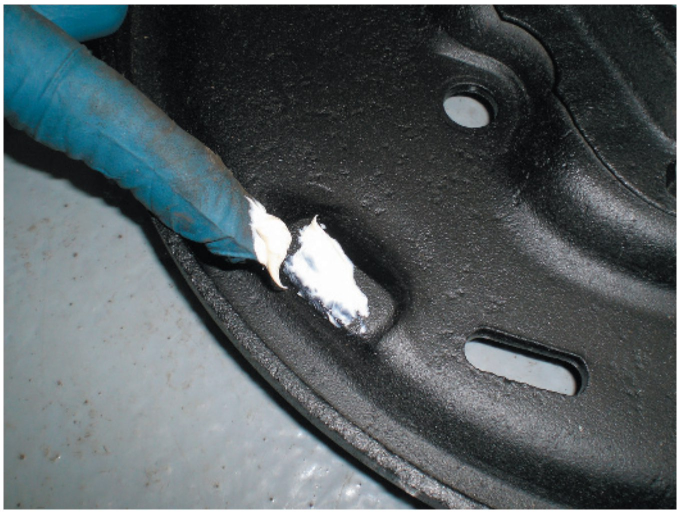

FIGURE 99–9 Applying lithium grease to the raised pads on the backing plate.

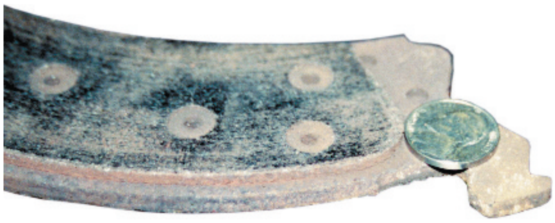

FIGURE 99–10 A rule of thumb is that the lining should be at least the thickness of a nickel.

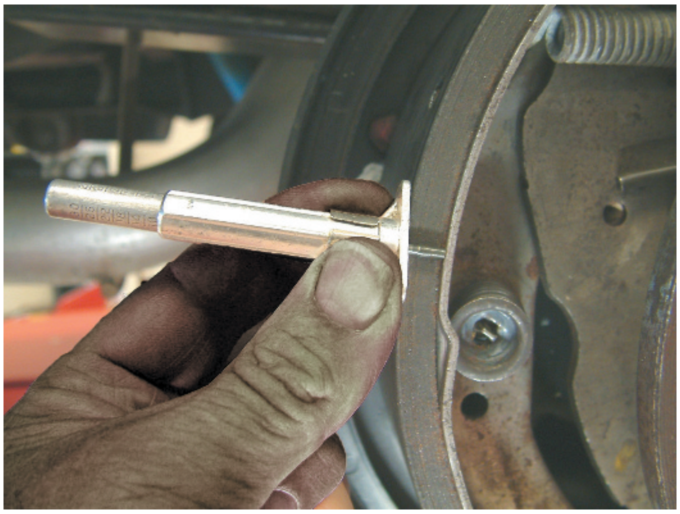

FIGURE 99–11 A tire tread depth gauge can be used to measure lining thickness. When measuring riveted linings, measure to the head of the rivets.

STEP 2 Most experts agree that the best possible inspection involves removing the brake drum and making a thorough visual inspection of the entire brake instead of just looking at the thickness of the remaining lining. If a riveted brake lining is cracked between rivets, the lining should be replaced. The lining must be replaced if cracked, as shown in ● **FIGURE 99–12**.

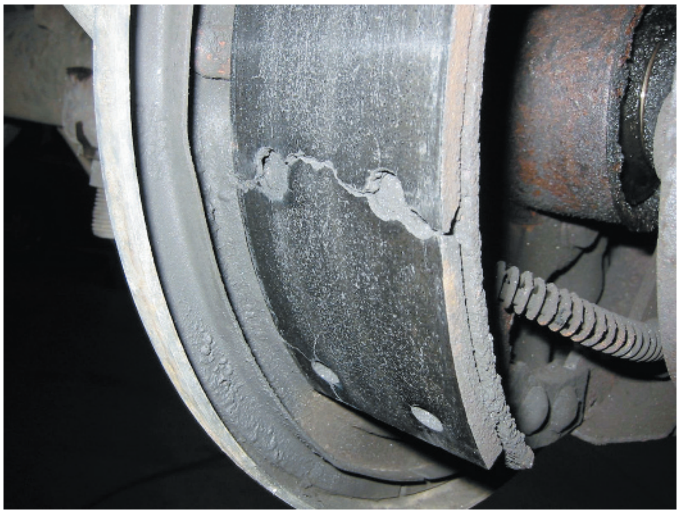

FIGURE 99–12 Cracked brake lining must be replaced.

BRAKE SPRING INSPECTION Each lining has a return spring (retracting spring) that returns the brake shoes back from the drums whenever the brakes are released. The springs are called primary and secondary return springs. The primary return spring attaches to the primary brake shoe and the secondary return spring attaches to the secondary brake shoe. These springs should be tested prior to a brake overhaul, especially when uneven lining wear is discovered.

Some drum brakes use a spring that connects the primary and secondary shoes and is commonly called a shoe-to-shoe spring. Return springs can get weak due to heat and time and can cause the linings to stay in contact with the drum when the brakes are released.

HOLD-DOWN SPRINGS Hold-down springs (one on each shoe) are springs used with a retainer and a hold-down spring pin (or nail) to keep the linings on the backing plate. Other types of hold-down springs include U-shape, flat spring steel type, and the combination return-and-hold spring. These springs still allow the freedom of movement necessary for proper braking operation.

TECH TIP

The Drop Test

Brake return (retracting) springs can be tested by dropping them to the floor. A good spring should "thud" when the spring hits the ground. This noise indicates that the spring has not stretched and that all coils of the springs are touching each other. If the spring "rings" when dropped, the spring should be replaced because the coils are not touching each other. ● **SEE FIGURE 99–13**.

Although this drop test is often used, many experts recommend replacing all brake springs every time the brake linings are replaced. Heat generated by the brake system often weakens springs enough to affect their ability to retract brake shoes, especially when hot, yet not "ring" when dropped.

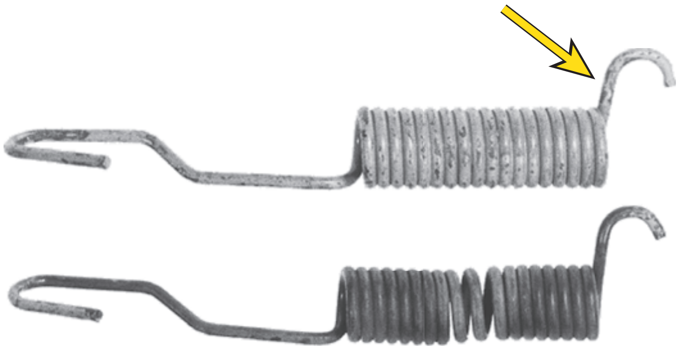

FIGURE 99–13 The top spring is a good-looking spring because all coils of the spring are touching each other. The bottom spring is stretched and should be discarded. The arrow points to the back side of the spring, which goes into a hole in the brake shoe. The open loop of the spring is not strong enough to keep from straightening out during use. Using the back side of the hook provides a strong, long-lasting hold in the brake shoe.

CONNECTING SPRING (ADJUSTING SCREW SPRING) The connecting spring attaches to the lower portion and connects the two shoes together. Check or replace at every brake lining change for best results.

WHEEL CYLINDER INSPECTION Drum brake wheel cylinders are cast iron with a bore (hole) drilled and finished to provide a smooth finish for the wheel cylinder seals and pistons. This special finish is called **bearingized.** The final step in manufacture of the wheel cylinder is to force a hardened steel ball through the bore to bend over the "grain" of the metal and to smooth the inner surface. This process provides a smooth porous-free surface for the sealing caps to travel over. It is this bearingized surface finish on the inside of the wheel cylinder that is often destroyed when a wheel cylinder is honed.

CAUTION: It is because of this bearingized surface finish that most vehicle manufacturers do not recommend that wheel cylinders be honed. Be sure to follow the vehicle manufacturer's recommended procedures. Some manufacturers state that the wheel cylinders can be overhauled using new (replacement) sealing cups and dust shields after cleaning the cylinder bore only.

Outside each wheel cylinder piston are dust boots installed to keep dirt out of the cylinder bore. Between both piston seals, there is a spring with piston seal expanders to keep the seals from collapsing toward each other and to keep pressure exerted on the lips of both seals to ensure proper sealing. ● **SEE FIGURE 99–14**.

On the back of each wheel cylinder there is a threaded hole for the brake line and a bleeder valve that can be loosened to remove (bleed) air from the hydraulic system. The wheel cylinder is bolted or clipped to the backing plate. ● **SEE FIGURES 99–15 AND 99–16**.

REASSEMBLY

DRUM BRAKE HARDWARE KIT If any spring is found to be defective, it is possible to purchase most parts individually or in pairs. However, for best results, many brake suppliers sell drum
